It is on the lower floor that Professor Dieulafoy has the two large wards, in the right and left wings respectively, that compose his service. It is here that the crowd surges every morning at half-past nine o'clock, to listen to his clear, brilliant, and incisive diction, as he stands by the bedside, diagnosticating, prescribing for, and lecturing upon each case, rapidly and with ease; not dwelling too long upon the greater and more obvious points, and bringing out into relief and their true importance symptoms that might otherwise escape attention altogether. His book, entitled "Manuel de Pathologie Interne," is truly his book; it is Dieulafoy, the profound, skilful pathologist, the ready, unerring practitioner, who writes just as he speaks. And it is for these reasons, as well as on account of his vast experience at the hospital and in private practice, that his work in four volumes, with its well-drawn woodcuts and artistically executed colored plates, due to the well-known talent of Dr. P. Bouvier, is considered the best epitome of the practice of medicine yet published. This is the tenth edition, and the volumes, which are of a convenient size for the table, the overcoat pocket, or the carriage, are a decided credit to the editors and publishers, the Messrs. Masson & Co., of Paris. The books, which are printed on a smooth agreeable paper, are tastefully bound. The first volume is devoted to diseases of the respiratory and circulatory systems—their etiology, semeiology, diagnosis, and treatment. The second volume opens with a long chapter in twenty sections on diseases of the urinary tract, comprising some two hundred and thirty-nine pages. The remainder of this volume is devoted exclusively to diseases of the nervous system. This subject is so eruditely, so concisely, and so exhaustively handled that it might by itself well make a monograph for specialists in neurology. Diseases of the digestive apparatus claim the entire third volume. The fourth and last volume embraces the remaining classes of disease, and treats successively of "General and Infectious Diseases," such as "Eruptive Fevers," "Typhoid Diseases," "Infectious Diseases belonging to Man," and "Infectious Diseases Belonging to the Animals." Then follow two chapters on "Venereal Diseases" and on the "Pathology of the Blood." The ninth, tenth, and eleventh classes into which Profes-

sor Dieulafoy has divided his work, irrespective of chapters and sections, are entirely taken up by "Rheumatismal and Dystrophic Maladies," "Maladies Affecting the Locomotor Apparatus," and "Intoxications."

The work throughout is replete with valuable pathological data, suggestions, and formulæ for treatment. It is, however, to the third volume that we would direct attention, and more especially to the exhaustive and masterly section on appendicitis, at the close of which he summarizes all that is known at the present day on the subject, including his own experience, as follows:

(*a*) Appendicitis is the result of the transformation of the appendicular canal into a closed cavity at any point; the length and narrowness of the canal rendering it particularly liable to such transformation.

(*b*) This transformation into a closed cavity takes place by different mechanisms, as proven by examination of appendices removed by the surgeons. The partial obliteration of the appendicular canal and its transformation into a closed cavity is due to the slow and progressive formation of a calculus, harder or softer, according as the inorganic substances (salts of calcium and magnesium) unite in quantities more or less considerable with the organic and stercoral substances of the calculus, to form not a calculus come from the cæcum, as has been wrongly asserted, but a veritable appendicular lithiasis, that Professor Dieulafoy compares to renal or biliary lithiasis. Having demonstrated by numerous examples the pathogenic similitude of these three lithiases, their coexistence in a same family, and the heredity of calculous appendicitis, he proposes to place it for the future in the pathological patrimony of gout and arthritism.

(*c*) In other circumstances appendicitis is not calculous, but the consequence of a local infection and tumefaction of the walls of the appendix, a process quite comparable to the obstruction of the Eustachian tube in cases of otitis and to the obliteration of the biliary canaliculæ in catarrhal icterus. The transformation of the appendicular canal into a closed cavity may in other cases be the result of a slow, progressive, and fibrous stricture, analogous to a urethral stricture; or finally of a veritable strangulation by bridle, bend, or twist; the closed cavity varying in size and form in accordance with the pathological anatomical conditions. But it cannot of itself cause accidents if the microbes contained therein are not endowed with sufficient virulence. The form may be ovoid or ampullaceous.

(*d*) The appendicular attack, whether benign, grave, light, or violent, only declares itself when the closed cavity is actually constituted. It is then that the microbes, until that moment inoffensive, multiply and exalt their virulence. The same process is observed here as in the very remarkable experiments of Klecki after ligation of an intestinal loop, and at times a terrible source of infection from toxins is set up, principally by streptococci and coli bacilli; the virulence and toxicity of the products (microbes and toxins) are sometimes so considerable that the patient may succumb from the infectious appendicitis *ipso facto*, the lesions and symptoms of peritonitis being hardly outlined.

(*e*) The appendicular attack can heal spontaneously, at least apparently, if the infectious agents contained in the closed cavity possessed but little virulence or have lost their virulence by phagocytosis; or if the canal has recovered its permeability. However, we must be on the lookout for "recidives," as the infection may continue its evolution through the appendicular walls, without a new formation of closed cavity being again necessary.

(*f*) In many cases the appendicular infection ends in ulceration, in purulency, in necrosis, in gangrene, or in perforation, and thus gives rise to all the different varieties of peritonitis. In others, microbes and toxins traverse the walls of the affected appendix without perforation, and become the direct cause of any of the different varieties of peritonitis, such as acute septicæmia of the peritoneum, general peritonitis, encysted peritonitis, abscess of the liver, metastatic abscesses in different regions.

(*g*) The medical treatment of appendicitis is entirely insufficient; the only rational treatment is surgical intervention, practised in time.

Professor Dieulafoy's section on appendicitis is certainly a *chef d'œuvre*, and is profusely illustrated with cuts of appendices containing calculi, and others transformed into closed cavities by means of twists and bridles. It is Professor Dieulafoy who has established the pathological principle of "closed cavity" in appendicitis. He pays a tribute to the work of American surgeons in this department of science, and accepts McBurney's point designated on the abdomen (the middle of a line drawn from the anter -superior iliac spine to the umbilicus) as corresponding exactly to the point of implantation of the vermiform appendix on the posterior and internal portion of the cæcum.

The work, as already announced, is the most important that has been presented to the Academy of Medicine for some time. In the discussion of this subject on the 23d of March at the Academy of Medicine, Professor Lucas-Championnière expressed the opinion that appendicitis was set up secondarily, and that obstruction of the intestine was the primary cause, producing accidents resembling appendicitis as well as true appendicitis. The proof was the cure of appendicitis without operation, or, again, the continuance of the accidents after resection of the appendix. In conclusion, he said, we must before everything else think of intestinal evacuation. Opium can give only bad results in cases of accidents due to intestinal obstruction. Subjects having repeated attacks of appendicitis should not be condemned to rest, but, on the contrary, made to exercise.

Numerous observations by Professor Potain tend to prove that appendicitis is not an habitual complication of entero-colitis.

Professor Reclus considers that appendicular accidents are due to the stagnation of a virulent liquid in the appendix. This would seem to be confirmed by the gurgling felt and heard on palpation over the right iliac fossa, and resembling that existing in typhoid fever. Professor Reclus then spoke of the difficulty of diagnosis in cases of hysteria, which by its abdominal phenomena may simulate the symptoms of appendicitis, even to the cæcal tumefaction by hysterical or spasmodic contraction of the muscles of the abdominal wall.

At the meeting of the Société Médicale des Hôpitaux, held on the 19th of March, Dr. Merklen reported three cases of grippal appendicitis, and Professor Jalaguier similar accidents after infectious diseases, such as measles, mumps, and typhoid fever. It would seem that in these cases the microbes of the intestine become more virulent and localize their action in the appendix.

Returning for a moment to the Hôtel Dieu, among the other professors of the faculty having services there are Dr. A. Proust, professor of hygiene and director of the service of hygiene of France; and Professor Cornil, the distinguished bacteriologist and senator. The chief surgeons are Professors Duplay and Panas. The hospital is supported largely by private donations, the municipality of Paris making up any deficit from the funds of the Assistance Publique.

This subsidiary system obtains for other hospitals and institutions in Paris, and not in Paris only but throughout France and in the larger cities of Europe as well.

THE DISPENSARY ABUSE.

To the Editor of the Medical Record.

Sir: I wish to reply to Doctor Rodman's letter of the 3d inst., which considered the suppression of the dispensary physicians' advertising dodges as impracticable to ameliorate dispensary evils, and instead suggested the following as a remedy: "Let the dispensary doctor discriminate between those who can and those who cannot pay." Continuing, he also writes: "At Vanderbilt Clinic, which is maintained for students . . . without exaggeration between one-third and one-half of the patients treated are capable of paying a doctor's fee. . . . What benefit is derived from statistics showing so many thousand patients treated?" I will endeavor to answer some of his inquiries.

1. Statistics are valuable to institutions chartered to teach medicine for private gain, because, in their catalogue announcements sent broadcast striving for pupils, those dispensary statistics are juggled with to the exclusion of the current report of the examination department of the University of the State of New York, which shows that the regular schools are deteriorating:

8% candidates for license rejected in 1892;
7% " " " " 1893;
20% " " " " 1894;
26% " " " " 1895;
28% " " " " 1896.

This sort of announcement would not make happy reading, especially when compared with the results of the irregular schools, which are advancing in standard and show a decided decrease in the number of rejections of their candidates each year since 1892.

2. Dispensary appointments are now held by physicians who hold office on suffrage. They are compelled to have their patrons' clinic supplied with material, no matter from what social scale or source of life obtained, and when off hand we take, for example, an institution like the New York Polyclinic, with its

30 professors,
14 adjunct professors,
31 lecturers,
24 instructors,
58 clinical assistants,

though the hospital contains only seventy beds, it will be at once apparent from what source patients are obtained, and how futile it is to expect a dispensary physician to reject an interesting patient, though rich, when he himself, in turn, would be rejected for doing so.

3. Doctor Rodman also states: "The evil applies to the younger physician especially, the very men who are only too glad to get work in the dispensaries, that take the bread out of their mouths." From frequent repetition this statement is supposed to be true, but, if the doctor would inquire how long the physicians in the various dispensaries have held office, he might be surprised to learn that the periods range from five to twenty years; any one occupying such a position for a briefer term is doing so because his predecessor is now reaping the rewards which his philanthropic life in this vale of tears deserved.

4. If nearly one-half the number of patients treated at the Vanderbilt Clinic are able to pay a physician, I would respectfully ask Dr. Rodman: Why are they not rejected? If not now, will leaving it to the honor of physicians controlling that institution bring about a change? Alas! no.

5. I would suggest that interested physicians obtain a card from each dispensary, and notice the personal advertisement of physician on the same; then read article 3, page 16, 3d ed., Code of Medical Ethics, adopted by the Medical Association, and consider whether the suppression of this disgraceful quackery should not be summarily dealt with. The inquirer will also notice that, the lower the standard of the institution as represented in the annual report of the University of the State of New York, he will find their representatives proportionately the greatest offenders:

"Let's take the instant by the forward top,
For we are old, and on the quick'st decrees
The inaudible and noiseless foot of time
Steals, ere we can effect them."

Martin W. Curran, M.D.
101 Lexington Avenue.

To the Editor of the Medical Record.

Sir: I have been watching with interest the articles on dispensary abuse in your valuable journal, especially the painstaking, well-written, definite, and practical one by Dr. Walter Brooks Brouner. The statistical table given on page 336 of the Medical Record for March 6th represents hard work and plenty of it (let disbelievers compile one for 1896).

"Are Dispensaries Abused?" Under this heading he states that those most competent to judge, viz., men officially connected with institutions, were of opinion that quite a percentage of those treated were able to pay a doctor, and that in his own capacity as assistant at one of these clinics he frequently comes in contact with men who can expend and have expended sufficient to buy a bicycle, say $30 to $100, and thus improve their health, but cannot afford $1 to a doctor for the same purpose.

"What Constitutes Ability to Pay a Moderate Fee?" He cites the difficulty of judging from external appearances, and of sifting the deserving from the undeserving; but very correctly adds that when carfare, ten to twenty-five cents for medicine, and loss of time are taken into consideration, the patients delude themselves. Only two months ago I had a letter from a friend in New York, who for a chronic disease had been going the rounds, as it were, of free clinics and dispensaries, and on account of these very reasons —time, carfare, etc.—this patient arrived at the conclusion that it was cheaper and better to employ a doctor privately and consult him.

"Who is Responsible for the Abuse?" Here again he is eminently just (to the public) and correct. The public is not to blame, and we must never look to it to remedy the evil. (Publicity in the daily papers will be a good thing.) The institutions are in a measure to blame, but so long as they are supplied with funds, whose business is it to see that these funds are not abused? Whose business and families suffer if they are misused? It comes straight home to the medical profession. The sooner this honorable body of men looks to its own interests the better. Unity is strength, and without it it is powerless against a fast-growing evil in the large cities, which will soon render the great majority of medical men unable to live respectably, and place those luxuries—medical journals, books, instruments, etc.—beyond their reach. Every person who practises medicine in the State of New York ought to belong to a protective alliance. All it needs is to be started, and here another difficulty presents itself. Your leading men are nearly all connected with hospitals, and owe their large and lucrative practices to these connections. Therefore you can hardly expect the usual promotors of movements to be the first to begin this organizing. All it needs is to be started, each request for membership to be accompanied by printed extracts giving a synopsis of the situation. One fact which you all seem to have lost sight

of is that in this movement we ought to have the hearty co-operation of the druggists (their societies). "A fellow-feeling makes us wondrous kind." Their interests are our interests in this matter.

"How Can We Remedy the Abuse?" This is well handled. The registration of applicants and investigation by inspectors as to their being worthy or unworthy of charity would soon deter the latter from applying, and you would never have the pleasure of meeting the president of one of the largest municipal railroad corporations, nor the free patient who owned the three houses on Third Avenue, nor other patients of excellent standing from outside cities (March 20th, p. 417).

If you consider this letter worth inserting in the pages of the MEDICAL RECORD, and it makes some of its many readers turn back to the number for March 6th, pages 335 to 338, and read or reread Dr. W. B. Brouner's article, it will have done something to advance the cause, and for this it was written.

HARRY E. DENNY, M.D.

SHEDIAC, N. B., March 24, 1897.

VOMITING AND INTUBATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reading your issue of the 27th inst., my attention was called to a communication from Dr. Greene, of St. Paul, entitled "Vomiting and Intubation." After a careful perusal of this article, I beg leave to call the doctor's attention to the following points: (1) That the closure of the glottis is not absolutely necessary to the performance of the act of vomiting. This is proven by the fact that in chloroform anæsthesia the patient sometimes vomits and the vomited matter gets into the trachea. That the glottis is usually closed during the act of vomiting, I grant you, but it is for the same purpose for which it is closed in the act of swallowing, viz., to keep foreign matter out of the trachea. (2) That although during the act of vomiting the ribs are elevated and expanded, forming the necessary firm support for the diaphragm, they (the ribs) are not held in this position by the forced pressure of the air contained in the lungs, but by the muscles of inspiration, viz., the serratus posticus superior, levatores costarum, and external intercostals. How then would opening the glottis prevent vomiting when it is not necessary for the performance of that act that it be closed?

Hoping that you will allow me thus, modestly, to disagree with the doctor in his physiology, I am,

J. H. LAIRD, M.D.

MOUNT CARBON, W. VA., March 29, 1897.

THE X-RAYS AND HOLTZ MACHINES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am glad to note Dr. Monell's article on static machines, for I have been doing a little in the same line.

For the last six months, in connection with Mr. James McCormick, Jr., a skilful amateur electrician, I have been making experiments with a small Holtz machine, and the results have been so satisfactory that I have come to the conclusion that any physician who has a plate machine can take *x*-ray pictures, of the extremities at least.

The machine which we worked with was a very small one, having only two plates fourteen inches in diameter; later we put on a third plate, which greatly increased the effect. If one has the machine the next thing is to get a Crookes tube, and much, very much depends on whether you get the right kind. Some are so highly exhausted and the terminals are so far apart that it takes a very high-tension current, a four or five inch spark, to illuminate them, and of course such a tube could not give good results with a current which yields only a one or two inch spark. The tube we used was a large imported one, and yielded splendid results, although the same machine failed to illuminate a very superior Edison tube, for the reasons mentioned. The proper way of passing the current through the tube has to be learned by experience. When it shows, we are told, a bright green glow over the part exposed to the aluminium focus plate, without any dark bands or shadows, it is right; but this does not convey much to the uninitiated.

With this small and inexpensive apparatus we are able to take radiographs of the hand in ten minutes, and of the forearm and elbow in twenty to thirty minutes' exposure; not only this, but we were able to use the fluoroscope; with it I was able to study the results of an old Colles' fracture, and to see the bones in the hand and wrist with startling distinctness. The fluoroscope, too, furnishes a ready means of telling if the current is going in the right direction; when it is, the screen is brilliantly illuminated, but when it is not, although the tube may present a greenish glow, the screen is almost absolutely dark.

No evil effects were noted, although my hand was exposed to the rays as long as an hour at a time. The plates we used for photographing were the so-called "*x*-ray plates," but we got just as good results with a slow B-plate in an ordinary plate holder.

Of course with these small machines the results are nothing when compared to those obtained with the larger ones; but then one may happen to have such an outfit, and it is interesting to know just what one can do with it.

HARVEY B. BASHORE, M.D.

WEST FAIRVIEW, PA., April 1, 1897.

SUTURE OF THE PERICARDIUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the last number of the MEDICAL RECORD, Dr. Daniel H. Williams gives a very interesting case of suture of the pericardium with recovery. The only criticism I would make is upon the remark near the close, in which he says: "This case is the first successful or unsuccessful case of suture of the pericardium that has ever been recorded." Allow me to say that Dr. H. C. Dalton, of St. Louis, reported a remarkable and successful case in the *Annals of Surgery* for February, 1895, which is mentioned in the "Annual for Universal Medical Science" for 1896, and also in "Gould's Year Book" for 1897.

F. W. HIGGINS, M.D.

CORTLAND, N. Y.

The Importance of an Experienced Anæsthetizer.—The following notice taken from the *Philadelphia Polyclinic* shows that the time is at hand when the folly of permitting inexperienced persons to administer anæsthetics will be generally understood: "Dr. W. Oakley Hermance has been appointed instructor in the administration of anæsthetics in the Philadelphia Polyclinic, and anæsthetizer in the Polyclinic Hospital. The faculty and trustees recognize the growing sentiment among the profession that the administration of an anæsthetic should be trusted to skilled hands only, and in providing for the proper instruction of the incoming residents of the hospital they at the same time afford an opportunity to the pupils of the college to gain similar knowledge and experience."

New Instruments.

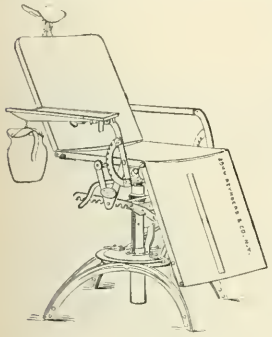
A NEW OPERATING AND DRESSING CHAIR.

DESIGNED FOR USE IN BELLEVUE HOSPITAL, NEW YORK.

By ROBERT MacLEAN TAFT, M.D.,

LATE HOUSE SURGEON TO BELLEVUE HOSPITAL.

While serving as interne in Bellevue Hospital, an idea occurred to me of a new operating-chair, which I thought would render the work of the staff more convenient, rapid, and pleasant. When asked for suggestions, I stated that a suitable apparatus upon which to dress cases was a necessary addition. The commissioner told me to speak to Dr. Rice concerning it, and that if he approved the institution should have one.



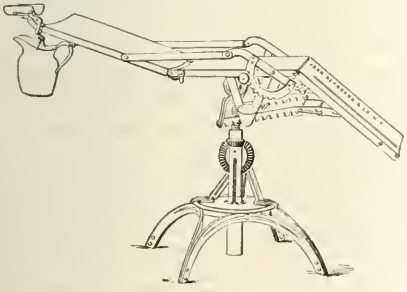
Dr. Rice approved, and the plans were given to the firm of John Reynders & Co. From these they skilfully constructed the chair.

The chair was introduced in Bellevue Hospital in September, 1896. Since that time it has been in constant use, and over eight thousand cases have been dressed upon it. It has not yet been found necessary to send it to the makers for repairs.

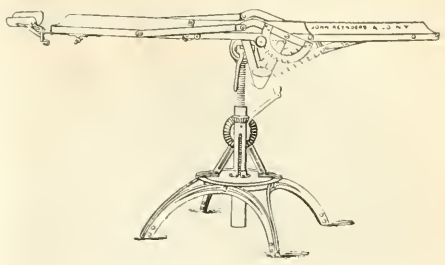
The chair, as will be seen by the accompanying illustrations, is constructed of an iron framework upon which rest thin plates of steel. These are made slightly convex for purposes of drainage. The mechanism is simple in construction and easily cleaned. It does not require much attention to keep it in order. There is no upholstery upon the chair, so that a shower of water can be played upon it without injury. Thus it can be kept perfectly clean and aseptic. It is not awkward, and like a bicycle can be made both light and strong and easy of transportation.

The chair can be raised with great ease when it contains a patient. This is due to a double set of cog-wheels, which work upon a central screw. It can be lowered in the same manner, and does not fall rapidly, but remains in position without locking whenever the power is removed from the crank.

When a patient is dressed he is placed in this



chair. If a hand happens to be the injured member, it rests upon a sort of miniature table or arm of the chair, which can be adjusted to correspond to the injured side. It is always easier for a patient to bear pain if he has support and something to brace against, and if he can turn away his head. The arm and

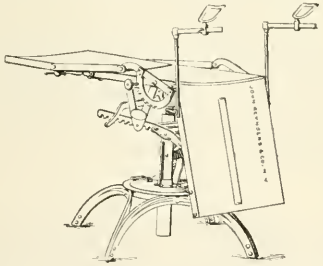


hand attachment consists of two nickel-plated sheets of brass. These are not so closely approximated but that a groove exists between them. This groove communicates with a sloping gutter, which carries the discharged products of disinfection to a drainage pan suspended at its outlet. This support and drainage leaves free the hands of the doctor and nurse. The hands of the nurse can thus be kept clean, so that she does not infect the contents of a jar when she removes one piece of gauze.

In operations about the head the chair is easily adjusted by lowering the backpiece, and a drainage pan hung under the headpiece catches all the solutions. It is much easier to dress cases in this position, and the head, which before was steadied by the doctor's hand, is not jerked away at a critical moment, upsetting all plans. If a patient be intoxicated, better control can be had raising the footpiece and strapping down the knees. A foot or leg can be handily dressed and all solutions are drained off by a groove in the centre.

Thus the chair is capable of suiting the working attitudes of the surgeon. It enables him to do better and more rapid work, with far less fatigue to himself.

The chair revolves upon a broad base, but can be made stationary by a small thumbscrew. This is ad-



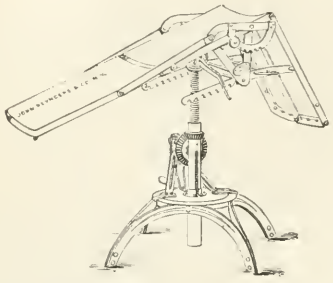
vantageous in perineal or gynæcological operations, as it is then frequently necessary to move the patient toward the best light. If the patient faint, it is only necessary to lift a lever and the chair tips backward; then by depressing this lever the chair is locked in that position until the patient has recovered.

The chair was designed for minor surgical use, but it is readily converted into a table, adaptable to any surgical procedure. If it is to be used as a table, the armpiece is removed, and it is then rendered perfectly flat by raising the footpiece and lowering the back section. In operations upon the neck or tongue, the head attachment is not removed, and the field of operation is then free from soiled towels. When the operation is finished this attachment is then removed, and a bandage is applied without dragging the head or shoulders over the end of the table.

In operations about the perineum an excellent short table can be formed by lowering the footpiece. It is not then necessary to drag the patient to the end of the table, after ether has produced its effects. This table can be raised or lowered within a limit of eleven inches, to suit any operator.

If a gynæcological operation be contemplated, the stirrup attachment is easily applied. In this position it can be used for examination or operation. Frequently during suprapubic operations upon the female, it is necessary to pass a catheter or sound. This can be done conveniently by temporarily lowering the foot section.

A number of Trendelenburg positions can be obtained by means of a simple mechanism. The chair is so constructed that it tips backward if the lever on



the right be elevated, and by depressing this lever the chair is locked in any position. This gives two inclined planes if an exaggerated position be desired. Now by raising the backpiece, the usual Trendelenburg is obtained.

If it be necessary to depress the head during an operation, it can be rapidly done by lifting the lever and then locking it at any angle desired.

In special work about the eye, ear, nose, or throat, the chair can be adjusted so that the operator will find it very convenient to reach any part of the face or neck. The drainage is collected in the pan underneath.

The apparatus seems to me a good application in general surgical work. It is not an expensive chair to build, and, as its mechanism is simple in construction, it needs little attention and no repairing.

I wish to apologize for its faults, as this is the first one which has been made. If others are to follow it, many improvements can be made.

Is Dollar Gas Desirable?—It seems that about two years ago Boston raised a cry for dollar gas, to which the legislature responded with laws under which gas could be furnished at $1 per thousand feet. This product contains about thirty per cent. of carbon dioxide, while coal gas contains only about six per cent. From February, 1896, to January, 1897, there were forty deaths from inhaling gas and many narrow escapes. From January 18, 1897, to March 4, 1897, there were twelve more deaths and an explosion which caused nine deaths and injured thirty persons. The record of deaths from inhaling fumes continues to increase. The gas has a very undesirable chemical action on the pipes. Dr. Draper, the medical examiner, says that many cases of invalidism are directly due to the gas that escapes in imperceptible quantities, and that as a purely refined system of producing death this plan could not be excelled. Boston seems to have obtained more than she bargained for when she got cheap gas.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 10, 1897:

	Cases.	Deaths.
Tuberculosis	199	104
Typhoid fever	6	3
Scarlet fever	225	12
Cerebro-spinal meningitis	1	4
Measles	196	6
Diphtheria	239	28
Laryngeal diphtheria (croup)	13	7
Small-pox	4	0
Chicken-pox	20	0

Breweries.—There are in the entire world 51,000 breweries. Germany heads the list with 26,240; next comes England with 12,874; then the United States with 2,300; Austria has 1,942 breweries; Belgium, 1,270; and France, 1,044.

Incontinence of urine in children and adults is treated by the Fiorani method, which consists in attaching to the wrist a weight of from fifty to one hundred grams, hanging over the foot of the bed. Considering the condition one of psychic origin, or, as he expresses it, a somnambulism of the bladder, the mechanical treatment is usually efficacious.

Eunuchs in China.—The London *Lancet* gives us some interesting information on this subject. The emperor and certain members of the royal family alone are allowed to keep eunuchs. His majesty maintains three thousand, while others are permitted to keep only thirty. Greed, predilection, poverty, and laziness are the four factors in the production of these eunuchs. Dr. Matignon describes the operation somewhat as follows: The subject, with his abdomen and thighs tightly bandaged, is placed upon a low bed and his legs are widely separated. The operator uses a knife resembling a pruning-knife or occasionally a pair of scissors. With his left hand he seizes the parts, twisting and squeezing them to diminish the supply of blood; a single rapid sweep of the hand serves to remove both penis and scrotum, the blade of the instrument passing as close as possible to the pubis. No anæsthetic is used. A small piece of wood or pewter, the shape of a nail, is then inserted into the urethra; the wound is washed two or three times with pepper and water, and, several pieces of paper having been applied to the surface, the parts are carefully and tightly bandaged. Immediately after the bandaging the patient is forced to walk up and down the room rapidly for three hours. For three days he is not allowed to eat anything, and he not only endures the pangs of thirst but he also suffers the agonies of retention, owing to the plug in the urethra. On the fourth day the bandage is removed, and the wretched creature is permitted to pass urine if he can. If the urine flows he is looked upon as cured, but if the overstrained bladder refuses to act he is allowed to die, as the Chinese know nothing of catheterization. Notwithstanding this primitive mode of treatment the operation is usually successful—the fatal cases do not amount to more than three or four per cent. The most frequent complication is said to be incontinence of urine, but if this persists after a reasonable period the patient is condemned to flagellation, which is reported to yield most excellent results.

THE OCULAR COMPLICATIONS OF TYPHOID FEVER.[1]

BY CHARLES STEDMAN BULL, A.M., M.D. COL., NEW YORK.

IN most infectious diseases the eye, if affected at all, is involved more frequently in the early stage or even in the prodromal period, but this is not so in typhoid fever; and this fact sometimes helps to a diagnosis, as in doubtful cases of measles. In typhoid fever, simple or complicated, the occurrence of eye symptoms seems to be either a part of the infectious disease itself or among its sequelæ. Generally speaking, if an acute infectious disease begins with severe symptoms of general poisoning, an acute state of degeneration, resembling a scorbutic condition, seems to be developed, and hemorrhages may occur very quickly in different organs. This is true of typhoid fever, and one of the symptoms met with in severe cases of this disease is retinal hemorrhage. The same may also be said in regard to the cause of the appearance of herpetic vesicles on the cornea, though this is a rare symptom in typhoid fever.

In cases of infectious disease of a low type and more chronic character, the walls of the blood-vessels undergo degeneration, the condition being known as endovasculitis and perivasculitis, and is due to inflammatory changes in the small arteries and capillaries. This condition is met with generally throughout the body, and is visible in the eye in the retina, where it gives rise to hemorrhages.

In typhoid fever various lesions may occur in the eye, not only during the height of the disease, but also during the period of convalescence. These lesions may be enumerated as follows, in the order of frequency:

I. Conjunctivitis of the catarrhal type, with little or no secretion, is a very common occurrence in typhoid, as it is in all fevers. The inflammation is usually confined to the palpebral conjunctiva, and the lids feel rough and hot to the patient. Very seldom is there any secretion of mucus, or sticking together of the lashes after sleep, or swelling of the lid, as in the ordinary forms of catarrhal conjunctivitis. The most grateful application is cold bathing, and a lotion composed of one grain of cocaine hydrochlorate and five grains of boric acid to one ounce of sterilized water may be used three or four times a day with benefit.

II. Phlyctenular Conjunctivitis and Keratitis.—Either of these is a not uncommon accompaniment or sequel of typhoid fever. There is a development of clear, transparent vesicles, usually along the corneal margin. These differ in no respect from ordinary phlyctenulæ, except that they do not suppurate, but ulcerate, discharge clear contents, and then dry up and leave no trace behind them. During convalescence, and according to some authors at a later period, there is a great tendency to these phlyctenular affections, and this same tendency has been observed in patients ill from Asiatic cholera. In severe and fatal cases of typhoid fever, in the somnolent or comatose stages, one very rare complication is a true xerophthalmia or xerosis corneæ, caused by desiccation of the conjunctiva and cornea and subsequent external infection. Warm boric-acid solutions, with cocaine and atropine added, and sterilized cocaine ointment, are useful applications in these cases.

III. Loss of Accommodation and Dilatation.—Partial loss of accommodation from paresis of the ciliary muscle, and dilatation of the pupil from partial paralysis of the sphincter muscle of the iris, are by no means infrequent symptoms in typhoid fever. Both these symptoms are due more to the general asthenic condition of the patient than to any lesion in the ciliary body or iris. Both occur during the height of the disease, as well as during the period of convalescence. Total and permanent paralysis of accommodation and of the iris is due to some central lesion, and does not occur in typhoid fever.

IV. Retinal Hemorrhages of various kinds, and more or less profuse, are by no means uncommon occurrences in the height of the disease. The outpour of blood may be so extensive as to break through the limitans interna and penetrate into the vitreous humor. These are the bad cases of tyhoid fever which terminate fatally, and are usually accompanied or preceded by intestinal hemorrhage. The ordinary forms of retinal hemorrhage met with in typhoid fever are of the punctate, linear, or flame-shaped variety, lie in the inner layers of the retina, and occur usually during the third week. They do not form the subject of complaint by the patient, unless they occur at the macula lutea, where they interfere markedly with vision. The patients are usually so lethargic or delirious from the toxic influence of the fever that the presence of small hemorrhages makes no impression on their minds. The profuse hemorrhages are uncommon, but cause marked impairment of vision. I was recently called in consultation to see a patient in the third week of a severe attack of typhoid fever, who had had a profuse intestinal hemorrhage in the morning, and shortly afterward complained that she could not see. I saw the patient a few hours later, and found an enormous retinal extravasation of blood in both eyes in the region of the macula lutea. Shortly after the occurrence of the intestinal hemorrhage, the patient's temperature, which had been 106.4° F., sank rapidly to 99.6° F., and in two hours rose again rapidly to 107° F., and the patient died in about thirty hours.

Sometimes a profuse intestinal hemorrhage will cause amaurosis from the great loss of blood, without there being any retinal hemorrhage. This is due to the general peripheral anæmia and contraction of the arterial walls caused by the loss of blood, and is of the same nature as the amaurosis met with after profuse epistaxis or menorrhagia. Should these patients recover, the blindness is apt to end in atrophy of the optic nerve.

The location of these retinal hemorrhages varies in different cases, and upon the location depends the shape and appearance of the extravasation presented in the ophthalmoscopic picture. In the innermost layer of the retina, nearest the hyaloid membrane, the

[1] A paper read before the Practitioners' Society, April 2, 1897.

extravasation is linear or flame shaped, and marked by meridional striations, because spread out in the direction of the nerve fibres. In the middle and more external layers of the retina, the extravasated blood follows the supporting layers of Muller's fibres or connective-tissue framework of the retina, which run perpendicularly to the retinal surface. The ophthalmoscopic appearance of hemorrhages here is punctate or irregularly circular or blotchy. In rare cases the hemorrhage is profuse, and breaks through the membrana limitans interna, another spreads out beneath the hyaloid membrane. Seen with the ophthalmoscope, such a hemorrhage appears as a large round or more frequently elliptical red mass, with its long diameter horizontal, and with sharply defined margin. Such a hemorrhage usually occurs at or just below the region of the macula.

The causation of these hemorrhages is somewhat obscure. They may be mere symptoms, or they may possess more of an independent nature. In all cases of spontaneous hemorrhage, a weakened condition of the walls of the blood-vessels is to be supposed, or a perverted quality of the blood, or both combined. The normal intra-ocular tension presents a natural obstacle to the rupture of a retinal blood-vessel, and there is no reason for supposing that this intra-ocular tension is in any way abnormal in typhoid fever. Moreover, the heart's action is usually enfeebled in typhoid fever, at least during or after the second week of the disease, and hence the intravascular tension is not increased. The ophthalmoscope does not reveal in these cases any evidence of a rupture of a blood-vessel, though of course such rupture may exist and be concealed by the extravasation. The cause of an intestinal hemorrhage we know to be due to ulceration of the intestinal lining, but such ulcerative processes do not exist in the retina. Hence we assume that, except in cases of profuse extravasation, the retinal hemorrhages are due to what is known as "diapedesis," resulting from a pathological relaxation of the walls of the blood-vessels, through which the blood corpuscles escape. In adults of middle age or over, this may be due to arterio-sclerosis or phlebo-sclerosis, but this is not likely to be the case in children. It may perhaps be more correct to regard the condition as one of extreme depression of the whole system, amounting almost to degeneration, somewhat analogous to what is met with in scorbutic conditions, and this is the view held by Deutschmann and others. There is neither embolism nor thrombosis of the vessels to be found in these cases, and hence there is no question of occlusion of the vessels.

Since this paper was written, a very interesting case has been reported by Dr. Finlay, of Havana, in the *Archives of Ophthalmology*, vol. xxvi., No. 1. The patient was a boy, aged ten, in the third week of typhoid fever, with a temperature of 40.5° C., with the intestinal symptoms but little marked. There suddenly appeared ecchymoses all over the conjunctiva of one eye, and two days later over the other eye, with rapid and enormous œdematous swelling of the conjunctiva and eyelids. A number of large ecchymotic spots appeared subsequently in various parts of the body. There were also some ecchymoses in the nose and mouth. The corneæ of both eyes sloughed out entirely, and the vitreous of the left eye was a mass of clots. The vitreous of the right eye did not suppurate, but appeared of a bright red color. Both eyes were of course sightless, and subsequently became shrunken. The case was undoubtedly one of spontaneous orbital and intra-ocular hemorrhage, occurring in the course of typhoid fever, and it is the only one of the kind on record. There was no spontaneous pain, merely an itching, and there were no local inflammatory symptoms until after the occurrence of the hemorrhages. The case might have been mistaken for a case of thrombosis of the cavernous sinus, as venous thrombosis from weakening of the heart's action is one of the complications of typhoid. But the ecchymotic spots on the eyelids, the multiple subcutaneous hemorrhages all over the body, and the absence of any œdema over the mastoid region, which is considered by Fuchs and others as of diagnostic importance in the differentiation of a thrombosis from an orbital phlegmon, are all points in favor of the diagnosis of an orbital hemorrhage. There must have been some degenerative changes in the walls of the blood-vessels, in connection with the general depressed vitality accompanying typhoid fever; or, as Finlay suggests, there may have been a complicating purpura. The boy had previously been well, was not a malarial subject, and there was no discoverable taint in the family. The case has been extremely carefully reported by Dr. Finlay, and is well worth perusal.

V. Paralysis of External Muscles.—Paralysis of one or more of the external muscles of the eyeball is also a not infrequent occurrence during the period of convalescence from typhoid fever. The paralyses met with some time after the close of the convalescent period are due, according to some authorities, to a chronic nephritis, which is a not infrequent sequel of typhoid fever. They are said to be nuclear in character, are rapidly recovered from, but also tend frequently to relapse. Other authorities regard these paralyses as due directly to a neuritis, caused by the typhoid poison. These muscle palsies almost never occur during the height of the fever, but appear during convalescence, and sometimes even long afterward. Hence either of the above causes might account for their occurrence. Some of the cases reported have appeared so long after the original disease as to make the connection doubtful. Nothnagel has reported cases of double ptosis and sixth-nerve paralysis, occurring during the third week, but these are very rare.

During the height of the fever paralysis of the ocular muscles almost never occurs. Should the patient recover and the muscle or muscles remain paralyzed, the resulting annoying diplopia may necessitate surgical interference in order to restore binocular single vision. A case of this sort is reported by Runeberg,[1] in which the paralysis affected the left superior oblique muscle, and occurred eighteen months after the attack of fever. This gives rise to perhaps the most annoying form of diplopia, which cannot be relieved by prismatic glasses, and the result of any operative procedure undertaken for its relief is always doubtful. Fortunately the paralyses occurring during or shortly after convalescence are the most frequent, and are almost always recovered from. The cases of paralysis which occur long after convalescence, and which resist treatment so obstinately, are very rare.

VI. Neuro-Retinitis or Retrobulbar Neuritis.—This is a rather rare complication in typhoid fever, and is supposed to be due to a more or less circumscribed meningitis at the base of the brain. This may subside, leaving a moderate or slight impairment of vision, but is more apt to end in atrophy of the optic nerve. The ophthalmoscopic picture resembles that of retrobulbar neuritis due to excessive indulgence in tobacco and alcoholics. Von Petershausen has reported a case of double neuro-retinitis, with hemorrhages in the region of the macula, but with little or no exudation, occurring during the height of the fever.[2] Leber and Deutschmann have reported a similar case ending in atrophy of the optic nerve, probably due to hemorrhage within the sheath of the optic nerve.[3] These patients are usually too sick to

[1] Jahr. f. Aug., 1875.
[2] *Ibid.*, 1893.
[3] Arch. f. Ophthal., xxvii., 1.

admit anything more than an ophthalmoscopic examination being made. If it were possible to examine the field of vision with a perimeter, there would undoubtedly be found a central or paracentral defect in the field; a scotoma for color, if not for form also.

Amblyopia or defective vision, and hemianopsia without ophthalmoscopic symptoms, have also been observed during the period of convalescence from typhoid fever. They are probably due to some lesion in the tractus, or to some cortical irritation at the convexity of the brain. They are rare sequelæ.

A case of annular defect in the field of vision without ophthalmoscopic evidence has been reported by Hersing. A very interesting case of extreme narrowing of the retinal arteries in both eyes, with paleness of the optic discs and loss of sight, has been reported by Heddaeus.[1] This patient had been very ill and had become greatly emaciated. Subsequently when he had entirely recovered, the retinal arteries regained their normal size, but the discs remained pale and the vision very defective.

VII. Inflammations of the Uveal Tract.—Inflammations such as iritis, cyclitis, and choroiditis, both serous and plastic, are occasionally met with during the height of the disease. They may be unilateral or bilateral, and of varying intensity. The inflammation is of the serous or plastic type, and is never purulent. When the choroid is involved, opacities of the vitreous humor are usually present. They are floating opacities of the punctate or stringy variety, and are never fixed or membranous. As a result of such choroiditis, the nutrition of the lens is interfered with and cataract may develop. Even when the lens remains transparent, the resulting vision in these cases is always impaired, as it is usually in all cases of choroiditis from whatever cause, owing to the retina becoming involved in the inflammatory process. Fortunately this complication on the side of the eye is a rare one in typhoid fever.

TRANSITORY DISTURBANCES OF CONSCIOUSNESS IN THEIR MEDICO-LEGAL ASPECTS.[2]

By WILLIAM HIRSCH, M.D.,

NEW YORK.

All those who have had experience in criminal psychology have met cases in which grave crimes have been committed, the perpetrators afterward claiming to have been entirely unconscious thereof. These cases acquire special medico-legal interest, inasmuch as criminals are apt to simulate a condition of unconsciousness during the time of their criminal action for the purpose of escaping punishment. It is a well-established fact, which needs no further comment, that there are many different forms of transitory insanity, that is, mental disturbances which may last only a few hours or days, and which are frequently followed by partial or complete loss of memory of the events which occur during the attack. The difficulty of forming a correct judgment in this class of cases lies to a great extent in the fact that the expert, as a rule, is not brought into immediate contact with the manifestations of the disease, as he is in the cases of other pathological conditions; but that he sees the individual only after some period of time has elapsed since the attack. His diagnosis, therefore, is necessarily based more on hearsay evidence, that is, on the description of the condition of the person by witnesses, than on the patient's own statements.

The important question thus arises: Can we in a given case decide with certainty whether an individual at a certain time was suffering from transitory mental disturbance, or whether he is simulating this condition by pretending to have no recollection of the events during this period? Although it must be admitted that here, as well as in all other mental diseases, there are certain cases which stand on the border line of health and disease, in which the question whether insanity is present or not cannot be answered by a simple "Yes" or "No," we can positively say that in the vast majority of these instances the psychiatrical expert should be able to give a definite answer to this question.

But, in giving this answer, it is not sufficient to make the simple statement that the patient is sane or insane. In order to prove the existence of a mental malady in court, it becomes the duty of the medical expert to diagnosticate a particular mental disease, that is, to show that the symptoms of the special case correspond to a well-established form of mental disturbance. Unfortunately, even at the present day the defence of "temporary" or "transitory" insanity is made in criminal cases. Transitory insanity does not constitute a scientific diagnosis. It can be considered only as a collective term or an expression of the laity. It is required of the expert in court to show what special form of transitory insanity he is dealing with. It will, therefore, be well to consider the most important forms of transitory disurbances of consciousness in which crimes may be committed.

Whenever we hear of a person who has committed a crime of which he claims to be unconscious, we must primarily think of epilepsy, since it is this neurosis which is more apt than any other neuropathic condition to produce such a state of temporary unconsciousness. The diagnosis of an acute attack of psychical epilepsy must further be based: First, upon the previous life and the present condition of the individual; secondly, upon the nature of the attack itself. Heredity is an important factor in deciding whether or not we have to deal with an epileptic individual. Mental diseases, epilepsy, or alcoholism in ancestors predispose to this neurosis. Injuries to the head may also form an etiological factor in this disease. It is of the highest importance to ascertain whether the person has previously had epileptic convulsions, and whether he presents what is known as the epileptic character. The physical examination must bring out any degenerative stigmata, as epilepsy is a condition of degeneration. In considering the attack itself, we have to bear in mind the relation of acute psychological disturbances to the genuine epileptic convulsions. Most frequently the mental disturbance is post-epileptic, that is, it occurs immediately after an epileptic attack. Less frequently it is ante-epileptic, the convulsions following the conditions of insanity. Those cases are comparatively rare, which are known as equivalents, in which the mental disturbances take the place of an epileptic attack. In the rarest cases, the attacks have always been purely psychical, actual convulsions never having taken place, a condition which is known as larvated epilepsy. If the mental disturbance occurs in close connection with an epileptic fit which has been observed by reliable witnesses, and if it can be proven, in addition, that the individual has suffered from previous epileptic attacks, the correct forensic view will generally be reached without difficulty. On the other hand, in cases in which we have to deal with so-called equivalents or with larvated epilepsy, a correct diagnosis may become much more difficult. Furthermore, if we consider that ordinary epileptic attacks may have escaped observation for a long time, having occurred at night, or in the absence of witnesses, the

[1] Monatsbl. f. Augenheilk., 1895.

[2] Read before the Society of Medical Jurisprudence, New York, February, 1897.

question will naturally arise whether we are justified in diagnosticating an epileptic transitory insanity without consideration of other facts, such as the previous life of the patient or actual epileptic convulsions, simply from the clinical aspect of the attack itself. It is by no means impossible for epileptic attacks to have escaped notice, since we know that such seizures may last but a few seconds or minutes, a condition which is called petit mal, and which is believed to predispose the individual to mental disturbances much more than ordinary epilepsy. I may say, however, without hesitation, that in most cases we are able to form a correct judgment as to the diagnosis.

Although there are many different types of psychical epilepsy, which I cannot here discuss in detail, and although these different types are apt to undergo manifold variations, there are still certain features common to them all, which prove their epileptic nature and which can hardly be simulated. In many cases the paroxysm, as in ordinary epilepsy, is preceded by the so-called aura, which consists of peculiar sensations, such as a severe headache, vertigo, etc., or of hallucinations, mostly of an anxious or terrifying character. The paroxysm generally begins quite suddenly. The face becomes pale, the eyes stare, and respiration is labored; hallucinations and illusions of persecution lend an expression of anxiety to the face; an explosion of ferocious impulses now bursts forth, sometimes resulting in crimes of the most violent and brutal character. The individual's actions may seem without motive, absurd, and contrary to the manifestations of his true character. This condition, which may last from a few minutes to several hours, usually comes to a sudden end. The patient becomes covered with sweat and passes into a stupor, which may last hours or days, and from which he cannot be aroused as from an ordinary sleep. When he awakens, there is either a total or a partial absence of recollection of the events during the paroxysm.

Any of these symptoms may vary within wide limits. Some of them may be missing altogether, while other unusual features may appear. The diagnosis, therefore, must never depend upon one or a few symptoms, but must be based upon the general aspect of the entire attack. The following case will serve as an illustration of a typical attack of psychical epilepsy. A peasant, twenty-nine years of age, had suffered since his sixth year from epileptic seizures with consecutive stupor, which usually lasted several days. After awakening from this stupor, he never had any recollection of the events which occurred during the attack. The attack itself was always preceded by an aura, which took the form of a sensation as of something arising from the stomach. For a few days before an attack he was usually depressed and irritable. One day, after he had experienced the usual aura repeatedly, he had a long series of epileptic convulsions within twenty-four hours, after which he passed into a semi-stuporous condition. The following day he appeared in the yard, where a boy and a girl were chopping wood. The boy asked him sympathetically if he would like something to eat. He raised his hand to strike the boy, who thereupon ran away. He then attacked the girl, who was unable to escape, and with a blow of his fist upon her head knocked her down. At the boy's cries of alarm, the neighbors rushed to the scene and observed that he was staring at the girl, who was lying at his feet. At the cry of the neighbors, "For God's sake, John, what are you doing?" he picked up an axe from the ground, struck the girl several times on the head with it, then turned toward the horrified, fleeing spectators. He overtook one of the women and beat her upon the hand until she fell in a faint. He next struck an approaching dog with the axe, then lifted his shirt before a laborer who was present, and with the words, "See here," exposed his buttocks. Then he tried to break in the door of a house with the axe, ran after a man and struck him lightly, was finally overcome and bound. He then passed into a stupor, which lasted for several days. When he regained consciousness, he inquired with tears why he was bound and chained. He had absolutely no recollection of the events of the preceding days, and was very weak and exhausted.

In this case, the mental disturbance occurred in immediate connection with the epileptic convulsions, which fact placed the diagnosis of epileptic insanity beyond any question of a doubt. A very instructive case from my own experience will serve as an illustration of the same affection without this diagnostic aid. A German prince of about fifty-five years of age was on a visit to St. Petersburg. He suddenly appeared one morning at the window of his hotel with a rifle, and shot into the street, slightly injuring several people. When his room was entered, he threatened to kill any one who approached him. It was only with the greatest difficulty that he was overcome, especially as he was a powerful man, who displayed enormous strength, struggling and fighting like a wounded tiger. He was immediately brought back to Germany, and placed in a hospital for the insane, where he was put under my care. When I first saw him two days after the onset of the attack, he was in a semi-stuporous condition, talked abruptly and incoherently, and answered questions slowly and illogically. Now and then he would come out of his stupor, then would attempt violence upon those about him, so that he had to be confined in a cell. After a very careful examination, I decided that he was suffering from epileptic insanity, the diagnosis resting upon the sudden onset of the attack of his baseless violence and upon his stupor. I was later informed by his relatives that about twenty years before he had been attacked as follows: At that time he was the captain in a cavalry regiment in the Franco-German war. While his regiment was engaged in a battle, he suddenly led his men against a German infantry troop. When he was approached by a lieutenant, he would not listen to any argument, but rode straight ahead with staring eyes, repeating the words: "They are French guerillas, let us kill the guerillas." He was disarmed by his officers, passed into a stupor, and subsequently remembered nothing of the incident. After he was under treatment in the institution for several weeks, I was called to his room one day, where I found him in typical epileptic convulsions. He again became stuporous for two days and when he awoke from this condition he appeared to be in a perfectly normal state of mind. He was, however, greatly astonished to find himself in an institution for the insane. He could not recall anything from the time of the beginning of the attack in St. Petersburg up to the present moment. Although I had seen him at least twice daily, I was apparently a perfect stranger to him. He remained in the institution as convalescent for several months longer, and never showed any trace of mental disturbance during that time.

In both these cases the behavior during the paroxysm was in itself characteristic of insanity. Any layman could recognize without difficulty the fact that these actions were the outcome of some mental disturbance. In both cases, the violent actions were entirely without motive. The furious attacks were directed against people who were perfect strangers, who had no connection or relation to the maniacal aggressor. The entire conduct stood in marked contrast to the real character of the individual.

There are, however, other cases, in which the action in itself may in no way indicate a condition of insanity. The behavior of the patient during the

attack may even astound one by its naturalness. He may show in his conduct scarcely any signs of the great change which his consciousness has undergone. The deed which he commits may harmonize fully with his natural mode of thinking and with his natural desires, and may present every aspect of a premeditated crime.

The psychical mechanism of this condition will become clear to us at once, if we recognize the close relation which this pathological change of consciousness bears to the normal dream. While, in the majority of cases, dreams are more or less abrupt and seem to have no direct connection with the mental proceedings of the individual in his waking hours, there are, on the other hand, instances in which the dream seems to be the continuation of the last waking thoughts. In a dream, things may be done which in the waking state may possibly be thought of but never be really executed. So, in analogous manner, it may happen that an individual has ample cause to hate another and that, in a condition of epileptic insanity, he may take his life, a crime which, in spite of his motive, would probably never be committed in a normal state of mind.

Cases of this kind will of course offer much greater obstacles in the way of correct diagnosis. We have to depend in the first place upon the other correlative symptoms, such as the patient's condition before and after the attack, stupor, convulsions, amnesia, etc. We have next to consider the patient's heredity and the history of his previous life. We must ascertain whether he has been subject to previous attacks of psychical epilepsy, and what resemblance there is in the present attack to former ones, as far as the character, the duration, and accessory symptoms are concerned. Finally, it may be possible to learn from witnesses whether or not the patient displayed during the attack certain somatic symptoms, such as staring eyes, pallor or flushing, mechanical movements, etc., all of which may be helpful in reaching a diagnostic conclusion.

A correct judgment might become still more difficult in cases of so-called psychical petit mal, that is, cases in which a disturbance of consciousness may last only a few minutes, during which time certain impulses lead to the commission of misdemeanors or crimes. Many cases of so-called kleptomania are to be referred to this kind of epileptic insanity. The objection, especially among lawyers, that was raised against the original doctrine of kleptomania, according to which a great number of habitual thieves were the subject of disease, was perfectly justifiable. Kleptomania is not a disease in itself, and, if this term is to be preserved, it can be used only as an application for one symptom of a general disturbance. It would be the duty of the expert in such an instance to discover and verify the existence of such a disease. Such attacks of psychical petit mal have often been productive of small thefts, and have brought people of prominence as defendants before the courts. Giraud reports, for instance, the case of a prominent judge, who stole money at his club and many other places, and who was found guilty of petit larceny. He denied the truth of all of the accusations, and the examination of the expert showed that he was suffering from epilepsy, and had committed these thefts during acute attacks of unconsciousness.

The fact, that during these attacks of psychical epilepsy erotic impulses of the most violent type may manifest themselves is of great forensic importance. The most brutal sexual crimes may be evolved during these seizures. Most unnatural perversions have arisen during a state of epileptic unconsciousness. Sexual murders, such as the well-known Whitechapel crimes, are in all probability the result of epilepsy. Sodomy, rape, exposure of the genital organs, are occurrences by no means rare during attacks of psychical epilepsy. A patient of von Krafft-Ebing attempted repeatedly to rape his mother during epileptic paroxysms. After the seizure he recollected nothing of it, and during the intervals he was a strictly moral man without any sexual desire whatever. In this connection I can cite a very instructive case in my own experience. An officer of the German army, twenty-five years of age, was denounced by his valet for having made an immoral attack upon him. A similar charge was made against him by a soldier in his company. He was brought before a court martial and denied any knowledge of the occurrence referred to in the accusation made against him. At the instance of an army surgeon, he was transferred to an insane asylum for an examination into his mental condition. He was brought under my care, and I had him under observation for two months. For the first two weeks nothing abnormal in his condition was noted. He was exceedingly polite, even servile in his manner. One morning, while making my rounds in the building in which he was confined, I heard cries for help emanating from his room. When I reached him, I saw him squeezing a male nurse against the wall. His sexual organ was exposed and in an erect condition. His pupils were widely dilated, and his face was absolutely white. He paid no attention to me when I called him, but stared at his victim and continued to press him against the wall, so that I was obliged to call upon another nurse for assistance. At this moment he had an orgasm, whereupon he began to tremble violently and became covered with sweat. He was put to bed and remained in a stuporous condition for several hours. Upon awakening he was totally ignorant of what had occurred.

This was an epileptic paroxysm and nothing else. As I was fortunate enough to witness the attack, I was able to send a detailed report to the officers of the court martial, on the strength of which the case was dismissed.

The variable conditions of the memory after a paroxysm may give rise to great errors in the correct judgment of a case, especially in its forensic bearings. In the cases which I have quoted thus far there was a total absence of recollection of incidents during the attack. In a certain proportion of cases, the memory may be a partial one, that is, certain events may be vaguely remembered, like those of a dream, while others have entirely vanished from the memory. Again there are cases in which the memory acts peculiarly. A man, for instance, in an epileptic paroxysm may conduct himself in the furious way described. When he becomes quiet and rational and is asked about his conduct, he may give perfectly intelligent answers, and will apparently recollect everything that he did, and everything that happened during the attack. Yet after some time, perhaps the next day, it will be impossible for him to recall these events from his memory. The following case will illustrate this condition: A man, who was under treatment in a hospital for some syphilitic affection, arose after a very restless night at half-past five in the morning. He performed his work as he did every morning, going down-stairs to get water and subsequently assisting in the kitchen. He was suddenly seized by frightful sensations of anxiety and screamed at the top of his voice, "I must die." He ran to the range, removed a kettle from its place, put his head into the fire, and burned the entire scalp from the root of the nose to the occiput. His hands as well were severely burned. With the greatest difficulty, a nurse succeeded in saving his life by forcibly preventing him from further injuring himself. He then became calm and was put to bed. When he was questioned several hours later, he recollected all the events of the paroxysm, which had been

diagnosticated as epilepsy, the patient having experienced several previous epileptic attacks. He said that he had had a very restless night, and frightful dreams, such as he had never experienced before. He thought that the ward in which he lay was hell, that the other patients were evil ghosts, and that the physicians were devils. He noticed that when he arose in the morning he was very weak. The fright came over him very suddenly and he ran to the range. He remembered distinctly having put his head into the fire, and even recalled the burning sensation at the time. He appreciated time and space perfectly, and his answers were all intelligent. His consciousness, however, still appeared somewhat clouded, and it was several days before his mind became perfectly clear. The recollection of all the events of the paroxysm had then entirely vanished from his memory. He could only recall the great horror he had felt that morning, but was totally oblivious of what had happened to him.

I have intentionally selected this case as an illustration of this peculiar condition of the memory, because the destructive impulse was directed against the individual's own person, and not against others, so that any motive for simulation may be excluded with absolute certainty.

In order to explain the psychical mechanism of this condition, I may again be allowed to refer to the normal dream. Most people have probably experienced an occasional distressing dream, from which they have been awakened at night. At this time, they are fully aware of the details of the dream and may even discuss some points of it with themselves. They again fall asleep, and the next morning may recall perhaps that they had had a dream of an unpleasant nature, but its character and details have entirely escaped them.

When it comes to legal matters, a knowledge of this mental condition in insane persons may attain vital importance. Let us take as an example a man who has committed murder during an epileptic paroxysm. The following morning he is hauled before a magistrate and admits that he has committeed the deed because of an irresistible impulse which involved the taking of his victim for an evil spirit or the devil. The man's manner appears to be perfectly normal, and his answers are seemingly intelligent. He is incarcerated and held for trial. After the lapse of some time he is again examined and now alleges total unconsciousness of the murder and denies absolutely the statement he had previously made in court. Would this not appear as the crudest lie? Would any one not thoroughly familiar with cases of this nature accept his statement as true? And yet how close the resemblance is between this supposititious case and the one I have just cited. I frankly admit that the peculiarities of these cases are such that it seems perfectly excusable for a layman to regard them with mistrust. But the professional man who has to deal with criminal cases must be familiar with such instances in order to do justice to his client.

Another important feature of this class of mental disorders lies in the frequently observed fact that immediately after the paroxysm during the stage of clouded mentality the patient may invent stories of all kinds to explain or to excuse his ferocious deed and hallucinations, and subsequently may be entirely unconscious of the history he has given. A medical student, for instance, who, in an attack of epileptic insanity, attempted to kill his comrades, pretended after the paroxysm, without any foundation of truth, to have suffered for a year from illusions of persecution. Another patient, a soldier of the German army, accused himself of pederasty, and gave a most minute description of how he tried to force one of his comrades to have intercourse with him, all of which was later proven to be pure fiction.

In spite of the many variations and peculiarities of these cases of transitory epileptic insanity, they have, as I have pointed out, certain common characteristic features, and, as a rule, should be recognized and diagnosticated as such by the psychiatrical expert.

Another cause of transitory insanity with aberration of consciousness is found in those cases whose sources lie in acute poisoning, either by narcotics, such as ether or chloroform, or by other drugs, such as belladonna, strychnine, etc. Cases of acute insanity induced by the use of alcohol may be of great forensic importance. In this country ordinary acute alcohol intoxication is not considered an excuse for crime. It is, therefore, much more important to differentiate this common physiological alcohol intoxication, if I may be allowed to call it so, from certain morbid conditions of the mind which arise from the use of alcohol, and which may be termed pathological alcohol intoxication. There are certain individuals whose nervous systems show a decided intolerance for alcoholic liquors. Comparatively small doses of alcohol, which would cause no disturbance in a normal person, may evoke a condition of temporary insanity in such an individual. This inferior condition of the nervous system is either congenital, that is, we have to deal with a degenerate individual, in which case heredity plays an important rôle; or this peculiarity may be acquired by injuries, by infectious diseases, or by chronic intoxication from alcohol, opium, etc. The clinical form of this mental disturbance is in many respects similar to the one we have just described as the psychical epileptic attack. In these cases, too, we have the sudden maniacal paroxysm, with wild, ferocious manifestations, followed by a deep stuporous sleep and subsequent loss of memory of the events during the attack. We shall appreciate the close relation between this condition and one of genuine epilepsy much better if we bear in mind that any acute intoxication may also produce epileptiform convulsions which resemble those of true epilepsy. It is but natural therefore that the psychical disturbances arising in this way should resemble the conditions which we recognize as epiletic insanity.

It may be exceedingly difficult, but it is nevertheless highly important in such a case to convince the court that, in spite of the alcohol's being the immediate cause of the mental disturbance, we have to deal, not with a condition of ordinary intoxication, but with an attack of genuine insanity which renders the individual irresponsible for his actions.

The data upon which the diagnosis of acute alcohol insanity must be based and which differentiate it from ordinary alcohol intoxication are these: First, the quantity of alcohol which has been taken bears no proportion to the effect produced. Very small quantities are sufficient to call forth the mental disturbance. The attack may sometimes be due to a combination of smoking and drinking. Secondly, there is usually no relation in time between the drinking and the onset of the psychosis. The latter may start immediately after the use of the liquor, or there may be an interval of time between the drinking and the paroxysm entirely free from manifestations. Further, the psychopathic symptoms and obscuration of consciousness do not develop gradually step by step, as they do in the ordinary intoxication, but make their appearance suddenly, sometimes without any warning. Thirdly, there is also a qualitative difference between the behavior during the acute alcoholic insanity and common intoxication. In the case of insanity the external world is misinterpreted or is not perceived at all. Delusions and hallucinations, mostly of the persecutory type, form the basis for the vigorous motor manifestations. The be-

havior is not the consequence of co-ordinated perceptions, but is purely impulsive, the direct manifestation of intensified propensities. The clinical aspect of this condition may resemble a maniacal delirium. Fourthly, the mental aberration is accompanied by certain somatic symptoms, such as a full, rapid pulse, a flushed face, with injected, staring eyes. There are no staggering gait, no ataxic movements as in ordinary intoxication. Under the high dynamic power of the irritated motor centres in the brain, the movements are firm and energetic and the muscular power becomes highly exaggerated. Fifthly, there is always complete amnesia for the whole period of the psychosis.

Individuals with an inferior nervous system, upon which small doses of alcohol may have the effect just described, are apt to develop a similar condition of temporary insanity without the use of any intoxicants, simply through stress of severe emotions or mental shock. It is a well-known fact that ordinary emotions may cause a suspension in high measure of the intellectual control; yet a normal man even under the greatest excitement will always have sufficient influence over his actions not to be carried away by his emotion to such an extent as to commit a crime. A weak-minded, degenerate individual, however, may in such a case lose all power over himself; his conduct may resemble that of a furious maniac, and after this stage he may exhibit the same lack of memory of the events which have occurred that I have previously described. We have to deal in these cases not with ordinary emotions or affections, but with the special form of temporary aberration well defined in its clinical features and known as "emotional insanity."

Similar to these are certain instances of infanticide, in which women, partly through loss of blood, partly through mental emotions, such as shame and grief, may pass into the state of transitory insanity.

In some cases it may be a combination of intense emotions and the use of alcohol which evokes this form of insanity. The following case will be illustrative: An innkeeper, thirty-nine years of age, was unhappily married. One night his wife eloped with her lover. The following morning he was very much depressed and agitated, and did not eat or drink during the entire day because of his keen disgrace. He served an unusually large number of guests almost continuously during the day, and seated himself about nine o'clock in the evening, fatigued by his day's work, at a table. He exclaimed, "This has been a cursed day for me," drank a glass of claret rapidly, and without another word went into an adjoining room, slamming the door noisily behind him. A few minutes later peculiar noises were heard, and smoke and an odor of burning furniture were perceived. The door was opened and the man's bedclothes were found in flames and he was throwing cartridges into the fire. When he was asked what he was doing he grasped a revolver and cried loudly with wildly rolling eyes: "Go to the devil, all of you, or I will shoot you down like mad dogs." The mayor was then called and soon appeared with abundant assistance. The fire in the mean time had gained headway. In the midst of the flames and smoke stood the man, cursing frightfully. He shot at those who approached him, but was fortunately thrown to the ground; although for twenty minutes it required seven strong men to withstand his furious and vicious attacks, he was finally bound and arrested. He fell asleep and in sixteen hours awoke lucid. His recollection served him only up to the moment when he had gone into his bedroom after drinking the claret. The man remained healthy. He had no hereditary taint, had always been able previously to drink spirituous liquors without having been an habitual drinker, had always been healthy, so that the cause of the attack must be sought in his anger, his physical exertions during the day, and the rapid drinking of a glass of claret on an empty stomach.

Of no less forensic interest are those instances in which the crimes have been committed in a state of deep sleep. Although I think that the great majority of cases which have been recorded properly belong to the class of transitory epileptic insanity, since they offer all the clinical symptoms of the disease, still there are other cases in which the peculiar conduct of the individual can be attributed to no other cause than this somnolence. As a rule these individuals, too, possess nervous systems with a number of pathological stigmata and with a diminished resistance. The history of the previous life of these patients will usually show that similar phenomena have occurred before during sleep, and the opinion of the expert must be based upon the general condition of the individual as much as upon the symptoms of the special event. The following case will illustrate a murder committed under these conditions: A rich young man, a gentleman, farmer by occupation, irritable, subject to sudden flushes, was given to exciting dreams and was regarded by his family as a sleep walker. As he lived in an isolated locality and therefore feared burglars, he always slept with a gun and a sword by his bed. One morning his brother called for him to go hunting. He was still half asleep, but jumped out of bed, swung his sword about as though to attack his brother, who seized him, however, and called him by name, whereupon he at once became conscious of his surroundings. Some time later under similar circumstances, his father appeared in the room early in the morning and was shot dead by his son.

In close relation to these conditions are cases of so-called somnambulism. While in normal sleep an equal diminution of all vital functions takes place, no transformation from simple dreams into co-ordinated movements occurring, in somnambulism, on the other hand, there is a marked disturbance of equilibrium. The psycho-motor sphere lacks the diminution of activity, which is essential for normal sleep, and consequently dreams are put into motion, while the highest psychical centres, which are responsible for self-consciousness, take no active part in the actions of the individual. Such a person walks about with staring eyes like an automaton, with no apparent purpose, or, according to the condition of his associative power, may perform quite co-ordinated movements, without, however, being conscious of them. The events during this condition may either not be recollected at all or there is merely the resemblance of a dream. In some rare instances, the occurrences during one are recollected only during the following attack, and in this manner a remarkable condition of so-called double consciousness is produced.

All these phenomena of somnambulism form a part of a general nervous disease. They are usually a complication of epilepsy. They never occur in otherwise healthy individuals.

Transitory disturbances of consciousness occurring during the course of a regular psychosis, will usually be recognized without difficulty as pathological when the underlying disease is recognized. Nevertheless they may escape notice, either on account of mildness of the symptoms or because of insufficient observation, and acute outbreaks with violent, sometimes even with criminal conduct, as in some forms of temporary insanity, first direct attention to it. The disease which is most likely to give rise to such a condition is melancholia. A person who has always been considered to be perfectly healthy may suddenly be seized by an attack of maniacal violence resulting in self-mutilation or suicide, or even in the murder of the nearest

relatives or friends. A careful examination of the previous history of such an individual may reveal the fact that for some time he has been suffering from mental depression. As attempted suicide, which is the most frequent outcome of such a condition, is, strangely enough, punishable by law in this State, these cases become of great medico-legal importance. The clinical feature of this form of mental aberration, known as raptus melancholicus, resembles acute attacks of epileptic insanity in many respects. Here, too, we have the sudden, violent, destructive outbreak. The furious motor impulses are not satisfied by simply destroying or killing their victim, but usually result in its most horrible mutilation. Attacks of this nature have been correctly called "psychical convulsions:" deepest anxiety and despair are the bases from which these impulses arise. After the enormous psychical tension has led to explosive acts of violence the patient becomes quiet and calm and feels relieved. The memory of events during such attacks may be partially or totally destroyed. Most frequently the involuntary uncontrollable psychical pressure for relief, the destructive impulse, is directed against the individual's own person, resulting in self-mutilation or suicide. In other cases, an unconscious transfer of the delusional sensation of misery is applied to the external world, which appears bad and wicked, and a subconscious impulse to save those dearest and nearest from such vicious surroundings might impel the melancholic even to the murder of his own children.

The correct diagnosis of these cases will generally be easily made when there is no apparent psychical cause for the desperate act of the patient, and when his previous life and environment form a marked contrast to his psychopathic conduct. On the other hand, a proper judgment might become much more difficult if the diseased mental condition were induced by severe blows of fate, so that the grief and despair seem to be well grounded, or when, for instance, parents have been known not to be very devoted to their children. Only a most thorough study of the entire psychical and somatic condition of such an individual can reveal the true nature of the sad event.

After having considered the most important forms of insanity which may give rise to transitory disturbance of consciousness, during which crimes may be committed, the question will naturally suggest itself to the minds of legal men, whether it is not possible for a criminal to claim unconsciousness during the time of the commission of his crime, and whether his case could not be made to correspond to one of the forms of insanity described. Especially is this true if the manifold variations of the different forms are brought to mind. The lawyer is perfectly justified in asking whether we are able to prove, with the same certainty as we make a diagnosis of insanity, that in a given case a criminal is lying, that he is wrongfully assuming a previous condition of unconsciousness. We must frankly admit that, unless we are able to do so, the advances and discoveries of forensic psychiatry cut like a double-edged sword. While it is true that on the one hand we should protect an innocent patient, who should not be held responsible for his criminal act, from unjust punishment, we should on the other hand give impunity to all evil-minded and wicked men by rendering their premeditated crime excusable, under the pretence that they suffered from one of these forms of temporary aberration.

While direct simulation of mental diseases is an extremely rare occurrence and, on account of the great difficulty of playing such a rôle correctly, is rarely successful, nevertheless we not infrequently meet instances in which criminals pretend to have committed their crimes in a state of unconsciousness. Now is it possible in such a case to prove forensically that we have to deal with an ordinary liar? I do not hesitate to answer this question in the affirmative, although I must admit that in these special instances it is far more difficult to make a positive diagnosis of simulation than to diagnosticate an actual disease.

The diagnosis of simulation must be based on two different factors: First, on the exclusion of any criminal features which may lead to the diagnosis of any form of transitory insanity, heredity, epilepsy, chronic alcoholism, previous attacks, post-epileptic stupor, etc.; and secondly, on positive facts establishing the falsity of the defendant's statement. If the individual is apparently normal, if he has never before suffered from a neurosis or mental disturbance, it is not very probable that the sudden attack of unconsciousness is genuine, although by no means impossible. We must not forget, however, that criminals are liable to offer many stigmata of degeneration without being insane in the legal sense. The diagnosis of simulation, therefore, cannot depend on the presence or absence of one or of a few elements, any more than can the diagnosis of disease: but it must be based on the general aspect of the case.

When a criminal untruthfully pretends to have been unconscious at the time of his criminal act, the amnesia is usually complete. He knows nothing of a partial loss of memory, and naturally considers it much more effective to assume to know nothing at all than to have a fragmentary recollection. Premeditated crimes are never committed without motive, although it may not be possible in all cases to prove its existence. Of great importance for the differential diagnosis is a careful consideration of the events occurring during the time immediately before and after the crime. The psychical mechanism of so-called unconsciousness does not consist in narrowing alone of the psychical field, in a suspension of part of the psychical functions, but it depends largely, and this is by far the more important factor, on disassociation of thought with both the previous and subsequent mental processes. As in the ordinary dreams, such a period of unconsciousness forms an individual entity, and, unlike normal psychical processes, is not a link in the great chain of thoughts. This disconnection is plainly marked by clinical symptoms, and their absence may be of great aid in the diagnosis of simulation. We may even be able to detect a direct connection between the period of pretended unconsciousness and the preceding chain of thoughts. The individual under suspicion may possibly have made some preparations for his crime, such as the acquisition of a weapon, conversation with others about his plans, etc.

While patients suffering from transitory insanity generally pass into a stupor after the paroxysm, or at least show a marked contrast in their behavior after the attack, the behavior of crimininals after the commission of their deed always stands in some relation to the crime. They try to escape or to conceal evidences of the act or may make some remarks indicating in some way the motive for the deed committed. There is no disassociation between the period of their alleged amnesia and subsequent time, as appears in pathological cases. While a pure and simple liar will as a rule be easily recognized as such, we may occasionally meet complicated cases in which it will be much more difficult to reach a correct conclusion. An individual may, for instance, suffer from epilepsy or from chronic alcoholism, and also present hereditary stigmata. He may still commit premeditated crimes. Epilepsy alone, so long as it has not developed into a psychosis, cannot be accepted as an excuse for criminal action; it is the duty of the expert in such a case to show that the crime has been evolved during a genuine epileptic attack or during any other psychopathic condition. Further, if we remember that what is known as the

epileptic character consists in an increased impulsiveness, augmented response to emotional stimuli, tendency to lie, it may become extremely difficult to reach a correct conclusion, and sometimes only a protracted study of the individual will lead to a right conception of the case. But it is not only due to this difficulty that we so frequently witness in criminal cases men of high standing and undisputed reputation arrive at quite diverse conclusions. The fault lies not so much in a deficiency of our special science, as in its incorrect application in practice. As long as the psychiatrical expert is compelled simply to answer questions which are put to him by a layman, instead of making a scientific elucidation; as long as he is obliged to appear in court to decide a sharply defined aut-aut, instead of making a psychological analysis, in order to explain the psychical mechanism to which the criminal action is due, so long will forensic psychiatry be unable to benefit mankind in a measure commensurate with that degree of perfection which it owes to modern investigation. I trust that I express no vain hope when I urge that in the near future we may no longer see psychiatrists appearing as allies of plaintiff or defendant, but that lawyers and psychiatrists may work in harmony together to the end that in every case the truth may appear, and that thereby the unfortunate victims of mental disease may receive just, honest, and conscientious treatment, and that, on the other hand, these combined efforts may not prevent society from its due protection against premeditated criminal acts.

A CASE OF A RARE FORM OF PSEUDOHERMAPHRODITISM; TYPE, ANDROGYNOUS; VARIETY, FEMALE SEXUAL PASSAGES SUPERADDED IN A MALE—"INTERNAL PSEUDOHERMAPHRODISM" (KLEBS); "BISEXUAL CONFORMATION OF THE MIDDLE SEGMENT" (HERRMANN).

By LEWIS A. STIMSON, M.D.,

SURGEON TO THE NEW YORK HOSPITAL; PROFESSOR OF SURGERY IN THE NEW YORK UNIVERSITY.

EUGENE P——, forty-eight years old, was sent to me by Dr. H. B. Douglass to be treated for an abdominal tumor. The patient was a negro, of medium muscular development and purely masculine type of body; the pelvis of average width; mammary glands undeveloped; growth of hair on face rather scanty, but about such as is commonly seen in the negro. The penis was normal in form and of medium size; the scrotum was small but complete; the left testicle was undescended; on the right side was a reducible inguinal hernia; the perineum was normal. The patient has been twice married, and has a son twenty-five years old. In the lower part of the abdominal cavity in front was a tumor, apparently as large as the closed fist, extending from the median line close above the symphysis to the left. It could be indistinctly felt through the rectum by bimanual palpation. Diagnosis, tumor of undescended testicle.

I operated at the New York Hospital, January, 1897. When the patient had been anæsthetized and placed upon the table, the tumor was found to be situated more centrally and nearer the umbilicus, and freely movable. The abdomen was opened by a median incision extending from the umbilicus nearly to the symphysis and exposing the tumor, which was white, irregularly globular, and attached only by a broad pedicle at its lower end. After the tumor was turned out through the wound, the appearances indicated in the accompanying cut were disclosed. The long broad pedicle of the tumor spread out from its left border over the left side of the pelvis, extended posteriorly to the bottom of the pelvis, leaving a roomy space between itself and the sacrum, Douglas' pouch, and was continuous anteriorly with a broad layer of peritoneum that extended downward and forward and then upward over the anterior pelvic and abdominal wall. Its right border curved inward to a structure (uterus) resembling in appearance, shape, and position the fundus of a medium-sized uterus. From the other side of this uterus ran the mesial border of a similar but much smaller pedicle, which terminated in a white, oval, flattened mass—the right testicle, which had been drawn back from the scrotum when the tumor was lifted out. From each cornu of the fundus ran a pale cord, the Fallopian tube, eight inches long, forward and outward and then backward and outward, ending far from the testicle and showing plainly under the peritoneum. The outer end of each cord was slightly pointed, and like the rest of the cord lay wholly under the peritoneal sheet. No round ligaments could be found. Numerous large veins showed plainly beneath the peritoneum behind and in front of the two cords. On the right anterior wall near the symphysis the peritoneum was raised in a loose fold, showing at its centre an opening through which the finger could be passed into the scrotum. The uterus on palpation appeared to be directed downward, forward, and a little to the right. It was soft, and its lower termination and lateral margins, as well as its relations, if any, with the bladder or prostatic urethra, could not be made out. The bladder lay empty behind the symphysis and on the floor of the broad pouch between the uterus and symphysis. Palpation of the pedicle of the right testicle showed a small cord resembling to the touch a vas deferens.

After showing the parts to my colleagues, Drs. Weir and Hartley, who were in the hospital, I removed the tumor, replaced the right testicle in the scrotum, and closed the wound. The patient made an uneventful recovery, but the testicle slipped back into the abdominal cavity. Examination of the tumor by Dr. Biggs, the pathologist of the hospital, showed the presence of seminiferous tubules, an epididymis, and a vas deferens. The tumor was a sarcoma.

The abnormality is of course due to the coincident development of Müller's ducts, which normally in the male atrophy and persist only as the utriculus hominis or sinus pocularis beneath the veru montanum in the prostatic urethra, and which in the female develop into the uterus and Fallopian tubes. A very slight grade of the abnormality is not infrequently seen in the deepening of the utricle and even in the presence

within it of transverse folds resembling those of the vagina, but examples of more marked forms are very rare.

Hermann[1] collected, in his article on "Hermaphrodism," six such cases more or less similar to the one here given. The supernumerary organs varied from a small vagina opening into the urethra and continuous at the other end with a uterus having only one cornu and a rudiment of tube, to a fully formed uterus with incomplete tubes and a rudimentary vagina formed by a fold at the veru montanum. The details are as follows:

Vagina and unicornate uterus: Betz[2] found in a stillborn male with normal external genitals a male uterus, opening through a vagina at the veru montanum and ending on the right side in a cornu with a rudiment of a tube. No seminal vesicles; left vas deferens obliterated; right testicle not descended. Eppinger[3] found a similar condition in an adult.

Vagina and bicornate uterus: Petit (1720) reported to the Académie des Sciences the condition found in the body of a man, twenty-two years old. The external genitals were normal, but the scrotum was empty; the testicles were small and occupied the position of the ovaries. The epididymis, vasa deferentia, prostate, and seminal vesicles were present. A uterus was attached to the neck of the bladder and opened into the urethra. "From the uterus arose on the right and left two tubes, which extended to the epididymides and had no fimbriated ends." (The heading indicates that Hermann considered the tubes in part the cornua of a bifid uterus.)

Mayer:[4] Four months' fœtus—normal external genitals, testicles, vasa, and prostate; male uterus distinctly bicornate. "The two internal canals are completely separated from each other by a median septum as far down as their lower ends, where they terminate in a blind pouch and project into the vagina. The latter opens, not at the veru montanum, but into the bladder."

Hyrtl:[5] Utero-vaginal canal—two horns uniting to form a single canal opening on the veru montanum. "The mucosa is arranged in transverse folds. Prostate exists; seminal vesicles absent; testicles and epididymides normal, and in the scrotum."

Vagina with partly developed uterus and tubes: Franqué:[6] adult male, cryptorchid, the testicles lying in the inguinal canal. Epididymides and vasa deferentia, the left obliterated. No ejaculatory ducts. Prostate small; two seminal vesicles. "The vagina is formed by a fold at the level of the veru montanum, and is continuous with a well-formed uterus showing cervix and body and surmounted by two tubes, the left complete, the right in great part obliterated."

Dislocations of the Hip.—Treves ("System of Surgery," vol. i., p. 1,006) tabulates as follows the methods of treatment by manipulation of the four common dislocations of the hip: 1. Flex the thigh in adduction in the dorsal and sciatic dislocations. Flex the thigh in the abducted position in the obturator and pubic dislocations. The object of the flexion is to relax the Y-ligament. 2. Abduct and rotate outward in the dorsal and sciatic dislocations. These manipulations cause the head of the bone to retrace its steps through the capsular rent, and relax the short rotator muscles. 3. Extend in all cases. This causes the head of the bone to enter the acetabulum.

THE DIAGNOSIS AND TREATMENT OF MULTIPLE NEURITIS.

By CHARLES LEWIS ALLEN, M.D.,

LECTURER ON NERVOUS DISEASES, GEORGETOWN UNIVERSITY, WASHINGTON, D. C.

The comparative frequency of multiple neuritis, its varied etiology, its prognosis, favorable as compared to the hopeless outlook in the chronic diseases of the spinal cord, with which it is most liable to be confounded, make its study of interest and importance, as well to the general practitioner as to the specialist. To the former, I would more particularly address myself, in asking attention to some points in its diagnosis, prognosis, and treatment, studied in the light of recent advances in our knowledge.

A knowledge of the etiological factors of a disease plays an important part in its diagnosis and treatment, and multiple neuritis is usually divided into different forms, according to its different causes.

With the exception of certain senile and degenerative forms—which differ considerably in their course and in the distribution of the lesion from the other forms—probably all cases of multiple neuritis are due to the presence in the blood of some poison, introduced from without or developed in the body, in the course of a morbid process. The poisons derived from without are definite in character and of known composition. Among them alcohol and lead play the greatest rôle, but arsenic, mercury, silver, and copper among the metals, and carbon bisulphide, nitrobenzol, aniline, and carbon monoxide among the non-metallic poisons, are capable of causing neuritis.

The poisons developed in the body have no such definite composition, or at least we have not yet been able to make out just what their composition is. Among these, that of diphtheria is the most apt to produce a neuritis, but neuritis may develop also as a result of typhus, typhoid, tuberculosis, variola, scarlatina, erysipelas, pneumonia, septicæmia, etc., as well as in rheumatism and diabetes. In lepra a peculiar and characteristic form of neuritis occurs; while in the very fatal beriberi or kakké, endemic in the East and in Brazil, we have a multiple neuritis, apparently infectious in origin and presenting a well-marked clinical picture, which differs considerably from that with which we are familiar in this country. A malarial form of neuritis closely connected with remittent fever has been described as coming from India and other countries, where severe malarial fevers are prevalent. In American books malaria is mentioned as a possible cause of neuritis, but it does not seem to be regarded as a common one. Possibly a closer study of cases of paralysis of the legs which occur in the malarial regions of the Southern States may show that neuritis from this cause is not so rare. Cases of neuritis due to cold are not uncommon. Perhaps they are rheumatic in origin: if not, they are most likely due to the action of some poison, developed in the system as a result of exposure to cold.

A neuropathic constitution is undoubtedly predisposing, and two or more causes may combine to produce an attack. As to the pathological anatomy of the disease, it will suffice to call attention to the fact that multiple neuritis is primarily a parenchymatous inflammation, while neuritis of single nerves is interstitial, confined at the start to the connective-tissue sheath, and involving the nerve fibre proper secondarily only. Multiple neuritis may be acute, but is more usually subacute or chronic. The acute cases may run a course not unlike acute ascending paralysis of Landry, or may present the same symptoms, only in more violent form, as the more chronic cases, being accompanied in addition by fever and constitutional disturbance.

The symptoms of multiple neuritis "are of three classes—motor weakness, sensory disturbance, and inco-ordination" (Gowers). According to the predominance of one or another of these, we have a motor, a sensory, and an atactic form of the disease. These symptoms vary in degree in different cases, but are generally combined.

Alcoholic neuritis is by far the most common, and can very well be studied as a type of the disease. It results from the continued use of alcohol, especially in the form of spirits, is a disease of adult life, and is said to be more common in women drinkers. Neuropathic constitution and exposure undoubtedly predispose to an attack. It begins with tingling and numbness in the finger tips and soles of the feet. Sooner or later this spreads up the limb, and is followed by pain and loss of power, the legs suffering earlier and more than the arms, often exclusively.

The pain is located along the nerves and in the muscles. It is burning, boring, or aching in character, and varies much in degree. The affected muscles are tender and painful on pressure, on account of involvement of the muscle nerves.

The disease shows a tendency to involve special nerves—in the leg, the peroneal: in the arm, the posterior interosseous—supplying respectively the flexors of the ankle and extensors of the toes, and the extensors of the wrist and fingers—homologous groups of muscles, which, when paralyzed, give rise to the "foot drop" and "wrist drop," so characteristic of neuritis.

Any other nerves may be involved in the progress of the disease, those of the extensor muscles suffering most. The "knee jerk" and perhaps other tendon reflexes are lost, or very much diminished; the skin reflexes suffer less. As the disease progresses the muscles atrophy and show altered electrical reactions. In mild cases the atrophy may be slight and electrical reaction only quantitatively altered; but in bad cases atrophy is great, "reaction of degeneration" is found, and recovery is very slow. Normally both nerve and muscle respond to stimulation by either galvanic or faradic current, and with galvanism the strongest contraction is produced by the negative pole (cathode) at the moment of closing the circuit. When degeneration of nerve fibres is present, however, there is loss of faradic irritability by both nerve and muscle. To galvanism the nerve does not reply at all: the muscle responds, and to a weaker current even, but no longer gives a quick, sharp contraction. It contracts with a slow vermicular movement, and may show greater irritability to the positive pole than to the negative. This change constitutes "reaction of degeneration." If the peroneal group of muscles is alone involved, the patient can walk, but cannot lift his feet well. If the other muscles of the legs are attacked he may be completely paraplegic. Sensory disturbance begins with tingling and numbness in the affected region, and hyperæsthesia and painful sensations are soon added. Later anæsthesia, more especially to touch, comes on. Temperature sense is little affected. Inco-ordination may occur to a greater or less extent. It is generally combined with motor and sensory disturbance. When it is the chief or only symptom, we have a special type of the disease, the atactic, and to it I would invite attention, as it is the form which above all others may give rise to an error of diagnosis, its resemblance to locomotor ataxia being marked. The idea that inco-ordination of the legs, with disturbance of sensation, was due always to sclerosis of the posterior columns of the cord was universally prevalent until, in 1883, Déjerine published the clinical histories and results of autopsy in two cases, which showed that these symptoms could be produced by lesions of the peripheral nerves, the cord being entirely uninvolved. For this new form of ataxia, he proposed the name of "nervo-tabes periphérique," and as peripheral neurotabes (or pseudo-tabes) it is described in English books. Déjerine's cases presented many of the chief signs of locomotor ataxia, viz., inco-ordination, diminished sensibility, pains in the legs, Romberg's symptom (inability to stand with the eyes shut), and loss of knee jerk. The spinal cords were found absolutely normal, while the nerves showed degeneration; and, specially to be remarked, this degeneration was almost entirely confined to the cutaneous nerves, the muscle nerves being but slightly affected. The resemblance to locomotor ataxia is still more striking in the rare cases in which the eye muscles are affected.

In neuritis, besides atrophy of muscles, trophic changes in skin, bones, and joints may occur. Slight œdema and "glossy skin" are most common.

In alcoholic neuritis the general symptoms of alcoholism—tremor, coated tongue, and gastric disturbance—are apt to be present. Aside from delirium tremens, there occur more chronic forms of mental disturbance, often following the course of the neuritis in its extension or improvement. The characteristic psychosis is hallucinatory confusion, with a forgetfulness which lasts a long time, being often as slow to improve as the paralysis. Such is the picture of alcoholic multiple neuritis, and sketches fairly well the symptoms of the disease in general.

Lead neuritis, the next in frequency, has a special tendency to involve the extensors of the wrist and fingers, and produces the "wrist drop," which when seen alone at once suggests lead poisoning. The long supinator usually escapes. The homologous muscles of the legs are sometimes affected, but not nearly so frequently as in neuritis from alcohol.

Arsenic affects the same groups of muscles as lead, but the legs are more frequently involved and sensory symptoms are more prominent. Mercurial neuritis has been described, occurring usually during a course of mercurial injections for syphilis. The legs are chiefly affected. Neuritis from poisoning by other metals is not common, but when it occurs it resembles neuritis from lead. Neuritis following acute infectious diseases is far more variable in its distribution, and tends to involve a greater number of muscles than the forms just mentioned. Of all diseases diphtheria is the most likely to be followed by neuritis, which assumes here its most dangerous form, having tendency to involve the nerves to heart and respiratory muscles. The palate is usually affected first; the voice becomes nasal, and liquids which the patient attempts to swallow regurgitate through his nose. The eye muscles are next attacked, there is loss of power of accommodation, and so of vision for near objects. The muscles which move the eyeball may also show weakness. Next in frequency the limbs are involved; less commonly the muscles of the trunk, neck, and larynx, the heart, the diaphragm, the bladder, and rectum. Neuritis is less common after other infectious diseases, and when it occurs its distribution is not very characteristic. Malarial neuritis is said to affect specially the legs.

Beriberi is an acute infectious multiple neuritis. It attacks particularly the legs and heart nerves, the resulting heart weakness giving rise to anasarca more or less widely distributed. In this country it is practically never seen, except in patients who have recently come from regions where it is prevalent.

Leprous neuritis differs considerably from the type we are studying, and will not be discussed in this paper.

An investigation as to possible cause is necessary, as well to diagnose the disease and its form as to institute suitable treatment. The presence or absence of antecedent infectious disease can usually be learned without difficulty, but it is well to remember

that a sore throat too slight to have attracted much attention may have been due to diphtheritic or rheumatic poison, and be followed by neuritis. Alcoholic neuritis occurs not infrequently in persons unsuspected of alcoholic indulgence, especially in women who for years have been tippling in secret. The occupation of the patient should be considered. Lead poisoning is apt to be present in painters, plumbers, and others who work with the metal or its compounds. Accidental sources of lead are drinking-water containing lead, lead glaze on earthenware, and cosmetics. The character of the paralysis has been mentioned. Other signs of saturnism are anæmia, colic, and especially the blue line on the gums. Arsenical neuritis may result from one toxic dose, but chronic arsenical poisoning is not so rare, the chief sources being wall papers and dyes—especially some of the aniline colors prepared with arsenic and not properly freed from it. Other metals are rarely a cause of neuritis, but the possibility of their being should be remembered. Rubber workers are exposed to the action of carbon bisulphide, dyers to that of aniline and its derivatives. When multiple neuritis begins acutely with pains in the limbs and fever, it may be mistaken for rheumatism, unless attention is paid to the seat of the pain—whether in joints or in muscles and nerves—and inquiry as to subjective symptoms of tingling and numbness is made. Neuritis differs from neuralgia in the greater persistence of the pain, in its more symmetrical and wider distribution, and in the loss of function, which is soon apparent.

Very acute neuritis may closely simulate acute ascending paralysis. The latter—a spinal-cord disease apparently—attacks the legs, and ascends rapidly to the trunk, showing no tendency to pick out different muscle groups, causes no loss of sensation, and generally proceeds rapidly to a fatal issue. Diffuse myelitis may at times resemble neuritis, as may spinal meningitis. There is usually wanting, however, the symmetrical distribution of neuritis. There is not so much atrophy and less altered electrical reaction. The tendon reflexes are exaggerated rather than lost, as in neuritis, and the bladder and rectum are apt to suffer. Sensation of constriction about the body, "girdle sensation," is common in myelitis, but almost never occurs in neuritis. Poliomyelitis anterior and locomotor ataxia are, however, the two diseases of all others with which multiple neuritis is apt to be confounded. Poliomyelitis, like neuritis, may run an acute or a chronic course. The acute form, however, is by far the most common, and, unlike neuritis, has a special tendency to attack young children. It begins with fever and constitutional disturbance, and loss of power comes on quickly, but sensory symptoms are wanting. There are wasting of muscles and change in electrical reactions as in neuritis, but the distribution is quite irregular. A few muscles of one leg, both legs, or a leg and an arm may be affected, or any other combination may occur. The age of the patient, the rapid onset of paralysis, its irregular distribution, and the absence of sensory symptoms are the chief diagnostic points.

Locomotor ataxia is slow in course; there is for a long time little or no loss of power in the muscles, but inability to co-ordinate their action. This "ataxia" never comes on until months after the onset of the disease. There is no muscular tenderness or pain, but special tendency to involvement of sphincters and eye muscles, and to optic-nerve atrophy. Romberg's symptom and failure of the pupil to contract for light, while it contracts for accommodation (the "Argyll-Robertson pupil"), are almost invariably present, and "girdle sensation" is very common. In the more acute motor form of neuritis, the distinction is seldom difficult. It is the sensory atactic form, the peripheral neuro-tabes, in which the difficulty occurs, and when the onset of the disease is slow, and there is some involvement of the sphincters and of the eye muscles, with pains in the limbs, the diagnosis may remain long in doubt. The most important diagnostic points of peripheral neuro-tabes are rapid evolution of the ataxia, muscular pain and tenderness, and absence of the "Argyll-Robertson pupil." There may be paralysis of the iris in neuritis, but it is always complete, never with dissociation of the reactions for light and for accommodation. Muscular atrophy is more characteristic of neuritis, but may come on in locomotor ataxia. Involvement of the sphincters only rarely occurs in neuritis, but is common in locomotor ataxia.

In a large number of cases of neuritis, the cause removed, the disease goes on to recovery: but, unfortunately, this is not always so. The acute cases, with involvement of the nerves to the heart and respiratory muscles, are very dangerous and apt to result fatally. Unless such involvement occurs, however, the immediate danger to life is small. With regard to restoration to function, the prognosis varies, depending upon the removability of the cause and the amount of change in the muscles and nerves and in the spinal cord. This latter brings us to a most important point. That in the course of multiple neuritis changes in the spinal cord may occur has long been known. In recent years considerable attention has been paid to the subject, the cords from cases of neuritis and those from animals whose nerves have been cut experimentally have been examined, and the results of a number of such investigations have been published.

That when a nerve fibre is cut degeneration takes place in the part separated from its ganglion cell was shown long ago by Waller. It has since been found that in the part still connected with its ganglion cell, degeneration also occurs. This has been called "retrograde degeneration," in contradistinction to Wallerian degeneration. It may extend into the spinal cord. The combined results of a number of investigations show that in multiple neuritis secondary changes in the spinal cord may occur. These changes may affect the anterior roots, the posterior roots, the anterior, lateral, or posterior columns, and the cells of the gray matter. The location of these changes varies in different cases, but involvement of the posterior columns and posterior roots is most frequent, though the anterior roots and cells of the gray matter often enough show changes. By no means all the fibres in the affected regions are attacked, but the Marchi method shows the presence of a greater or smaller number of degenerated fibres among the healthy ones.

In cases with involvement of the spinal cord, the prognosis is unfavorable. Three signs of spinal-cord involvement given by Gowers are: impairment of the functions of bladder and rectum, girdle pain, and loss of sensation, or paralysis of all muscles below a certain level, *e.g.*, below the knees.

In all except the mildest cases of neuritis, recovery is slow, and is preceded by a stationary period, which lasts one or two months. Some power may be regained after two or three months, but the average duration of the weakness is six or seven months, and it may be a year before all the muscles recover. In all but the mildest cases there is rapid change in electrical reaction. This may be only diminished irritability, or may go on to partial or complete reaction of degeneration. The more the deviation from the normal, the greater the wasting and the longer the duration of the paralysis. Usually power returns before normal reaction, but a recovery of electrical irritability by nerve and muscle, especially to faradism, is a favorable sign. When reaction of degeneration is present and persists, the prognosis is unfavorable, though an exact time limit can hardly be given. In the treatment of

neuritis the first and most important indication is to remove the cause.

The alcoholic should be warned that persistence in his habit will prevent a cure, and if resumed is likely to cause another attack. The elimination of lead from the system can be hastened by a course of potassium iodide with an occasional purge of Epsom salts. Malarial infection calls for quinine; rheumatism for salicylates or salicin. The acute cases due to cold may be treated as rheumatic, alkaline bromides being added to the salicylates. The pain may be so severe as to call for morphine, but the newer analgesics, antipyrin, acetanilid, or phenacetin, may be tried, due regard being paid to their tendency to depress the heart. The pains in the limbs may be relieved by warm or cold applications, though the muscles are usually too tender to bear much weight. Absolute rest of the affected part should be secured, the limbs being best supported on soft pillows.

In diphtheritic paralysis of the palate muscles, it may be necessary to feed with a tube. The diet should be nutritious, with plenty of fat, as cream and cod-liver oil, as soon as the process of regeneration is commencing. As tonics, iron, arsenic, phosphorus, and strychnine should be given. The last is specially valuable, but should not be persisted in for more than three weeks at a time. By judicious changes, a therapeutic course can be kept up for a long time. When pain and tenderness are gone, warm and cold douches to the affected limbs, with massage, are useful, and electrical treatment should be begun. The best results are from use of the galvanic current. It should be applied daily for about ten minutes at a time, first stabile, then labile. A strength of ten milliamperes will usually be sufficient. Later the muscles should be exercised, by interrupting the current, with one pole, preferably the negative, on one motor point after another. For this the faradic current may also be used. When anæsthesia is present and persists, this latter current, with the wire-brush electrode rubbed gently over the affected area, is useful. In chronic cases tendency to secondary contractions should be combated by suitable apparatus. When they occur, orthopædic measures are indicated. I add a sketch of four cases, which illustrate some of the points discussed.

Case I.—A girl of fourteen years, with obstinate chorea, while being treated with large doses of Fowler's solution, suddenly developed weakness in the legs, with foot drop and slight sensory disturbance. The arsenic being stopped she improved, and, receiving electrical treatment, at the end of a month or six weeks was able to walk about again.

Case II.—An imbecile girl of twenty-one, an inmate of an insane asylum, was taken with a number of other patients into the grounds and kept there during the greater part of one day, while something was being done to the ward. She lay upon the grass all the time. In a day or two she was noticed to have a weakness of the muscles of the arms and legs, and wrist drop and foot drop developed. When seen by the writer, about a month or six weeks later, she had foot and wrist drop on both sides; there were weakness and wasting of the muscles of the front of the legs and back of the forearm. She could not walk without support. The electrical reactions in the affected muscles were quantitatively reduced, but no reaction of degeneration could be found. No satisfactory information as to sensory symptoms could be gotten, owing to her mental condition. Under general tonic and electrical treatment she improved, and when last seen, two months later, could walk about the ward. Neuritis from cold (probably).

Case III.—A healthy, athletic young man of nineteen received, on November 29, 1895, a slight wound on the back of the second finger of the left hand, to which he paid no attention. A week later the finger was greatly swollen. Lymphadenitis extended up the arm, and the axillary glands were enlarged. The wound became gangrenous, and the patient presented evidences of a mild septicæmia. His condition improved under treatment, but the wound sloughed and was a long time healing. He returned to school about the middle of January, but soon noticed that he saw double and could not read. His tongue became affected and his articulation bad. He complained of numbness and tingling in his fingers, and his arms grew weak. There was some weakness of the trunk muscles. Next his legs were attacked, and he became paraplegic. Under treatment he improved somewhat, and was sent out of the city to recruit. He then could walk a little. While away he had a relapse, and by the end of February could not get about at all. When seen on March 1st by the writer, he could not stand or walk without crutches. The eye, face, and tongue muscles were normal; the muscles of the arms acted normally, but were slightly weak. Trunk muscles normal, legs weak and their movements atactic. Slight wasting of leg muscles. Tendon reflexes absent; sensation normal, except on soles of feet. Electrical reactions quantitatively reduced in peroneal group and quadriceps; extensor otherwise normal. Under tonic treatment (mainly strychnine and electricity) the patient improved, and by July was perfectly well. Septicæmic multiple neuritis.

Case IV.—A man of fifty years, a habitual user of spirits though never intemperate, had in 1891 an attack which he says was similar to the present one, and from which he recovered entirely, except for slight weakness and a little ataxia of the legs. In February, 1896, he noticed increasing weakness in his legs, but paid little attention to it. In March he consulted a physician, who found some weakness of the muscles of the front of the legs, with tenderness in these muscles and their nerves, and loss of knee jerk. The extensors of the hands were involved, but to a lesser degree. His condition became gradually worse, the affected muscles wasted, the legs became anæsthetic, and paresis of the bladder (affecting the detrusor alone, the sphincter continuing to act) appeared. When examined by the writer, on May 10th, he was bedridden and could not sit up without assistance. The pupils reacted normally; the eye, facial, and tongue muscles were unaffected; the arms were weak, but there was no wrist drop. Back muscles weak. There were great wasting and weakness of all the muscles of the legs. The thighs could be flexed on the body and the legs on the thighs, but the latter only when the thigh was supported. There was foot drop—complete on the left, partial on the right. Tendon reflexes were absent. Below the knees, complete anæsthesia; on the thighs and arms below the elbows, diminished sensibility. The electrical examination was not very satisfactory, but as far as made showed reduced irritability, but no reaction of degeneration. As the legs could not be raised well, inco-ordination could not be made out, but there was some loss of ability to locate the position of the limbs (loss of muscular sense). On October 6th the attending physician reports but little change in his condition, though he has gained some flesh. Alcoholic multiple neuritis, with probable involvement of spinal cord; prognosis unfavorable.

EPILEPSY PROBABLY CURED AND PARALYSIS IMPROVED BY RELIEVING IRRITATION AND COMPRESSION RESULTING FROM AN OLD COMPOUND DEPRESSED FRACTURE OF THE SKULL, REPLACING THE LARGE AREA OF DEPRESSED FRAGMENTS BY HEAVY GOLD FOIL.[1]

By J. E. SUMMERS, Jr., M.D.,

Professor of Principles and Practice of Surgery and Clinical Surgery, Omaha Medical College.

C. J——, aged twenty, entered the Clarkson Hospital, June 8, 1895. He gave the following history: In the fall of 1891 he had suffered a compound depressed fracture of the skull, involving the frontal and left parietal bones, extending over an area of about four inches by one and one-half inches. An attempt had been made by the surgeons in attendance to elevate the depressed bone; the patient's condition being so critical at this moment, all operative procedures were abandoned, the case being regarded as hopeless. However, the patient recovered from the immediate effects of the injury and the wound healed, leaving a large area of depression; there was hemiplegia on the right side. In the course of four or five months the paralysis had improved to such a degree that the boy was able to get around unaided, but was very much crippled. In the spring of 1893 he went to Chicago, entered the Presbyterian Hospital, and was operated upon by Professor Senn. The operation consisted in chiselling loose and elevating the bone involved in the depressed area. No bone was removed. The result of this operation was negative in so far as improvement of the paralysis was concerned. A few months after the boy's return home from Chicago, epilepsy developed, at first mild in character, but gradually merging into a very severe type. During the few months prior to my seeing the case, the seizures had become so frequent and violent that the boy's life was despaired of. In one of the seizures I am informed by the family physician that the inferior maxilla was dislocated on one side; in another, the shoulder-joint. The convulsions occurred almost daily, sometimes several within the twenty-four hours. An examination disclosed a marked depression of the skull over the injured area, the bone, which had been freed and elevated, having sunken back into its position prior to the operation in Chicago. There was great loss of strength in the right arm, with considerable wasting of the muscles; the same condition was present in the right lower extremity, which was dragged along when the patient attempted to walk. There was a peculiar hesitancy of speech. Although so great a length of time had elapsed since the original injury, and although the epileptic habit had been long established, I determined to see whether or not the removal of the depressed bone and its replacement by heavy gold foil might not be of benefit. Accordingly, after the usual preparation, on June 8th I proceeded to operate in the following manner:

After applying a strong elastic band around the forehead and occiput, a large horseshoe-shaped flap, convexity downward, was raised over the involved area, with chisels and gnawing forceps, all of the depressed bone was removed, some of which was so strongly adherent to the dura mater that I was compelled to expose the brain substance proper at several points. A piece of heavy gold foil was placed between the scalp and the bone, covering the whole space from which the depressed bone had been removed, and the wound sutured. Drainage was provided for, and suitable dressings were applied. Convalescence from the operation was smooth and uneventful; the wound healed *per primam*, and there were no further convulsions so long as the boy remained in the hospital, which was until July 11, 1895, and he has remained free from convulsions to date (March 10, 1897). So soon as the stomach had recovered from some irritability which immediately followed the operation, the administration of potassium bromide was commenced, in fifteen-grain doses three times a day, and continued up to the period of the boy's discharge from the hospital. This dosage was also kept up for several months after the boy's return home, when it was discontinued.

In addition to the freedom from the epileptic seizures which to date has followed the operation, there has also been a considerable improvement in the paralysis, and likewise in the speech, which now is apparently normal. While this case cannot be declared as a cure, still the result has been most satisfactory, the outlook for the future is bright, and I am inclined to think that the result obtained will be permanent. However, I appreciate that this is not necessarily so, and that perhaps a recurrence of the convulsions may be anticipated. I have operated upon four other cases of epilepsy resulting from fracture of the skull, in two of which the results have been positively negative as to benefit, the seizures recurring in both cases within two months. In two others great benefit has followed the operation. In one the seizures, which occurred almost weekly, are now separated by intervals of three to six months. In the other there has been no seizure since the patient was discharged, this being now seven months.

These results are certainly encouraging, as in the case reported in detail nearly four years had elapsed between the date of primary injury and the operation by me, and about three years had elapsed since the commencement of the epileptic seizures until the date of operation, and one and one-half years have elapsed since the operation to the present time, there not having been any epileptic seizures in the interval—although arbitrarily it has been fixed that three years must elapse from the date of operation before it can be said that a cure has followed an operation on the skull for the relief of epilepsy resulting from traumatism, just as we fix the same period of immunity after operation in cancer of the female breast.

In one of the cases operated upon in which great improvement followed the operation, there was an interval of five years from the date of injury until the operation was done, the convulsions in this case having developed within a very few months after the injury. In the last case, convulsions developed eight years after the fracture, and the operation was performed within six months after the development of convulsions. In the two cases in which the results have been positively negative, the operation was done after the epileptic habit had been formed for many years. These results are as good at least as any I have observed which have been published, and I attribute the favorable showing somewhat to the technique of operation, which has consisted in every case in a complete removal of all depressed bone, and in two cases in addition the removal of a considerable portion of thickened indurated tissue of new formation, that had taken the place of the dura mater, which had evidently been destroyed at the time of the

[1] Read before the Omaha Medical Society, March 23, 1897.

injury; and the introduction of gold foil between the scalp and the bone, in order to prevent adhesion of the scalp to the dura. In one case it was necessary to remove a considerable piece of the dura, and the gold foil was placed between the bone and the brain substance. This was the last patient operated upon.

I have never known in my own practice, nor in that of my colleagues, who with me make it a rule to elevate the depression in every case of depressed fracture of the skull, whether simple or compound, with or without brain symptoms, that epilepsy has developed; and in every case of epilepsy following fracture of the skull which I have observed, no attempt at elevation of the fragments had been made at the time of injury: and I am also of the opinion that in every case of compound fracture of the skull when it is necessary to remove bone fragments, especially when they may be of large size, and more especially when there has been a loss of dura and the brain itself has been injured, gold foil or some other suitable material should be introduced, either between the scalp and the skull, or between the skull and the injured dura just outside the margin of the wound.

I have long since ceased to consider opening the skull for epilepsy in any other cases except those in which the epilepsy has followed trauma of the skull, as I am convinced from my own personal experience, independent of that of other surgeons, that such an operation is useless and simply tends to bring surgery into disrepute, although possibly in a few rare cases excision of smaller or greater cerebral surfaces will prevent for a time the recurrence of focal epilepsy, and in an occasional case may prove curative. It is also only in the rare, exceptional case that a removal of the uterine adnexa when diseased will be beneficial or curative in epilepsy. When the adnexa are healthy their removal will never benefit the epilepsy, but will do good in that it will prevent a possibility of propagation of species.

I reported a few years ago, in the *Omaha Clinic*, a case of insanity which was cured by the removal of diseased uterine adnexa, the patient having been an inmate of a hospital for the insane for about a year, but this was a comparatively very rare and very exceptional result, and teaches very little.

I wish to refer, however, to a case with whose history I am familiar, and which teaches much. A supposed epileptic consulted a gynæcologist in this city, who discovered a diseased ovary and removed it, leading the patient to hope that such operation would cure the epilepsy. She returned to her home, the epilepsy not only unimproved, but worse. She consulted her country physician about some decayed teeth which were annoying her. The physician extracted the teeth, and presto! she was cured of her epilepsy.

Hematoporphyrinuria.—From a study of the literature, in conjunction with an analysis of two hundred and fifty specimens of urine from one hundred and forty-four patients suffering from various diseases, Nakarai (*Deutsches Archiv fur klinische Medicin*, B. 58, H. 2, 3, p. 165) has been able to confirm the statement that hematoporphyrinuria is a constant symptom of various forms of lead poisoning. It occurs also in connection with sulfonal intoxication and intestinal hemorrhage, but it is in general a rare manifestation of other disorders. The pathogenesis of the condition and its prognostic significance appear to differ with different diseases. Whether or not intestinal hemorrhage alone is capable of inducing hematoporphyrinuria in cases of poisoning with lead, sulfonal, etc., as has been maintained, is yet a matter of doubt. Nothing at all is known concerning the origin of hematoporphyrinuria under normal conditions.

A CASE OF CHRONIC GOUT, WITH ROENTGEN RAY ILLUSTRATION.

BY CHARLES E. NAMMACK, M.D.,

ATTENDING PHYSICIAN, NEW YORK HOSPITAL, OUT-PATIENT DEPARTMENT.

EDWARD F——, forty-seven years old, has been a sufferer from gout for twenty-one years. At the beginning he suffered from the usual acute paroxysms, which are believed to clear the organism of accumulated uric acid, but when, by reason of repeated attacks and advancing age, the power of reaction became diminished and the attacks lost their typical intensity, deposits began to form around various joints, which now show the considerable masses presented for your inspection and which constitute a permanent disability. These deposits are made up of infiltrations of urates, chiefly the urate of sodium. The deformities in this case resemble those of arthritis deformans, but the following are the differential points: In gout,

fixation and deformity of the fingers occur through the deposit of urate of sodium in large amounts about the joints, in their tendons and sheaths, so that the fingers are as in splints. In arthritis deformans, the distortion of the hand may be far more marked than in gout, for here there is not a splint-like deposit about the joint, but, in its stead, the development of exostoses on the edges of the articular surfaces, while at the same time the opposite side of the joint may be partially absorbed.[2] The absence of destruction of interarticular cartilage, and of alterations in the ends of the bones, is well shown in the accompanying skiagraph. Since "in doubtful cases it is necessary to pass beyond mere inspection of the affected members,"[3] the Roentgen ray will here prove a valuable aid to diagnosis at the beginning of a case, for it is well known that grave changes in the joint surfaces themselves may occur secondarily in long-continued gout, and the commencement of such changes is now apparent here.

Patient presented before New York Academy of Medicine, section on general medicine, March 10, 1897.

[2] Hare: "Practical Diagnosis," pp. 51 to 55.

[3] Lyman: "Twentieth Century Practice," vol. ii., p. 443.

The forced flexion of the first phalanx of the middle finger into the palm of the hand, which this case presents, is said to be common in gouty men, and is considered by Paget to be pathognomonic of gout. But the deformities of gout may take every position assumed by those of arthritis deformans. When this drawing down of the finger or fingers occurs alone, without deposits of urates or other unequivocal symptoms of gout, it may be due to Dupuytren's contraction. The theory of the gouty origin of Dupuytren's contraction is generally accepted, but discarded by Dr. Robert Abbe[1] because of the almost universal absence of gouty inheritance of the patients who came under his observation, and because he has but once seen a truly gouty knuckle in these patients. Dr. Abbe believes that Dupuytren's contraction is caused by traumatism of the nerve ends in the palm, reflected to the central nervous system and thence to the opposite hand. A second patient presented this evening has a typical Dupuytren's contraction in the right hand, which the patient himself attributes to the use of a saddler's needle in repairing harness. In this second case, there is neither history nor objective evidence of gout.

Progress of Medical Science.

The Incubation of Parotitis.—In children's institutions the duration of this affection appears to be on an average eighteen or nineteen days; in garrisons twenty-one to twenty-two days. The incubation varies in like manner from fourteen to eighteen days for young subjects, and from eighteen to twenty-two for adults. Since the disease is not contagious after its full development, fifteen days of isolation are sufficient.—Poirrier.

The Surgical Treatment of Peritonitis Following Intestinal Perforation Complicating Typhoid Fever.—From a consideration of the conditions attending peritonitis following typhoid perforation and of the results that have been attained through surgical intervention, Monod and Vanverts (*Revue de Chirurgie*, March 10, 1897, p. 169) conclude that while these results are not particularly encouraging, having been attended with a mortality of eighty-eight per cent., they are more favorable than those that attend simple expectancy, with a mortality of ninety-five per cent. The chances of success from operation under these circumstances will be the better the later the perforation occurs, and especially during convalescence or at the end of a relapse. In the absence of counterindications arising from the general state of the patient, surgical intervention is permissible, however, at any period of the attack at which perforation takes place. To increase the chances of success, the operation ought to be undertaken as soon as possible after the diagnosis has been made. The effects of such intervention, especially those of suture, are excellent as regards the matter of the closure of the perforation, but unfortunately they are not equally good as regards the recovery of the patient. The causes of failure are numerous, and include, for instance, progressive septic peritonitis, new perforation, a bad general state. The last may in itself constitute a counterindication. If the patient is so debilitated or so collapsed as probably to be incapable of withstanding the operation, it will be better not to undertake it. Ordinarily median cœliotomy and suture of the perforation are all that will be required. Intestinal resection and the establishment of an artificial anus may be necessary in more complicated cases. Irrigation and drainage are to be commended. In case of encysted peritonitis, incision and evacuation may be sufficient; sometimes the perforation may be found and sutured.

The Operative Treatment of Carcinoma of the Rectum.—From a thorough study of the operative treatment of carcinoma of the rectum, Taylor (*Annals of Surgery*, April, 1897, p. 385) recommends great care in the selection of cases for operation. Carcinomata that have exceeded the limits of the bowel and have formed adhesions with neighboring parts, had better be left alone. The preparatory treatment is deserving of the utmost attention, having as its object the improvement of the patient's general condition and as great a degree of intestinal asepsis as it is possible to obtain. Free purgation, intestinal antiseptics, and rectal irrigation cannot have a really useful effect, so long as there exists an ulcerating carcinomatous surface swarming with virulent micro-organisms. The use of the curette, whenever possible, followed by irrigation, should accompany the other measures. A preliminary colotomy can scarcely be recommended as a matter of routine. It appears to be chiefly indicated when attempts to empty the intestine and cleanse it have either been impossible or attended with difficulty. A certain number of types of carcinoma of the rectum may be recognized, both as regards their site and their extent, with a view to determining the methods best suited for their removal. Three cardinal rules are suggested as applicable to all cases: 1, Control of bleeding as perfectly as possible; 2, observance of the principles of aseptic surgery as strictly as the field of operation will admit; 3, avoidance of rough manipulation in the separation of the diseased structures, which may be effected for the most part by a process of careful dissection. The perineal operation is best employed for ano-rectal carcinomata—that is, for carcinomata involving the sphincteric zone and extending for some distance above it. If possible, the rectum should not be split in its removal; nor should the finger be introduced to serve as a guide in its separation. Elastic ligatures should be applied and sterilized gauze placed beneath before it is cut. Carcinomata situated in the suprasphincteric region had better be removed by the sacral method. As contrasted with the perineal, this gives more room, while bleeding is more easily controlled and separation of the diseased structures is more readily effected; and finally, it yields the best functional results. Temporary sacral resection should not be entirely disregarded, owing to its manifest advantages over the more extensive mutilation of Kraske and Bardenheuer. If, when the carcinoma is excised, it is found that the upper healthy segment descends easily, it is worth making an attempt to suture it to the anal margin, having previously removed the mucous membrane from the lower segment. In cases in which the ends of the bowel have been united after removal of the carcinomatous segment, it is well not to close the sacral wound completely, for fear of accidents. For carcinomata situated high up, as well as for those of wide extent in the rectum, the formation of a sacral anus is often the only means at our disposal. In such cases it appears advisable to follow the advice of Gersuny and give the bowel a twist in its long axis before attaching it to the skin, the object being to establish a modified sphincteric apparatus. The perineo-abdominal and sacro-abdominal operations are grave; they involve serious risks and can be required only in very exceptional cases. However, attempts must be encouraged that help to extend more widely the indications for complete removal of the disease, and such as are suitable for those desperate cases in which the palliative treatment afforded by an artificial anus has hitherto been the only resource.

New York, April 24, 1897.

THE NEW TUBERCULIN.

In spite of the fiasco of 1890, Koch's is still a name to conjure with in the study of tuberculosis, and the announcement that he has again published to the word a remedy for this disease cannot fail to arouse eager expectancy among physicians, and to kindle the hopes of the new generation of consumptives which has followed upon that which the tuberculin of seven years ago could not save.

The article descriptive of this new tuberculin appears in the *Deutsche medicinische Wochenschrift* of April 1, 1897, but any sinister significance which this date might have is removed by the fact that the article itself is dated November 14, 1896, its publication having been delayed, possibly by reason of the author's absence in South Africa. Koch begins with an answer to the objection that there can be no such thing as a provoked immunity against tuberculosis since we never see it in nature. People have tuberculosis for years without acquiring any lessened susceptibility to it, and even cured patients are liable to renewed infection. But this, he believes, is because there is little or no opportunity for absorption of the bacilli or their products in the chronic form of the disease. The organisms are present here in the tissues only in small numbers, and are usually surrounded by dead tissue, or when present in large numbers, as in cavities, the conditions are absolutely unfavorable to the production of immunity by gradual absorption. In acute miliary tuberculosis the bacilli are present at first in great numbers, and then in great part disappear. This, the writer believes, is the result of an acquired immunity, but unfortunately in the acute disease this comes too late. If, however, we can by any means imitate what takes place in acute tuberculosis, while avoiding the fatality of this disease, we shall then be able to confer immunity upon the organism. This is a problem which Koch believes he has now solved, at least so far that he can safely publish his process and its results to the world.

He reviews briefly the steps which led him up to this discovery, and the history certainly furnishes an interesting example of patient working and of perseverance in the face of many obstacles and discouraging failures. He first tried injections of dead bacilli, but these caused bad abscesses and absorption was thereby hindered. Injections into the peritoneal cavity gave better results, and even conferred apparent immunity in some instances; but they also caused pathological changes in the peritoneum, leading to adhesions, constrictions of the intestine, and other disturbances, which often destroyed the animals. When introduced directly into the blood stream these dead bacilli gave rise to the same tuberculous nodules as the live microbes. Then he tried destruction of the bacilli by chemical means and succeeded in preventing abscess formation, but obtained no immunity, for the process destroyed the peculiar chemical constitution of the bacilli and consequently their specific action. Now he tried a glycerin extract, and so fell upon the discovery of tuberculin. This substance, when first injected, causes a reaction, but continued injection finally leads to the point where there is no reaction. We have here an immunity, but it is a toxin immunity and not a bacillary immunity; there may be both, but unfortunately the former usually comes before the latter. Before dismissing tuberculin, the writer said that seven years ago he laid the greatest weight upon its diagnostic value, and it could still be claimed for it that it affords a most efficacious means of diagnosis at a very early period, before any characteristic physical signs are present, and this not in animals alone, but in man as well.

He then comes to a description of the new tuberculin, which is prepared through a mechanical destruction of the bacilli. The great difficulty has been to destroy the protecting layer of sebacic acids, but this was finally accomplished by triturating dried cultures in an agate mortar with an agate pestle, adding distilled water, and separating in a powerful centrifugal machine. In this way he obtained a whitish opalescent fluid, free from bacilli, and a slimy sediment containing the débris of the bacilli and some undestroyed specimens. This sediment was again dried, worked about in a mortar, mixed with water, and separated in a centrifugal machine, the process being repeated until every vestige of the bacilli had disappeared, and nothing remained but a series of clear fluids. The first of these fluids differed from all those subsequently obtained, the latter, however, being identical with each other. The first of these fluids he calls tuberculin O, or "T. O;" the second tuberculin R, or "T. R." Treated with glcyerin, T. O. is found to contain the substances soluble in this fluid, and is similar therefore to the old tuberculin. It also acts like tuberculin, causing a reaction but not conferring immunity. When glycerin is added in quantity to T. R., a cloudiness is produced, showing that this contains substances insoluble in glycerin. It is this fluid, the "T. R." which Koch believes is the remedy for tuberculosis.

The remedy is given in the same way as tuberculin, beginning with a very minute dose, and increasing gradually until the maximum is reached. The fluid contains eight milligrams of the active principle in one cubic centimetre, and is diluted with salt solution in order to obtain a small enough dose. The initial dose is one-five-hundredth milligram, but if a reaction

follows the dose it must be still further reduced. The injections are made every second day, and the dose is gradually increased during a period of two or three weeks to twenty milligrams. If any elevation of temperature occurs, it must be allowed to subside before another injection is given.

The preparation of T. R. requires the exercise of many precautions. In the first place, not every culture of tubercle bacilli is fit for the preparation of an efficacious T. R. Koch's experiments, which he will describe at some future time, have shown him that all tubercle bacilli are not so uniformly virulent as is generally supposed. Cultures which have been grown through many generations in the laboratory will, as a rule, be found to have lost their virulence in great measure, but for the preparation of T. R. only virulent cultures are to be employed. The drying of the culture must be done in a vacuum exsiccator, and all chemical contamination in the process of manufacture must be avoided, for T. R. is very unstable. The cultures and the completed preparation must also be kept away from the light. Complete separation of T. O. and T. R. is obtained only when the completely clear T. O. has taken up at least fifty per cent. of the solid substances, and it is very necessary that the two should be completely separated, for if T. R. contains any T. O. an undesirable reaction will follow the injection. Naturally the preparation of this new tuberculin, with its trituration of perfectly dry cultures of exceedingly virulent tubercle bacilli, is in the highest degree dangerous to the operator, and Koch says that he felt always as though he were dealing with high explosives. The preparation of large quantities should, he thinks, be undertaken only in establishments where the danger could be reduced to a minimum by the use of suitable mechanical appliances. The fluids can be preserved by the addition of about twenty per cent. of glycerin, which is not enough to cause a precipitation of the T. R.

As to the results of T. R. injections in guinea-pigs and in man, Koch speaks with confidence. He has tried it in lupus and in pulmonary tuberculosis, and the results have been such as to cause him the greatest satisfaction. It is useless, he says, to give the remedy with any hope of success to patients who are in the last stages, with but a few months to live, or to those in whom a secondary infection, especially a streptococcal, exists, and in whom the symptoms of sepsis have pushed those of tuberculosis into the background. Furthermore, patients with a temperature of over 38 C. (100.4° F.) are only exceptionally influenced for good by the specific treatment of tuberculosis. In suitable cases, however, an improvement is invariably obtained. He says that he uses the term "improvement" advisedly, although according to the ordinary usage he would be justified in speaking of the patients as cured. He is unwilling, however, to regard any as actually cured until after the expiration of a certain period without any relapse. There were no unpleasant general symptoms observed, and there was no reaction whatever when the dosage was properly graduated. In the case of pulmonary tuberculosis, the only effect of T. R. was a slight increase in the râles, but this symptom soon disappeared, the sputum rapidly diminished in amount and its formation ceased, and the temperature curve declined.

It is possible, Koch says, that some other method of administration may be found more efficacious, or possibly the desired end may be reached better, and more speedily, by some combination of T. R. with T. O. or by a serum preparation obtained by means of T. O. or T. R., experiments with which are now being conducted. But he maintains with entire confidence that any further improvement in the preparation itself is not to be looked for. This preparation is made from fresh and highly virulent cultures, which were alive immediately before the trituration process, and the bacilli are brought into a soluble state without the employment of any chemical means. Nothing better than this can be done, and anything that can be accomplished with cultures of the tubercle bacillus can be accomplished with T. R. and T. O.

Whether the confident assurance of this distinguished investigator will be justified by the results of a general application of his new preparations must be left for the future to decide. At present we can only say, in the words of our Berlin correspondent: "Hoffen wir, dass einem zweiten Tuberculin-Rausch nicht ein zweiter Katzenjammer folgt."

THE PREDIAGNOSTIC TREATMENT OF ABDOMINAL DISEASE.

WHAT to do when first called to see a person suffering from severe abdominal pain is often one of the most perplexing problems of medical experience. The patient's distress, often agony, makes an urgent appeal to the physician's human sympathy, and the impulse to give morphine for its relief is almost like an instinct, unless the wisdom which comes from experience overcomes, for the patient's good, the unreasoning desire to give instant relief. Morphine is, when given at the proper time, a drug of inestimable worth in certain forms of abdominal disease, but when given blindly and in ignorance of the actual condition it may do infinite harm.

In *Treatment*, of March 25, 1897, Mr. Greig Smith proposes a course of treatment in such cases, which will, he says, certainly do no harm, but will probably do good, and which will not obscure the symptoms but will rather help in their evolution and so facilitate the diagnosis. He supposes the case of a person whom the physician finds in bed suffering severe pain, shock, and with the usual symptoms of abdominal disease. It may be colic, intestinal obstruction, perforation of a viscus, rupture of an appendicular abscess, or some other grave condition. In such a case, the writer says, the first thing is to give an enema of an ounce of brandy or whiskey in about three ounces of milk. Hot blankets are then wrapped round each leg and the chest, but the abdomen is covered by a hot flannel cloth, which can be removed without disturbing the patient when it is desired to examine the surface of the abdomen or to auscultate it. Warmth is

furthered also by hot bottles placed in the bed about the body and extremities.

The effect of the alcohol and warmth is speedy and gratifying. The pulse improves, color comes into the patient's cheeks and lips, excitability and nervousness are diminished, pain is probably lessened, and soon the surface is covered with warm perspiration. No single therapeutic measure, Mr. Greig Smith says, with which he is acquainted, does so much good in the early stages of grave abdominal disease as rectal injection of alcohol, and it is a fortunate thing that, while the rest of the intestinal tract is paralyzed, the rectum still retains its power of absorbing liquids.

Now, as the shock passes off, the individual symptoms of special diagnostic significance stand out more clearly, and by carefully observing these and studying their import the surgeon gradually arrives at a knowledge of the case, and can then formulate intelligently his plans for treatment.

The prediagnostic treatment of abdominal disease, which the writer advises, may be summed up under four points: Two negative—give no morphine and give no ice nor anything else by the mouth; and two positive—give alcohol by enema and apply heat to the body. The question of operation is one to be settled after the diagnosis is made.

THE THERAPEUTICS OF METHYLENE BLUE.

Until comparatively recent times blue pyoktanin was known as a local and general remedy in the treatment of inoperable malignant growths. The Record readers are familiar with the varying success in carcinoma and sarcoma which has followed the use of this remedy as well as methyl violet in the hands of different observers since Mosetig in 1890 first advocated its employment.

Among the many diseases in which pure methylene blue has been more or less largely employed as an internal remedy may be mentioned acute and chronic Bright's disease, gastric hyperacidity, malaria, headache, diphtheria, cystitis, and gonorrhœa. In the first Netchaieff, among others, has reported favorable results, even to the disappearance of albumin and hyaline casts from the urine, along with general improvement in various directions. Berthier has stated that it may be given with advantage in indigestion attended with pain, vomiting, and hyperacidity; the dose recommended is from one to three grains daily for several days, followed by a few days of rest, when it is to be resumed. Conflicting reports have been made upon the value of the drug in malarial affections by Guttmann, Ehrlich, Muehll, Lava, May, and others. In many instances it has seemed to act very beneficially, while in others it has failed. Lewy recently claimed in the *Berliner klinische Wochenschrift* that marked relief follows its administration in various forms of headache, especially angiospastic migraine, nervous cephalalgias, and especially the head pains of neurasthenia. The relief is not alone temporary, but in many instances lasting. Ten doses of one and one-half grains each usually sufficed for a cure.

In diphtheria the use of the remedy either as a local application or internally has seemed to be overshadowed by antitoxin and other methods of treatment. Recently several observers have advocated the remedy in acute gonorrhœa, and Moore (*British Medical Journal*, January 16th) has seen it cut short the acute stage and decrease the suffering. Allen has reported great improvement in some instances of chronic cystitis, and this in spite of the fact that several observers have noted strangury when the drug has been pushed, and Mya as well as Lewy advise powdered nutmeg to be given at the same time to prevent bladder irritation. The usual dose is one decigram or one and one-half grains in capsule once, twice, or thrice daily. The urine becomes blue or greenish within five hours of the initial dose, and remains so for several days after the last dose has been given. It must be remembered that toxic symptoms may be produced, and in all instances it is well to give in tentative dose until the patient's susceptibilities are tried. Methyl violet and impure pyoktanin are most apt to cause vomiting or other disagreeable symptoms.

News of the Week.

New York University-Bellevue Hospital Medical College.—Dr. William H. Welch and Dr. William Osler, of the Johns Hopkins Medical School of Baltimore, have declined the call extended to them by the University of New York, which has lately been consolidated with Bellevue Hospital.

Dr. Emma Wakefield, a colored woman, has received a license to practise medicine from the Louisiana State board of medical examiners. She is the first woman of her race to receive a medical license in the South, and, it is claimed, in the Union.

Hospital Staffs and Close Corporations.—A committee of physicians recently called upon Mayor Strong to protest against the method by which appointments are made to the public hospitals, and to ask that the selection be made from the body of the profession instead of from the comparatively small number of those connected with the medical schools. They said with truth that there were very many physicians in the city, not connected with the schools, who would gladly give their services as members of the visiting staff of any of the city hospitals. They also suggested that it would be a wise thing to appoint a physician on the board of charity commissioners.

Quarantine of the House of Refuge.—The health board recently quarantined the House of Refuge on Randall's Island because of its alleged unsanitary condition. The count against the institution is that "the plumbing, drainage, water closets, and privies in said premises are filthy, emitting foul and offensive odors; that children now on said premises are suffering from contagious diseases of the eye, and are not properly isolated, and that proper and sufficient nurses have not been provided, so as to secure to the inmates due and proper care as to the personal health and

cleanliness of said children." In consequence of these defects the board of health has decided that no persons shall be received as inmates of the house until the defects are remedied. Several children suffering from measles have been removed to North Brother Island. The result of the publicity given to the condition of affairs in the institution will probably be to put the House of Refuge fully under the control of the State authorities, taking it out of the hands of the board of trustees, concerning whose management there has been much complaint.

Obituary Notes.—Dr. de Saint Germain, of Paris, died a short while ago. He was surgeon to the Hospital for Sick Children, and was well known for his works upon orthopædic surgery, and as the advocate of a method of rapid tracheotomy in which the operation was done in one stage.—Dr. Andrew Otterson, of Brooklyn, died at his home in that city on April 14th, of heart disease. He was born in 1822, was graduated from the University Medical School in 1844, and began practice soon after in Brooklyn. He was present at the first operation performed in the Brooklyn Hospital, and himself performed the first operation in the Long Island College Hospital. He was four times at the head of the health department of Brooklyn. In 1895 he celebrated his fiftieth anniversary as a practising physician, and was tendered a complimentary dinner at the Montauk Club by the leading physicians of Brooklyn and New York.—Dr. Enis L. Brooke died at West Pikeland, Chester County, Pa., on April 9th, at the age of nearly eighty years, in consequence of burns received a week before from falling with a lighted stable lantern.—Edward Drinker Cope, Ph.D., professor of zoölogy and comparative anatomy in the University of Pennsylvania, died on April 12th, in the fifty-seventh year of his age. As paleontologist to the government geological surveys in 1867 and the years following, he discovered more than a thousand new species of extinct and as many recent vertebrata. It has been said that the titles of his papers, which number in the neighborhood of four hundred, "form a systematic record of the development of paleontology in the United States."

The Dispensary Bill.—A telegram to the daily papers from Albany says that a bill introduced by Mr. J. J. Sullivan regulating the operation of dispensaries and bringing them under the supervision of the State board of charities was approved by the board, and has passed both houses of the legislature. A report presented by Dr. Stephen Smith, of New York City, with relation to the dispensary system of New York City and Brooklyn, stated that there are one hundred and five dispensaries in New York City, and in a large percentage of these no examination or investigation is made to decide as to the need of applicants for charitable assistance. In Brooklyn there are twenty-two dispensaries, and in at least eighteen of these no examination or investigation is made to determine the needs of applicants.

A Health Officer Accused of Blackmail.—A telegram from Cincinnati announces the arrest of the health officer of that city and another physician on a charge of attempted blackmail of a manufacturing drug company. According to the company's charges, the health officer at first demanded $10,000, claiming that certain tablets were impure or short in strength, and that the pure-food commission would consequently prohibit their use by the health department. This fact on being noised abroad would work the company injury. The sum demanded, according to the complainant, was finally reduced to $2,000. The company denied that the tablets were not as represented, and caused the arrest of the two physicians. The charge is now being investigated by the grand jury. We trust the result of this investigation will be to free the accused from this disgraceful charge.

Small-Pox on Randall's Island.—Three cases of small-pox were discovered on Sunday last in the institution and schools for weak-minded children, on Randall's Island. This is an institution under the charge of the city and is distinct from the House of Refuge, which was recently quarantined by the board of health. There are one hundred and forty-five inmates of the institution. All the inmates of this institution and those of the House of Refuge and of the Infant Asylum have been vaccinated.

The Plague in Bombay.—The latest dispatches from Bombay, dated April 15th, state that there has been a great decrease in the virulence of the plague. Only 390 cases of that disease and 194 deaths from the same cause occurred last week in that city, compared with 360 plague cases and 323 deaths during the preceding week. According to a telegram to *The Lancet* from Bombay, the Yersin serum treatment of plague has practically failed. So far the mortality has been fifty per cent. in the selected cases within forty-eight hours of the attack. The hospital mortality is stated to be sixty per cent. in all cases. On the other hand good results have been claimed for Haffkine's serum, which is credited with curing, among others, Hankin, who was attacked with the plague while studying it at Agra.

The Yellow-Fever Bacillus.—The Rome correspondent of *The Lancet* writes that Dr. Giuseppe Sanarelli, who believes that he has discovered the bacillus of yellow fever as well as a remedy for the disease, has embodied his researches in a monograph which has for some time been in the possession of the Accademia Medica di Roma, that body being thus empowered to protect his claim to priority should that claim in the interval have been challenged. The supplementary studies by which he has sought to check the laboratory and clinical work leading up to his discovery are now completed, and the whole series—including the substance of the provisional monograph aforesaid—will be published in three successive numbers of the *Annali dell' Istituto Pasteur*. Coincidently with the appearance of the first of these fasciculi (that is, within a few weeks' time) he will deliver before the Montevidean Society of Medicine a lecture, accompanied by illustrative preparations, in which the nature of his discovery and the successive stages by which it was arrived at will be fully set forth.

The Tariff on Mineral Waters.—The Dingley bill raises the duty on "mineral waters, all not artificial," which were formerly on the free list, from eighteen cents a dozen, as under the McKinley law (and now thirteen and one-half cents a dozen), to forty cents a dozen. In some cases, it is said, this duty would be prohibitive, and a petition has been presented to Congress praying that these waters and the bottles containing them be placed on the free list.

A New Hospital at Mineola.—The board of directors of the Nassau Hospital Association of Mineola, L. I., has engaged an architect to prepare plans and specifications for a suitable building to be erected for the use of the association. The new building will be erected on a prominent site which covers more than an acre of ground, and is owned by the association. It is the intention of the hospital association to erect a structure to be provided with all the latest appointments. It is hoped to have the building completed this summer.

The College of Physicians and Surgeons of Chicago has recently legally become the medical department of the University of Illinois.

An Aged Medical Student.—An item has been going the round of our exchanges, concerning a medical student in Maine who is said to be a sexagenarian. That seems to be rather late to start in to work up a practice, but the record has been broken by another wild young medical student named Borysik, who has just obtained his degree in Warsaw at the age of seventy-five years. Fifty-four years ago he matriculated, but through lack of funds was compelled to work as tutor for twenty years in order to save enough money to enable him to continue his studies. At the end of that time he passed the entrance examination with distinction, but before he could begin his studies the Polish rebellion of 1863 broke out, and he threw himself into the movement with enthusiasm. The revolt was suppressed, and Borysik was exiled to Siberia, where for thirty-two years he underwent hard labor in the silver mines. In 1895 he received free pardon, and returning to Warsaw took up his studies where he had left them off in 1863. After a two years' course Dr. Borysik has now, at the age of seventy-five, passed the final medical examination with honors, and will begin to practise in Warsaw. We wish him many years of usefulness and a large clientèle.

A Private Hospital Room for Sick Doctors.—"*Resolved*, That the trustees of the Philadelphia Polyclinic and College for Graduates in Medicine, wishing to show their appreciation of the public services of physicians upon whose skill and faithfulness all successful hospital work depends, order that one of the private rooms in the Polyclinic Hospital be called the Room of the Mutual Aid Association of the Philadelphia County Medical Society, and direct the superintendent to admit to said room, without charge, any member of the Mutual Aid Association of the Philadelphia County Medical Society who may be sick and require medical treatment, provided that the officers of said association first certify that the applicant's circumstances require such concession in regard to hospital charges; and that the rules of the hospital in other respects in regard to the admission and duration of stay of patients be observed, and that nothing in this resolution shall be construed to prevent the use of the said room for other patients, at regular rates, when it is not occupied by a member of the association named."

The Commission appointed by the legislature of Richmond, Va., to determine the best methods of caring for the State's epileptics, will meet in Baltimore, May 13th, and will visit epileptic institutions there and in other States.

The Medical and Chirurgical Faculty of Maryland will hold its annual meeting in Baltimore at the end of April.

Some Ladies of Baltimore are anxious to establish a hospital for infectious diseases, and promise, if the city council will appropriate half of the $50,000 necessary for the plan, that they will raise the other half.

A Homœopathic Journal states that the late Enoch Pratt, of Baltimore, had intended building a new homœopathic hospital in that city, to rival the Johns Hopkins Hospital: so much wrangling and ill will, however, existed among the homœopathic physicians that Mr. Platt abandoned the idea, and gave a large sum to the Sheppard Asylum.

The University of Maryland will probably lose Dr. William T. Howard from its faculty, as he has announced his intention of resigning from that institution. It is interesting to note that the University of Maryland was the first medical school in this country to establish a chair of diseases of women and children: this chair has been occupied by Dr. Howard since its foundation.

An Epidemic of Hiccoughs.—Berdach, of Vienna, has recorded an endemic attack of hysterical singultus that occurred in a school and confined itself to one class. One of the girls, aged five, became ill one day with inspiratory singultus of a hysterical nature. A second girl suddenly took ill with similar symptoms associated with hystero-epileptic cramps. In the course of eight days sixteen other girls out of the class of thirty-five were attacked. All the children were anæmic. The characteristics of the disease closely agreed with Charcot's description of hysterical inspiration cramps; the contractions ceased during sleep, the cramps could not be suppressed voluntarily, they generally attacked anæmic children, and the attacks had a tendency to recur. The disease in Berdach's case had a favorable course, as seven days' absence from school sufficed to bring about convalescence.—*The Medical Press.*

Deaths of Centenarians.—There seems to have been an unusual number of deaths within the past few weeks of persons reported to have lived over a century. Dr. de Bossy, the oldest physician in France, died during the latter part of March, in Havre, at the age of one hundred and four years. Alexander Freeman, a negro, died at Sailors' Snug Harbor, Staten

Island, on January 22d, at the reputed age of one hundred and eight. He was a native of New York City, and there is reason to believe that the extreme age given is not an exaggeration. Ignacio Francisco de La Cruse Garcia died at Los Angeles, Cal., on March 17th, at the age of one hundred and seventeen years. He was a native of Sinaloa, Mexico, but went to California when he was twenty-five years of age. His age had been questioned, but he claimed to have documents which sustained his claim. Jesus Campeche died early in March in Guadalajara, Mexico, and, according to his affirmation and other more or less reliable testimony, he was one hundred and fifty-four years old. He was born in Spain, and came to Mexico when he was twenty-four years old. He had copies of the church register at Valladolid, Spain, showing the date of his birth and baptism. According to these papers, he was born on December 12, 1742. A priest in the church which he attended, who is now eighty-four years old, says he remembers Campeche as being an old man when he, the priest, was a boy. John Bradbury, an Englishman, died near Eureka, Cal., early in April, at an extreme old age. He had lost count of his years, but it was estimated that they numbered between one hundred and twenty and one hundred and thirty. Joseph Field, familiarly known as "Uncle Josie," said to be the oldest inhabitant of Monmouth County, N. J., died at his home in Middletown, a short distance from Red Bank, a few weeks ago. According to records he was born on September 26, 1792, and had he lived until next September would have been one hundred and five years of age. He was born in Middletown, and resided there all his life, with the exception of a short time while he was in the produce business in New York.

A New Form of Artificial Respiration.—In *Science News*, Dr. Berthold Reed recently recommended that the mucous membrane of the lips of the mouth should be rubbed slowly with a piece of ice, the rhythm of the motion corresponding as nearly as possible to that of normal respiration. He claims that the inevitable result of this is the return of respiration, at first, in a very pronounced form, but becoming, on the continued application of the ice, very regular, quiet, and deep. Ice thus used has also a sedative effect, and its quieting action has been successfully turned to account in the treatment of cerebral troubles. Dr. Joyes has obtained equally favorable results with this treatment in cases of suffocation. This method may be employed for several hours at a time, and is said to be harmless for the patient, and easy for the physician.—*London Medical Times.*

The Closing of a Diploma Mill.—The arrest of the president of the "Wisconsin Eclectic Medical College," a diploma mill chartered in Wisconsin and doing business in Chicago, which we noted some weeks ago, was brought about through the exertions of a reporter of a German paper, the *Herold*, of Milwaukee. At the request of a United States postal inspector, the reporter, Mr. M. H. Ahner, wrote to the college and obtained a diploma for $10, and on his evidence the arrest was made by the United States authorities. The man admitted using the mails for fraudulent purposes, and will probably be unable to follow his nefarious trade for some time. Dr. Seaman, of Milwaukee, to whom we are indebted for an account of this capture, writes us that the "college" has surrendered its charter, and it is said that there is now a suit pending in the courts to annul the diplomas. This, however, is only a temporary relief from the abuse. The corporation laws of Wisconsin and some other States are so lax that one of these "colleges" may spring up any night. There is at present in Chicago another "mill," doing a thriving business, called the "Independent Medical College," where diplomas can be had at rock-bottom prices.

Schuylkill County (Pa.) Medical Society.—At a meeting of the Schuylkill County Medical Society, held at Pottsville, Pa., on April 6th, Dr. Hermany read a paper on "Diphtheria." Delegates were elected to the Medical Society of the State of Pennsylvania and to the American Medical Association.

Moscow Congress papers should be announced by title and with *résumé* of conclusions addressed to the executive committee before June 1st.

Increase in Boston's Death Rate.—Cerebro-spinal meningitis and meningitis appear to be unusually prevalent in Boston at the present time. The death rate during the past week was larger than usual, and the principal increase seems to be in cerebro-spinal meningitis and meningitis. The board of health has been looking up cases in these diseases, but has as yet been unable to learn the cause of the increase which has been noticeable for several weeks. There is an increase in the number of deaths from several causes. The number of deaths reported to the board of health for the week is 260, as against 202 the corresponding week last year, showing an increase of 58 deaths, and making the death rate for the week 26.2. The number of cases and deaths from infectious diseases is as follows: Diphtheria, 83 cases, 9 deaths; scarlatina, 76 cases, 6 deaths; typhoid fever, 9 cases, 4 deaths; measles, 129 cases, 2 deaths. The deaths from consumption were 30; pneumonia, 34; whooping-cough, 1; heart disease, 23; bronchitis, 11; marasmus, 6. The number of children who died under one year was 59; under five years, 99; persons more than sixty years, 38; deaths in public institutions, 74.

College of Physicians of Philadelphia.—A stated meeting of the College of Physicians of Philadelphia was held on April 7th, the president, Dr. J. M. Da Costa, in the chair. Drs. F. A. Packard and J. Dutton Steele reported "A Case of Tumor of the Lung, with the Signs of Addison's Disease and Involvement of the Suprarenal Capsules." The right femur was found also to be the seat of the malignant disease—it was believed to be the primary focus—and deposits were present also in the pancreas. The various growths proved all to be giant-cell sarcomata. Dr. Arthur Van Harlingen read a paper on "The Hysterical Neuroses of the Skin." Dr. John B. Deaver read a paper enti-

tled "Some Mooted Points in the Pathology of Appendicitis, with Especial Reference to that Form known as Appendicitis Obliterans," illustrated by photographs, photomicrographs, and skiagraphs. Paramount importance was attached in an etiologic relation to foreign bodies, fæcal concretions, and the bacillus coli communis. Reference was made to some observations upon the action of the blood serum from suspected cases on cultures of the colon bacillus in inhibiting the motility and causing agglutination of the bacilli. Dr. H. A. Hare read a paper on "The Rapidity of the Elimination of Drugs in Relation to their Administration," in which he pointed out a number of facts that should govern the frequency of administration and the dosage of certain medicinal agents. Dr. John B. Roberts made a brief verbal communication upon "Fracture of the Lower End of the Radius with Forward Displacement," which he supplemented with numerous wet and dry specimens, casts, photographs, and skiagraphs.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on April 8th. Dr. Joseph P. Tunis exhibited the enlarged prostate and the bladder from a man upon whom castration had been performed. The operation was followed by relief of the symptoms and was unattended with complication, but death resulted from uræmia. Microscopic sections of the gland showed an immense deposit of interstitial connective tissue. Dr. Tunis exhibited also the brain from a girl, nineteen years old, recently delivered of an infant, without a history of syphilis, showing profuse ventricular and also cortical hemorrhage. During life there had been convulsions, and albumin and tube casts had been found in the urine, but the kidneys upon post-mortem examination showed little macroscopic alteration. Drs. Thompson S. Westcott and D. L. Edsall exhibited a specimen of tuberculous pericarditis. Dr. M. H. Fussell exhibited a specimen of gangrene of the lung, and read the report of a fatal case of hemorrhagic purpura. Dr. D. L. Edsall exhibited a specimen of mitral stenosis and slight tricuspid changes, with multiple pulmonary emboli. Dr. Joseph Sailer read a report of a case presenting hyperplasia of the mucous membrane of the duodenum, and exhibited a microscopic section. He exhibited also a section of recent hemorrhage into the pituitary body discovered accidentally.

The Medical Society of the State of North Carolina.—The date of the annual meeting of this society, which was set for June 1st, has been changed to June 8th, in order not to conflict with the meeting of the American Medical Association.

The Late Professor Gross.—The unveiling of the statue of the late Prof. Samuel D. Gross, near the Army Medical Museum in Washington, will take place on Wednesday, May 5th, at five o'clock in the evening. It will be under the auspices of the American Surgical Association and the Alumni Association of the Jefferson Medical College of Philadelphia.

Resignation of Professor Thomson.—Prof. William H. Thomson has resigned from the chair of practice of medicine at the New York University-Bellevue Hospital Medical College.

An American Memorial of the Queen's Diamond Jubilee.—The American residents of Great Britain have formed a committee to promote a memorial of the sixtieth anniversary of the Queen's reign. The present idea is to raise a fund for the endowment of special beds in the hospitals.

The Jubilee of Prof. E. De Rossi.—The editorial staff of the *Archivio Italiano d'Otologia, Rinologia e Laringologia*, with the assistance of many Italian practitioners of those specialties, have issued Volume V. as a jubilee number, in honor of the twenty-five years of service of Dr. De Rossi as a professor in the University of Rome. The volume contains many papers of great interest to students of laryngology and otology.

A Falling Death Rate.—A report giving the comparative death rate of the city for the first three months of every year since 1891, which was submitted to Mayor Strong recently by President Wilson of the health board, shows that the death rate for January, February, and March of this year is the lowest in six years. The death rate so far this year is only 20.31 in a thousand.

Dr. Lauder Brunton, of London, has accepted an invitation from the executive committee of the International Medical Congress to give one of the general addresses at the forthcoming congress in Moscow.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending April 10, 1897. April 3d.—Surgeon C. U. Gravatt, when finished with examination for promotion April 5th, detached from the Museum of Hygiene, ordered home, and then to hold himself in readiness for sea. April 4th.—Passed Assistant Surgeon J. A. Guthrie, detached from the *Katahdin* and ordered to the *Alliance;* Assistant Surgeon J. F. Leys detached from the *Alliance* on relief and ordered to the *Vermont.* April 8th.—Medical Director R. N. Penrose detached from the New York hospital, June 5th, and placed on waiting orders; Medical Director G. W. Woods detached from the Mare Island Hospital, May 10th, and ordered to the New York Hospital, June 5th; Medical Inspector G. P. Bradley, ordered to the Mare Island Hospital, May 10th. April 9th.—Passed Assistant Surgeon E. P. Stone detached from the *Indiana* April 12th, and ordered to the *Bennington.* Changes in the Medical Corps of the United States Navy for the week ending April 17, 1897. April 10th.—Surgeon J. W. Baker, detached from the *Bennington* on relief and placed on waiting orders. April 14th.—Surgeon M. H. Simons, orders to the *Columbia* revoked, and placed on waiting orders. April 15th.—Surgeon E. Z. Derr, orders detaching him from the *Columbia* revoked. April 16th. Passed Assistant Surgeon E. S. Bogert, detached from New York navy yard and ordered to the marine rendezvous, New York.

Reviews and Notices.

Abdominal Surgery. By J. Greig Smith, M.A., F.R.S.E., Surgeon to the Bristol Royal Infirmary, Professor of Surgery, University College, Bristol. Fifth edition. Two volumes, 1,171 pages. London: J. and A. Churchill. 1896.

The author states that this edition is practically a new work, which is borne out by an examination of the text. The wide scope of abdominal surgery is apparent when we note the first chapters on symphyseotomy, subphrenic abscess, the surgery of the ureters, etc.; in fact, it would seem to the general reader as if a few additions would make this a tolerably complete work on general operative surgery. As stated in the preface, "the space given to appendicitis compares with that given to ovariotomy," and "to the surgery of the intestines more space is devoted than to the whole surgery of the ovaries." The book is a fair type of all-absorbing modern gynæcology, which claims the whole abdominal cavity as its legitimate field. In the introductory section we are interested in the observation that equally good results may be obtained in general and in special hospitals, the skill and experience of the individual surgeon being the most important factor. The question of the limitation of the number of onlookers is immaterial.

The paragraphs on aseptic technique, instruments, etc. (pp. 77–96), are excellent. We note the introduction of the word "septicism," which does not seem to possess any claims to permanence. "Cœliotomy" is formally adopted "as meaning any incision made through the abdominal parietes, for whatever purpose performed and in whatever position situated." In a new section on Trendelenburg's posture (wrongly spelt Trendelenberg), the author states that he has "tried it now in a few cases, and cannot speak of it with enthusiasm," the explanation of his lack of enthusiasm being self-evident.

One notes with surprise that the descriptions of antique methods of draining the peritoneal cavity after pelvic operations are still retained. Most American gynæcologists have long since ceased to drain up hill with glass tubes, and are practising nature's method—drainage per vaginam.

Section III., on the surgery of the ovaries and tubes, has been carefully revised, and concludes with a new section on conservative operations, as to the value of which the author expresses himself rather cautiously. "Absolute safety," he thinks, "follows complete removal only; it is not worth while running the risk of recurrence when there is the slightest doubt. Conservatism has most claims when disease exists on both sides. Moderate risk of imperfect cure or recurrence might be run in the effort to leave behind some working portion of the uterine appendages." Total extirpation of the cancerous uterus is recommended in preference to all other operations, though the latter are described. The method of drainage with a T-tube will not commend itself to the present generation of operators. One can hardly regard the chapters on hystero-myomectomy as up to date, considering the scant attention devoted to complete extirpation and intraperitoneal treatment of the stump. The same criticism applies to the section on Porro's operation and the barbarous and obsolete procedure, laparo-elytrotomy, on the revival of which Americans have no reason to pride themselves. Symphyseotomy scarcely belongs in this volume, and we have read better descriptions of the operation.

The section on hysteropexy, including "inguino-hysteropexy" (a new substitute for Alexander's operation), is rather brief and unsatisfactory, considering the importance of the subject and its voluminous literature.

The writer is apparently unfamiliar with our more recent statistics on vaginal section for ectopic gestation.

Sections VI. and VII., on the surgery of the stomach and intestines, include nearly three hundred pages and are most exhaustive, the various methods of suture being carefully described and illustrated.

Appendicitis receives due attention. It must be confessed that the author's conclusions with regard to the proper indications for operation are not very helpful, granting that he is right in stating that "it is impossible to be definite and would be wrong to be dogmatic." His conservative position is in marked contrast to that of some of our ultra-enthusiasts.

The valuable sections on operations on the urinary organs have been rewritten and are fully up to date, containing a new chapter on ureteric surgery. This applies also to the chapter on gall-bladder surgery. The concluding section, operations for peritonitis, is most interesting and instructive.

It is impossible, in a hasty review, to do justice to a work of such acknowledged excellence. That the new edition is a great improvement over former ones it is hardly necessary to state. We have indicated a few directions in which there is still an opportunity for judicious pruning. Abdominal surgery is a sufficiently broad subject without still further enlarging it by the introduction of operations which belong to vaginal and obstetric surgery.

The author's style is, as it has always been, clear and pleasing. The personal (or statistical) element is singularly absent—a rare virtue with surgical writers. In spite of the excellent additions to special literature, his work still maintains its original place.

Transactions of the American Surgical Association. Edited by De Forest Willard, A.M., M.D., Ph.D., Recorder of the Association. For sale by William J. Dornan, Philadelphia. 1896.

This is the fourteenth volume of the society's transactions, and one of which it may well be proud. It contains in its seven hundred and forty-two pages, printed on good paper and in good type, a great variety of valuable papers which were read at the last meeting. Among others may be especially mentioned the address of the president, Dr. Tiffany, on intracranial operations for the cure of facial neuralgia; tuberculosis of the male genital organs, by Dr. Senn; and tuberculosis of the female genital organs, by Dr. Vander Veer. Dr. Matas also contributes an interesting paper on the surgical peculiarities of the negro.

Braithwaite's Retrospect of Medicine. A half-yearly journal, edited by James Braithwaite, M.D. Lond., assisted by G. F. Trevelyan, M.D. Lond., etc. Volume CXIV. London: Simpkin, Marshall, Hamilton, Kent & Co., Limited. 1897.

This volume (July to December) includes synopses and abstracts of most of the original work of the semester, alphabetically arranged, as usual. It is always an instructive and interesting work. G. P. Putnam's Sons are the American publishers from advance sheets of this production, which has now existed for half a century.

The Year-Book of Treatment for 1897. Philadelphia and New York: Lea Brothers & Co. 1897.

This is a critical review for practitioners of medicine and surgery, prepared by some thirty contributors, mostly English, and is classed among the "handy annuals" of medical literature. A great variety of subjects is discussed, and original work and contributions in many fields are reviewed. Being now in its thirteenth year, the work speaks for itself.

Les Sanatoria Traitement et Prophylaxie de la Phthisie Pulmonaire. Par Dr. S. A. Knopf. Paris: Georges Carré. 1895.

After visiting all the sanitary stations where consumption is treated, the author makes this the subject of an extensive thesis, illustrated with photographs. In his conclusions, he believes phthisis curable, and that hygienic and dietetic measures in closed establishments are the true treatment. The founding of sanatoria for the poor in all stages and degrees of their disease becomes more and more a necessity. In this way those not curable may not become foci of contagion.

Transactions of the American Ophthalmological Society. Thirty-second Annual Meeting. New London, Conn. 1896.

The secretary has presented us this year with a very neatly prepared and freely illustrated volume, containing rather more than the average number of instructive papers.

Transactions of the British Orthopædic Society. Volume I. Sessions 1894–95. Birmingham: Hall and English, Printers.

This is a short illustrated report of the first meetings. It includes the constitution, by-laws, and list of members.

HANDATLAS DER ANATOMIE DES MENSCHEN. Mit Unterstützung von WILHELM HIS, Professor der Anatomie an der Universitat Leipzig. Bearbeitet von WERNER SPALTCHOLZ, ao. Professor an der Universitat Leipzig, etc. Zweiter Band, I. Abtheilung. Leipzig: S. Hirzel. 1896.

THIS part, beginning with page 237, includes regional anatomy and the muscles of the body; fasciæ, heart, and vessels being contained in the second fasciculus. The colored pictures are beautifully drawn from dissections, and when the work is completed it will undoubtedly be one of great value.

ŒUVRES DE LÉON LE FORT, Professeur de Clinique Chirurgical à la Faculté de Paris. Publiées par le DR. FÉLIX LEJARS. Tome Troisième, Chirurgie. Paris: Félix Alcan. 1897.

THE editor has here reproduced the works of Le Fort, which present originality of research and are marked by his personality as a surgeon. Like the other volumes, it is large and covers a great variety of topics, observations, and operative procedures, some of them classic. There are also extensive descriptions of apparatus and instruments which are the result of this surgeon's inventive genius.

A PICTORIAL ATLAS OF SKIN DISEASES AND SYPHILITIC AFFECTIONS. In Photo-Lithochromes from Models in the Museum of the Saint Louis Hospital, Paris, with Explanatory Woodcuts and Text. Parts VI. and VII. By ERNEST BESNIER, A. FOURNIER, TENNESON, HALLOPEAU, DU CASTEL, HENRI FEULARD, and L. JACQUET. Edited and Annotated by J. J. PRINGLE, M.B., F.R.C.P. London: The Rebman Publishing Company, Limited. Philadelphia: W. B. Saunders. 1896.

PART VI. contains photo-lithochrome plates of ulcers and scars in an habitual cocaine consumer, trichophytosis of the skin, syphilitic hyperkeratosis, psoriasis figurata. The text accompanying these beautiful pictures is particularly clear and concise.

In Part VII. there is a certain sameness about Plate XXV., showing bromide eruption, and Plate XXVI., hypertrophic papular syphilide, which emphasizes the necessity of care in differentiation. Rupoid syphilide accompanied by gangrenous ulceration makes an excellent picture, and more characteristic than the next plate, showing later gangrenous lesions. The proportion of unusual lesions in this part outweighs that of the ordinary types.

A COMPLETE CASE RECORDER IN GENERAL MEDICINE AND GYNECOLOGY. By S. B. LYON, M.D. Chicago: A. L. Konish and Company, Printers.

THIS is a general medicine and gynæcologic medical sheet, for the use of physicians, students, dispensaries, and hospitals; for the latter, it would appear, rather more than for the former, because of the numerous subdivisions. There is too much in the "Recorder" to make it practical for the uses of the busy general practitioner.

TRANSACTIONS OF THE COLORADO STATE MEDICAL SOCIETY.

THIS is the Twenty-sixth Annual Report, and contains not only a large number of excellent papers with their discussions, but a frontispiece plate of the president, Dr. F. B. Perkins. The corresponding secretary is Dr. H. B. Whitney. The report is published with care, and contains, besides a list of members, a good index.

HYPNOTISM, AND ITS APPLICATION TO PRACTICAL MEDICINE. By OTTO GEORG WETTERSTRAND, M.D., Member of the Society of Swedish Physicians at Stockholm, etc. Authorized translation (from the German Edition) by HENRIK G. PETERSEN, M.D., Member of the Société d'Hypnologie et de Psychologie, Paris, etc. Together with MEDICAL LETTERS ON HYPNO-SUGGESTION, ETC., by HENRIK G. PETERSEN, M.D. New York: G. P. Putnam's Sons. 1897.

AFTER appearing in Swedish, German, and Russian, Dr. Petersen now presents the author's views to the English-speaking public, along with some of his own.

Among the latter are some rather good points brought out in his translator's preface. Hypno-suggestion should undoubtedly be studied by physicians, and what there is of worth in it be made the most of for the patient's benefit.

One may find here discussed in a true scientific way the various therapeutic uses to which suggestion can be put. The sceptic will find sufficient points for his criticism. There is a bibliography of questionable utility, and no index, which might be useful.

HANDBOOK OF MASSAGE. By GUSTAF NORSTRÖM, M.D., of the Faculty of Stockholm. New York. 1896.

THIS work is written in such a way as to be of value to the clinician as well as to the professional masseur. It contains much that is of scientific interest and a chapter that bears upon the present controversy as to the utility of massage in fractures. The correction of the author's English leaves something to be desired.

TRANSACTIONS OF THE AMERICAN ORTHOPEDIC ASSOCIATION. Tenth Session. Held at Buffalo, N. Y., May 19–21, 1896. Volume IX. Philadelphia. 1896.

FOLLOWING an address by the president, Dr. Royal Whitman, there are the usual number of papers upon the topics of interest. The paper and print are far above the average of such reports. The illustrations are good and include a number of instructive *x*-ray pictures. The secretary deserves credit, and we regret that his name does not appear, so that we might mention it.

RECHERCHES SUR L'ÉPILEPSIE, L'HYSTÉRIE ET L'IDIOTIE. Par Bourneville, Médecin de Bicêtre. Paris: Félix Alcan. 1896.

THIS is Volume XVI. of the publications of the *Progrès Médicale*. It is a clinical and therapeutic work prepared with the collaboration of a number of well-known men, and contains thirty-one figures in the text and eight plates. It contains many data gathered during the year 1895 bearing on these important questions.

PATHOGENESE DER MERCURIELLEN STOMATITIS UND SALIVATION. Von DR. ALFRED LANZ, Privatdocent für Derm. u. Syph. an der Kaiserlichen Universitat Moskau. Berlin: Oscar Coblentz. 1897.

A CLINICAL and experimental study, with one plate. Brochure of one hundred and sixty-seven pages, of especial interest to those occupied with syphilis and extensive use of the mercurials.

A MANUAL OF THE PRACTICE OF MEDICINE, PREPARED ESPECIALLY FOR STUDENTS. By A. A. STEVENS, A.M., M.D. Fourth Edition, revised and enlarged. Illustrated. Philadelphia: W. B. Saunders. 1896.

THIS is another manual added to the long list of such works already given to the profession by these publishers. In the preface to the first edition the writer says: "At the request of many students the author has written this book with the hope that it may serve as an outline of practice of medicine, which shall be enlarged upon by diligent attendance upon lectures and critical observation at the bedside." Aside from its use in cramming for examinations, the work has little to recommend it.

A TREATISE ON OBSTETRICS FOR STUDENTS AND PRACTITIONERS. By EDWARD P. DAVIS, A.M., M.D., Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic; Clinical Professor of Obstetrics in the Jefferson Medical College of Philadelphia; Medical Director of the Jefferson Maternity; Clinical Professor of Pædriatrics in the Woman's Medical College of Philadelphia; Visiting Obstetrician to the Philadelphia Hospital; Physician to the Children's Department, Howard Hospital. Illustrated with 217 Engravings, and 30 Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Co. 1896.

THIS work is divided into seven sections, dealing with pregnancy and labor; pathology of labor; obstetrical operations; abortion, extra-uterine pregnancy, the puerperal state; infancy in health and disease; diseases of infancy; and the jurisprudence of obstetrics.

Although the work, as the title page indicates, is intended "for students and practitioners," still we fail to find any detailed descriptive anatomy of the female generative organs

or of the bony pelvis as a parturient canal. The physiology of the female genital organs, especially regarding ovulation and menstruation, is practically ignored. In the chapter on normal labor and its management, the mechanism of labor, which is the foundation of the subject of midwifery, is not discussed. The phenomena of labor, however, we find here thoroughly and attractively set forth. The chapter upon forceps is one of the best written in the book. The author is an ardent advocate of axis traction, and particularly of the variety in which the fenestræ of the forceps are adjusted with tapes, a traction bar being fitted to the tapes about opposite the butt of the handle of the instrument. The subject of version and extraction is completed in four pages, and we find here but one illustration. Surely two such subjects demand more attention. The descriptions of symphyseotomy and cœlio-hysterectomy are all that could be desired, and many of the illustrations are original and new. Two valuable features we note in the concluding chapters: one is a section upon infancy in health and disease—which is extremely well written and goes more deeply into the subject than any text-book of obstetrics with which we are familiar—and another is a section devoted to the jurisprudence of obstetrics.

Elementary Bandaging and Surgical Dressing. With directions concerning the immediate treatment of cases of emergency. For the use of dressers and nurses. By Walter Pye, F.R.C.S. Revised and in part rewritten by G. Bellingham Smith, F.R.C.S. Seventh Edition. Philadelphia: W. B. Saunders. 1897.

This little book treats of apparatus for restraint and support (bandages and knots, etc.); of the simpler ways of dressing wounds, burns, and scalds; of the treatment in the first instance of accidents and other emergencies.

It is a very compact book of over two hundred pages, and the fact that it has reached its seventh edition is proof of its kind reception by those to whom it was intended to be of service.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 2, 1897.

Andrew H. Smith, M.D., President, in the Chair.

Total Amputation of the Tongue for Epithelioma by Whitehead's Method (glands of neck removed on each side.)—Dr. R. F. Weir presented the patient, George W——, age fifty-four years, a great pipe smoker. For fourteen years a scaly spot had been observed upon the dorsal surface of the tongue, about in the middle. For three months the lump had been larger, painful, and fissured. When he entered the hospital, May 2, 1896, the tongue was moved only with difficulty. In its centre was a hard, rough, ulcerated oval tumor, three-fourths of an inch by one inch, raised about one-half of an inch. Microscopical examination showed the growth to be an epithelioma. A leathery white slough covered the ulcer and surrounding surface of the tongue. No indurated glands were to be felt on either side of the neck. The base of the tongue was infiltrated. May 6th, without tracheotomy, incisions were made in front of the sterno-mastoid down to the clavicle and along the hyoid bone on the right. The whole right side of the neck was thoroughly exposed without opening into the mouth and explored, and then the left side was similarly treated. Three or four small glands were removed on both sides of and under the sterno-mastoid, particularly at its upper part. The glands removed did not show by subsequent microscopic examination the presence of any tumor growth, save along the edges of the sublingual and submaxillary ducts (a not uncommon though not always a recognized invasion, though the salivary glands themselves are rarely involved). Through the incisions both lingual arteries were tied in their first portions, that is to say, above the outer end of the hyoid bone. The tongue was then pulled forward and was cut off at the level of the hyoid bone, together with the mucous membrane from the inner surface of the jaw and deeply from the muscular tissues of the floor of the mouth. The wounds were closed with silk sutures over posterior drains of iodoform gauze. The floor of the mouth and the stump of the tongue were painted with Whitehead's solution and stuffed with iodoform gauze, which was removed in four hours. An hourly douche of Thiersch's solution, half-strength, was then employed, and the wound packed with gauze wet with the same solution.

After describing the operation, Dr. Weir said: "The patient is shown at the present time as evidence of the extent of the operation and its aims, in cleaning out the neck as one does the axilla, in order, if possible, to get beyond the gland infection. The total absence, so far, of recurrence is encouraging, but the time limit of two years should be insisted on in all cases claimed to be cured. A further point of importance in cancer of the tongue affecting one side is that the cervical glands on the opposite side of the neck on account of cross infection should always be explored as well as those on the affected side, and, further, that in every case the region beneath the upper part of the sterno-mastoid muscle should be looked after particularly."

The patient said in reply to questions that he could taste as well as or even better than before the tongue was removed, but it was necessary to have sufficient food in the mouth to bring it in contact with its roof. Taste had returned gradually after the operation. He was able to speak plainly enough to be understood by all present. There was no difficulty in swallowing. The absence of the tongue interfered with bringing small quantities of food between the teeth to be chewed.

Case of Achillodynia or Achillobursitis Treated by Operation.—Dr. Weir presented the patient, Jacob M——, aged fourteen years. He gave no history of tuberculosis in the family. He entered the New York Hospital in October, 1896. Three months previously he sprained his heel by getting his foot caught in a railing. After a week, as he continued limping, he was kept in the house and liniments were applied. He remained a good deal of the time in bed, with pain in the heel and ankle. On examination the foot was found strongly extended, with fulness and much tenderness on either side of the tendo Achillis. Active motion was prevented by pain. Passive motion was also painful. No pain was produced by crowding together the joint surfaces. October 10th, under ether, a curved incision was made from below the outer malleolus and running upward along the tendo Achillis. The bursa underlying this tendon was opened. It contained about two drachms of sanguino-purulent material, and its walls were found thickened and much congested. The bursa was dissected out, and the posterior portion of the os calcis, thought to be softened but unchanged in color, was scooped out to a moderate extent with a Volkmann's spoon. Iodoform powder was rubbed into the tissues and the wound was sutured with fine silk over a drain. The cavity closed by granulations, and at the time the patient left the hospital, four weeks after the operation, there was still a sinus discharging sero-purulent fluid. No tubercle bacilli were found in the fluids at operation, nor did the secretions show the characteristic lesions of tuberculosis. April 2, 1897, about five months after the operation, he was again seen. The functions of the foot were fully restored.

Dr. Weir said in his remarks that achillodynia, in its obstinate form, has but recently been treated by operation. The observations of Rössler, of Vienna, of two

hundred and twenty-five bursæ underlying the tendo Achillis have shown frequent lesions, not only those belonging to acute inflammations, but changes, such as bone hypertrophies, calcific plates, tuberculosis, and even sarcoma, all of which can be attacked only surgically. Wiesenger, of Hamburg, has published four cases of tuberculous achillobursitis treated by extirpation of the bursa and adjacent bone, and also one case of sarcoma of the same bursa. He suggests, if necessary, to cut across the tendon to expose the bursa, and subsequently to suture it together again.

Dr. Joseph D. Bryant, in discussing Dr. Weir's first case, expressed the opinion that a good prognosis as to ultimate result could be given a patient with epithelioma of the tongue and glands of the neck when the operation for removal was carried out extensively, as described in this case. A sufficient number of cases had been operated upon in this manner by German and also by American surgeons to justify that opinion. He agreed with Dr. Weir, that hemorrhage was best controlled by ligating the lingual artery in the first portion. He selected a point between the greater cornu of the hyoid and the hyoglossus—not more than one-fourth of an inch above the greater cornu and beneath the hyoglossus. Several facts had always actuated him in selecting that situation. 1. The head could be better turned, and by pressing from the opposite side the hyoid bone was made to stand out more prominently, constituting a first-class guide. 2. Having exposed the cornu of the hyoid, if one should hook under it with a tenaculum it would be found that the artery was under as perfect control as if it were in the hand. In one case, however, he had found transposition of the vessels, the artery lying above, the vein beneath the hyoglossus. 3. Ligation in this portion of the lingual gave better control of the circulation of the tongue than when ligation was practised in any other place. The branches of the dorsalis linguæ in particular were much more apt to be controlled than if one ligated farther forward.

Dr. Bryant emphasized the importance of removal of the lymphatic glands. Too much stress could not be laid on the fact that the glands might be diseased, even though their increase in size was not perceptible on ordinary examination. It had occurred to him on several occasions to remove lymphatic glands during the course of an operation for malignant disease, not so much because they were thought to be diseased as that they might become diseased, yet microscopic examination proved them to be already infected.

Dr. Abbe was inclined to think that tracheotomy was a desirable aid in this operation. He thought it added very little to the risk, while it certainly gave better control of etherization and was of great service in handling the tongue without obstruction. It would shorten the operation somewhat, and add none to the risk. He regarded removal of the complete lymphatic system in the neighborhood of the disease as an essential procedure. Without it, the operation was a hopeless one. The patient's life would not be much prolonged, nor his comfort much increased.

Dr. Bryant asked Dr. Weir whether he experienced any difficulty because of not having performed preliminary tracheotomy.

Dr. Weir replied by saying that the first step in the operation was the outside work, removal of the glands and tying the linguals. After this the ether sponge could be removed and the operation quickly completed. Removal of the tongue itself did not require more than three minutes. In answer to the further question whether he had any unexpected bleeding from the posterior portion of the stump, Dr. Weir replied in the negative. There was a little hemorrhage from the pillar of the fauces, which was cut upon, but none from the stump itself. He was much impressed with the fact, and Kocher had also called attention to it, that one had a much freer operation by ligating the lingual in its first portion instead of anteriorly.

The Ocular Complications of Typhoid Fever.—Dr. C. S. Bull read the paper (see page 577).

Dr. C. L. Dana said he had not heard the first part of the paper, referring to optic neuritis, but, to judge by his experience in Bellevue Hospital, the optic complications of typhoid fever must be very rare. He did not recall a case in his service in which there had been anything to call attention to the eye. The author had stated that there was sometimes paralysis of the muscles of the eye, but his interpretation of it, that it was due to nephritis, was not the one usually given of paralyses following typhoid fever. Typhoid fever, like diphtheria, had some tendency to cause paralysis of the legs and arms, and occasionally of the face and eye muscles, but this was supposed to be due to a neuritis, and not to be of nuclear or central origin. So far as he knew, it was not considered that nephritis caused neuritis. The ocular paralysis was due to the specific poison of the fever, just as diphtheritic paralysis was due to the poison of that disease. Dr. Dana had always thought that some of the post-typhoid paralyses, especially those of the feet, might be due to alcohol, which was given rather freely in some cases of typhoid. The typhoid poison had more affinity for the peripheral nerves than for the blood-vessels. One very rarely saw post-typhoidal hemiplegia from embolism or cerebral hemorrhage, while paralysis due to neuritis of various nerves was not infrequent.

Dr. Bull said his authorities for the statement connecting nephritis with paralysis of the muscles of the eye were Leber and Deutschmann, both of whom had spent a good deal of time in investigating the subject for a number of years. Deutschmann referred to a number of cases with post-mortems, in which no evidence was found of neuritis in the nerves involved. With regard to the frequency of ocular symptoms in typhoid fever, he believed that those referable to the extrinsic muscles of the eyes—paralyses of various kinds—were not common, but he was convinced from the examination of a large number of cases that hemorrhages were not uncommon. Not involving the macula, they did not cause enough trouble to lead the patient to complain. During the past four years he had examined the eyes in about two hundred and fifty cases of typhoid, and had found retinal hemorrhages quite frequently. In a member of his own family, with prolonged typhoid but temperature not very high, there were small hemorrhages in both eyes. They were afterward entirely absorbed, as they were likely to be in young patients.

Globus Hystericus and Enlargement of the Laryngeal Tonsil.—Dr. Beverley Robinson called attention to a condition not commonly recognized in general practice. Within the past two weeks two women patients had visited him on account of an irritative cough and so-called globus hystericus or a feeling of choking band about the neck. Dr. Robinson stated that before making a laryngoscopic examination he expected to find the laryngeal tonsil engorged, inflamed in appearance, and pressing upon the larynx. So it was. He referred to these recent cases in order to impress the fact that acute swelling of the laryngeal tonsil was a frequent cause of irritative cough, of a tickling sensation about the larynx, and of what was called hysteria in these patients. It was not, however, hysteria, but pressure around the larynx giving rise to symptoms commonly spoken of as hysterical. The condition could be relieved by internal remedies and local applications. It was because laryngologists had done little to direct attention to the trouble in acute form that he now mentioned it.

Hemorrhage from the Laryngeal Tonsil.—Dr. Kinnicutt inquired whether Dr. Robinson had seen

such varicose condition of the veins of the laryngeal tonsil as to give rise to hemorrhage. He had himself seen such cases, and twice had been able to detect it at the time of its occurrence. In one instance a man whom he knew was walking past his office, when he was attacked apparently with hæmoptysis. When he entered his office he was spitting blood freely and was much frightened. On examining the throat at once, Dr. Kinnicutt observed a markedly varicose condition of the veins of the tonsil. One of them was bleeding. He had observed the same thing in situ in another case. He mentioned it as a possible source of hemorrhage from the mouth which in his reading he had not seen fully recognized.

Dr. Robinson was glad attention had been directed to this condition by Dr. Kinnicutt, for it was one which gave rise to hemorrhage and had not been mentioned with any emphasis in the majority of the textbooks. At the next meeting he hoped to read two letters on the subject recently received.

Dr. Kinnicutt added that the lungs in his case were carefully examined and no signs of disease were found, and the patients were still in good health, it being some years since the occurrence of the hemorrhage.

The President said he had recently been called in great haste to see a young woman who was supposed to be bleeding from the lungs. On examination he found blood stain on the posterior wall of the pharynx, and by use of a sponge obtained ocular evidence that the hemorrhage was from the nasopharynx. There had not been the slightest discharge of blood from the nostrils.

Elephantiasis Arabum.—Dr. Kinnicutt passed photographs of a case of elephantiasis arabum, limited chiefly to the left leg, although the right leg was affected in some degree. The left leg had a circumference of over twenty-nine inches. The largest on record known to him measured thirty and one-half inches. His patient was an obese woman, five feet three inches high, and weighing four hundred and fifty pounds. She was bedridden, entirely helpless, and had entered the hospital to have the leg amputated. It had been proposed, instead, to ligate the femoral artery, which had been done in similar cases with some amelioration of the condition. The veins and lymphatics could be felt, thickened and cord-like, in the subcutaneous tissue. The skin had the color and general appearance of an elephant's hide. No filaria were found.

Traumatic Bend of the Radius.—Dr. Bryant presented an *x*-ray photograph showing a marked bend in the shaft of the radius, the convexity directed toward the ulna and the lower end of the ulna projecting markedly. His attention was called to the case on passing through his ward in Bellevue Hospital and seeing the house surgeon wiping the perspiration from his brow from efforts at reduction of supposed dislocation of the lower end of the ulna. The patient was a young man of eighteen, who had sustained a blow upon the side of the radius by a bowling pin, while his weight was resting against the hand, the fingers above and the thumb beneath the edge of a table. The case seemed of some interest from the manner in which the injury occurred, the nature of the deformity, the distinctness with which it was shown by the radiograph, and the fact of the great effort to reduce the deformity.

Case of Appendicitis.—Dr. Bryant showed an appendix which contained a large concretion, but presented on the exterior no evidence of inflammatory disease. The symptoms leading to an operation were three attacks in as many days, characterized by chills, elevation of the pulse (120), some tenderness over the appendix on pressure, but no evident tumor, later tympanites, high temperature (103.5° F.). The symptoms were relieved promptly by the operation, and the patient recovered without any untoward event. The gridiron method was practised.

Four Cases of Tic Douloureux Relieved by Medical Treatment.—Dr. C. L. Dana wished to put on record four more cases of tic douloureux, which he had treated the past year with the result of relieving all of the patients of their pain. Some present might remember that a year ago at the meeting of the Association of American Physicians he had reported six cases relieved in a similar manner. Besides these ten cases treated successfully the past three years, he had treated three others, one with total failure, the other two with failure because the treatment was not carried out. All of the four cases which he had to report to-night were in women, about the age of fifty, who had suffered from tic douloureux in its most typical form. The pains were terrific, agonizing, and had been present from one year and a half to four years. One patient had been operated upon twice, and portions of the nerve removed.

All of the patients were treated in the manner described a year ago; they were put to bed, given a milk diet, and a daily injection of strychnine, beginning with one-thirtieth of a grain and increasing gradually to one-fifth of a grain. In some cases one-third of a grain was given. The treatment was continued about six weeks, during the latter part of the period the dose of the strychnine being gradually reduced. In two cases the first course of treatment had to be supplemented by a second one of three weeks' duration. In one instance the patient was under treatment three months. He did not undertake to treat cases unless it was understood that the treatment could be continued three months if necessary.

One of the four patients had not only a most severe form of tic, but also the morphine habit, which increased the pains. There had lately been some exploitation of the opium cure of tic douloureux, but in spite of the fact that it had been recommended by such men as Charcot and Ferrier, the speaker thought it was unfortunate for the general practitioner to get the idea that opium was good in this disease. He had seen some very disastrous results from its use. His reason for again mentioning the treatment which he had practised for three years, was that there seemed to be great misapprehension of its nature by many. Some had said they had given strychnine a few days, or a week or two, but it had done no good, and they had pronounced the method a failure. There was no use of commencing the treatment unless it was carried to the full extent, for very often the symptoms were even aggravated the first two three weeks.

In reply to interrogatories, Dr. Dana said the injections of strychnine were not made over the seat of pain, but anywhere convenient. He had not tried administering it by the mouth, but thought there might be some danger of an accumulated dose from temporary retention in the tract. One of the ten patients had been a sufferer for thirty years and had been operated upon by Dr. Carnochan and nearly every surgeon in New York; the face was badly scarred in consequence, but the pain had not been permanently relieved until this medicinal treatment was given. It was important to keep the patient abed during the treatment. The pulse tracing was taken in one case, and showed increased amplitude after injections of a quarter of a grain of strychnine. The drug was a heart stimulant.

Dr. Beverley Robinson raised the question of the advantage of administering certain remedies by hypodermic injection over administration by the mouth, and mentioned a preparation from which some patients had claimed to derive much benefit by injection,

whereas the same ingredients given by the mouth had been without result.

This statement of Dr. Robinson's was confirmed by Drs. Peabody and Polk, and Dr. Peabody thought the explanation suggested by Dr. Dana was the probable one in this instance also. The drug might not be absorbed at all when taken into the stomach.

Accident to a Distended Bladder.—Dr. Weir related the case of a boy, twelve years of age, who was a great water drinker, taking a quart to two quarts a night, without diabetes or other known cause for his thirst. One day when out skating, and not having urinated for an hour or two, he began to have pain in the stomach. The pain increased as he went home, and troubled him for ten days. It was supposed to be due to distention of the bladder, for there was swelling extending from the symphysis up to the umbilicus. A catheter was passed; the urethra was free; water was withdrawn which was bloody. Finally the conclusion was arrived at by the practitioners in the country who saw him that there was rupture in the anterior portion of the bladder with extraperitoneal effusion. Dr. Weir then saw the patient, opened the abdomen, found a large collection of urine and pus, and at first thought it was in the free peritoneal cavity, but it proved to be limited by the peritoneum of the anterior and lateral parietes of the bladder which it had dissected up. The escape of urine seemed to be from the left side of the bladder, somewhat low, but not low enough to permit of making perineal drainage. The opening was not seen. Suprapubic drainage was established and the patient did well for about twelve days, and then some symptoms of peritonitis developed. Dr. Elliott went up to see the patient, opened the abdomen, and found that perforation into the peritoneal cavity had taken place at the upper angle of the wound. Perhaps it had occurred at one of the dressings. The patient lived a few days longer.

An interesting point in the case was the fact that autopsy revealed no laceration of the bladder at the point where they expected to find it, down on the left side. It was only after considerable searching that they found an opening the size of a pinhead with some surrounding inflammatory tissue. Near by were a number of small spots where the bladder wall was extremely thin, almost perforated.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 15, 1897.

Edward G. Janeway, M.D., President, in the Chair.

Report from the Trustees.—Dr. A. Jacobi made the following motion for the trustees: "*Resolved*, that the trustees of the New York Academy of Medicine be authorized to negotiate a loan of $7,000, said loan to be used to retire the academy bonds and bear not more than four per cent. interest."

The object was to retire bonds which bore five per cent. interest and thus save at least one per cent. to the academy. The motion was carried.

The scientific proceedings consisted of a discussion on gall stones, five papers being read on various phases of the question.

Gall Stones, Their Effects and Diagnosis.—Dr. George L. Peabody limited his remarks on the effects of gall stones to their bearing on the diagnosis. That gall stones might remain for many years without producing symptoms was evident from their frequency at autopsy when no symptoms had existed. The diagnosis of typical biliary colic from the passage of a stone was easy enough. But gall stones did not always produce typical attacks of biliary colic. They might be complicated by other diseases or symptoms due to functional derangement of other organs. He had seen one case in a woman who at intervals could not take ordinary food without pain and low fever, but who obtained relief after a large calculus had been removed from the gall bladder. Some modern authors had noted gall-stone symptoms complicating typhoid fever, and one explanation which had been suggested was that of peristalsis of the duct and gall bladder excited from the intestine. There might also be infection by the typhoid or other germs. It was possible to confuse such attacks with gastralgia, but in the latter there were apt to be distention by gas and relief by belching. Pressure gave relief rather than pain. Fever was more likely to accompany biliary calculi than gastralgia. The diagnosis would be rendered certain if after a day or so jaundice should develop, and positively so if a stone should pass with the fæces. Attention had already been called to the frequency of biliary colic without icterus. The gall bladder might be enlarged and palpable. The diagnosis from gastric or duodenal ulcer with pain was more difficult. Taking food might increase the pain in both, but was more likely in ulcer. If the vomited matter contained an abnormal amount of acid it favored ulcer. Swelling of the gall bladder and icterus spoke loudly for gall stone. Lead colic and peritonitis sometimes simulated gall stones, and hepatic neuralgia was said sometimes to occur in nervous people, sembling gall stone. Dr. Peabody had seen gall stone mistaken for appendicitis, and referred to the case operated upon by Dr. Weir. When the appendix lay near the gall bladder, the differential diagnosis might not be possible until after laparotomy.

When the gall bladder became distended and presented a fluctuating tumor, it must be distinguished from floating kidney, from ovarian tumor, from urinary bladder, etc. Facts which pointed to distention of the gall bladder were the shape and position of the tumor, and the fact that it moved up and down with the liver on respiration. It admitted of some lateral displacement. An element of confusion was the fact that the gall bladder sometimes partly emptied itself, the stone acting like a ball valve. The absence of jaundice would favor location of the stone in the cystic duct. The gall bladder had also been mistaken for a liver lobe of abnormal shape, and for empyema and some other conditions. The gall bladder might be atrophied; it might contain pouches with stones in them. In gall stone lodged in the common duct there might be complete or only partial obstruction, jaundice more or less marked, and recurring at irregular intervals. The jaundice might be followed by serious results, or persist for years without other developments. Of common occurrence was catarrhal choledochitis, which was sometimes mistaken for malaria, especially when there was enlargement of the spleen and the attacks were of an intermittent nature. The nature of the intermittent fever was still under discussion. Osler had suggested infection of the gall passages by germs, several kinds of which had been found. Obstruction of the bile passages by tumors outside of their lumen was less common. The effect upon the liver of obstruction of the common duct was variable. It was seldom enlarged, but the connective tissue was likely to be increased, although this had recently been questioned. Dilatation of the branches of the hepatic duct had been observed, and in one instance the sac formed was mistaken by a surgeon for the gall bladder. Varying degrees of violence had caused rupture of unwalled sacs. Perforation of the gall bladder and ducts occurred frequently. The symptoms depended upon the organs involved. The penetration might be into the abdominal cavity, lead-

ing to peritonitis or a localized abscess. In one of his cases the perforation had been into the duodenum, with passage of the gall stone into the intestine and obstruction leading to death. Communication with the stomach, jejunum, and ileum was rare. Perforation into the colon was frequent, into the kidney rare, into the urinary bladder possible. Perforation into the lung had sometimes been followed by recovery. But of all the fistulous communications, the one leading to the exterior was most common. Continued irritation of calculi in a duct or in the gall bladder had been the starting-point of carcinoma. From the point of view of surgical therapeutics, it was important to distinguish between obstruction of the common duct by calculus and by external pressure, as by carcinoma. In favor of calculus were persistent jaundice or jaundice recurring for years, former attacks of biliary colic, passage of calculi, fever more or less intermittent, absence of tumors other than of the gall bladder. The symptoms pointing to calculi in the hepatic ducts were so vague as rarely to lead to exact diagnosis until autopsy.

The Chemistry of Gall Stones.—Prof. R. H. Chittenden, of Yale, read the second paper. Biliary calculi could be divided on the basis of their chemical composition into three great groups: 1, Those which were composed in great part of cholesterin; 2, those of bile pigment combined with calcium; 3, those mainly of calcium carbonate and calcium phosphate. We met chiefly with calculi containing a large predominance of cholesterin, with some admixture of bile pigments and calcium. The largest amount of cholesterin found in any one stone was, he believed, ninety-eight per cent. The amount of cholesterin contained in human bile varied according to the length of time the bile had remained in the gall bladder. So-called liver bile contained from 0.048 to 0.16 per cent. of cholesterin, while bladder bile might contain as much as one per cent. When the bile was retained from any cause, absorption resulted in great concentration of the fluid, so that while human liver bile rarely contained more than 0.035 per cent. of solid matters, gall-bladder bile might contain 0.17 per cent. The difference could be attributed to withdrawal of the watery constituents. This was generally considered the primary condition in the formation of gall stone. The mere concentration of the bile, however, with increase of cholesterin, did not necessarily imply the crystallization or separation of the solid elements and the formation of stone.

The author next considered the theories of the primary origin of cholesterin found in the bile. There were two distinct views, one being that the liver simply separated the cholesterin from the blood flowing through it and passed it over to the bile; the other that the cholesterin was of local origin, formed chiefly by changes taking place in the epithelial cells of the mucous membrane of the gall bladder and ducts. It was a well-known fact that cholesterin was widely distributed throughout the body in all of the cells and in the blood. Unquestionably some cholesterin was formed in the liver, but its presence in the bile was to be accounted for mainly on the ground, the author said, of this being the only channel through which it could be excreted from the body. It was apparently a waste product, and its excretion took place through the liver mainly, probably because the bile was the fluid best adapted for its solution.

At this point the author took up the question of the nucleus of gall stones, their solubility, the solubility of cholesterin, and other ingredients. The nucleus, composed of bilirubin, calcium, etc., had its origin in pathological states which were little understood. A negative answer was given to the question whether the calculus could be removed by reaction on the salts. A far more plausible assumption was that solution could be brought about, in part at least, by agents which tended to increased flow and alkalinity of the bile, aided by increase in peristaltic action. Cholagogue effects, however, were not readily obtained, and obviously such treatment, if practical, would be safe only in case there was free outlet for the bile through the ducts.

The Medical Treatment of Cholelithiasis.—Dr. W. Gilman Thompson read the paper on this subject. The medical treatment of cholelithiasis fell naturally under two heads: That of the attack of colic, and the use of prophylactic measures. The pain of hepatic colic excited by the passage or impaction of one or more gall stones was often among the greatest physical agonies, and demanded prompt and vigorous measures for relief. From one-fourth to one-half grain of morphine with one-one-hundredth grain of atropine was to be injected at once, and fifteen to thirty minims of spirits of chloroform to be administered in cherry-laurel water, either alone or with one drachm of Hoffman's anodyne. The chloroform was promptly absorbed by the stomach and passed into the portal system, reaching the liver and lessening spasm of the walls of the biliary ducts. Belladonna and sulphuric ether might be used, but were less effective. Meanwhile a large very hot flaxseed poultice should be applied over the gall bladder and maintained for several hours. Complete immersion of the body in water at 104° or 106° F. was often soothing. Should these measures fail, resort should be had to first stage of chloroform narcosis.

A much more complex question was the possibility of accelerating the passage of the stone. Theoretically this might be accomplished: 1, by increasing the driving force behind the stone—the hepatic pressure and the peristaltic action of the gall ducts; 2, by lessening the resistance in advance by facilitating the relaxation of the muscular walls of the ducts; 3, by reducing the size of the stone by some solvent. The solution of these problems had been discouraging.

1. To increase the expulsive force, ordinary cholagogues, such as podophyllum and calomel, had been of little avail, and were too slow in action to relieve the immediate attack. Massage was dangerous as well as impracticable. Irrigation of the colon by cold water was believed to excite reflex peristalsis of the biliary passages, but it had been more successful in catarrhal duodenitis than in cholelithiasis. The best remedies to relieve spasm had already been mentioned.

2. Much had been written of the value of olive oil in large doses, but after giving it a fair trial the reader had not been convinced of its benefit.

3. Attempts to dissolve the stones *in situ* must prove as futile as attempts to dissolve renal or vesical calculi once formed. Chloroform and ether were both good solvents of cholesterin but it was highly improbable that they could reach an impacted calculus in sufficient strength to act upon it when given in justifiable dose. Permanent impaction was the exception, and the chief indication for the treatment of an attack was to mitigate the patient's suffering.

Prophylaxis.—Prophylaxis would be more promising if the bile were a less complex fluid, and gall stones were not found frequently at autopsy when they had caused no symptoms. Theoretically the prophylaxis might be divided under three heads: 1. Prevention of hepatic engorgement and of accumulation of bile in the liver or gall bladder. 2. A dietetic regimen, withholding such foods as were likely eventually to furnish the elements of cholesterin in excess. 3. Giving sufficient fluid to dilute in some degree the bile and prevent too great viscidity of the vesical mucus.

The prevention of hepatic engorgement was to be accomplished by familiar hygienic measures, by chola-

gogues and cathartics. Alcohol, over-eating, lacing, sedentary habits with cramped position should be avoided. Horseback riding should be practised. As a hepatic stimulant the author found a drachm of sodium phosphate, taken in bitter infusion or hot water on rising, of value. Some praised citric acid, bicarbonate of sodium, Carlsbad salts, calomel. Abdominal massage would benefit the obese.

Differences of opinion existed with regard to the dietetic treatment. Dr. Thompson thought it well to forbid sugars and fats in every variety, calves' brains, and the viscera of animals, particularly the liver. Fresh green vegetables and acid fruits, which, by virtue of their alkaline salts and organic acids, easily combined in the blood with alkaline bases, should form the basis of the diet in cholelithiasis. Fluids should be used freely for diluting the blood and through it the bile. Aerated and mineral waters containing salts of lime were best avoided, but other alkaline waters were beneficial. The patient was better without alcohol in any form. While the therapeutist often groped in the dark in vain efforts to reach the hidden calculi, the surgeon now threw full light on them by operations which promised not only relief but permanent cure, and with a measure of safety which was constantly increasing.

Surgery of the Gall Bladder for Biliary Calculi.—Dr. Arpad G. Gerster said he would confine his paper to an endeavor to sketch the variations in the anatomical situation of the gall bladder and the manner in which these variations would influence the surgical treatment. Whenever the enlarged gall bladder occupied the normal position an easy operation could be expected, so far as the anatomical conditions were concerned. A longitudinal incision over the mass exposed it; then one should bring the mass out and conduct the rest of the operation extraperitoneally. He should pack around it to prevent soiling and slipping back, evacuate the liquid contents, and remove the stones by suitable manipulations. A small calculus forceps or blunt spoon-shaped scoop would be found useful. If the stone were impacted in the cystic duct, he should try to displace it with the finger passed down under it; failing, he should pass two fingers down to the stone through the opening in the gall bladder, and finally if necessary enlarge the external incision or meet it with a transverse incision, so as better to reach the stone, and crush it, or pack around the cystic duct and incise it to permit of extraction of the stone. If the opening in the duct were sutured, the sutures should not be passed through the mucous membrane. There was tendency to spontaneous closure. The packing should be left in for a few days. The tendency to hernia in this region was only slight, and Dr. Gerster did not hesitate to make a free opening by an L-shaped incision. Some additional precautions were mentioned in connection with incision into the gall bladder. When there was empyema or gangrene of the gall bladder, the procedure should be directed with special attention to safe evacuation. The septic element having been got out of the way, there would be time enough to search for the stones. Stitches in these cases were not likely to hold, and chief reliance must be placed on packing. If the peritoneum of the gall bladder alone were stitched to the parietal peritoneum, fine silk was preferable to catgut. In fat people and those who had bronchial catarrh, a double line of sutures might be necessary to prevent rupture or escape of gut during coughing.

Dr. Gerster then considered unusual cases, those in which the gall bladder was found embedded in a mass of omentum and gut, deep situations of the gall bladder, gall bladder shrunken to a tight sac around the stones.

The reader had had no experience with so-called ideal cholecystotomy, or immediate suture both of the gall bladder and abdominal openings. It seemed to him that the advantage of immediate restitution to the normal was more than offset by the dangers. Whenever the cystic duct was found so changed as to lead to the suspicion of neoplasm, it was justifiable to excise it. Unusual peritoneal coverings and attachments and blood supply were mentioned. Cholecystenterostomy or anastomosis with the intestine was indicated in hopeless obstruction of the common duct by neoplasm or intractable stricture. It could be done quickly and safely with Murphy's button.

Surgery of the Common Bile Duct for Stones.—Dr. F. Lange read the paper on this question. Every practitioner had seen cases of protracted jaundice due to obstruction of the common duct finally end in spontaneous recovery. As long as such a possibility existed, even as an exception, it would be impossible to give general indications for surgical interference. The clinical conditions of each case must decide the question of surgical interference. Two groups of cases might be recognized: 1. Cases in which pure obstruction was the governing feature. 2. Cases in which obstruction was complicated with inflammatory or infectious processes. The physician should be made aware of the fact that long-persisting icterus diminished the safety from surgical interference, especially from the point of view of hemorrhage. He had had the misfortune to lose three patients after operation from uncontrollable hemorrhage due to cholæmia, all of whom presumably could have been saved had operation not been put off from month to month for trial of various measures for expulsion of stones. The attacks in the second class of cases were accompanied by chills, fever, and other signs of inflammation or infection, which added to the gravity of the situation. The saving of life depended often upon the time selected for the operation, not putting it off too long. Dr. Lange also read on the operative procedure.

Dr. Graham, of Toronto, said in the general discussion that the paper of Dr. Peabody would lead him to suppose the diagnosis of gall stones was easier than he had found it in practice. He thought further study of the chemistry of the urine and of the fæcal passages might yet give us more definite indications of threatened attacks of gall stones or of conditions of the system in which they were likely to form. On one fact we were agreed, namely, that a sedentary life predisposed to the formation of gall stones. Taking too much food had a similar tendency.

Dr. W. H. Draper gave two clinical cases of stones of very considerable size ulcerating through the gall bladder into the duodenum and causing intestinal obstruction. The first occurred about twelve years ago in a man, sixty years of age, who had never had any attacks simulating gall stones. He was seized suddenly with violent and persistent vomiting; he did not complain of much pain, but there was some abdominal tenderness. A purgative failed to act, and Dr. Draper suspected acute obstruction of the intestine. Dr. Sands was called in, and several other surgeons saw the patient, and while intestinal obstruction was the diagnosis, gall stone was not suspected as the cause. The patient died of exhaustion the ninth day and a large gall stone was found in the duodenum. Early in the attack but little urine was passed, which might lead one to suspect obstruction high up in the intestine, on the explanation that but little of the intestine was afforded opportunity to absorb fluids which might be taken. The second patient was a lady of about sixty, who had had attacks of pain followed by jaundice. He saw her in the attack in question about the third day. Vomiting was a striking symptom. There was a flat condition of the belly, indicating obstruction high up; also partial suppression of urine. He ventured the diagnosis of intestinal obstruction caused by

gall stone in the small intestine. The family was reluctant to allow an operation, but finally consented. Dr. Bull operated, and removed a stone engaged in the ileum without doing much injury. There was some indication of local peritonitis. The patient died.

Dr. Draper thought treatment other than surgical would have to consist in preventive measures, for there was little hope of causing absorption of stones once formed. The sedentary life of women probably was a reason for their having gall stones oftener than men.

Dr. Charles McBurney observed that all of the speakers had acknowledged the hopelessness of treatment other than surgical after gall stones had formed. Regarding prevention of gall stone, he thought none would suffer who formed proper habits as to exercise, and maintained healthy elimination before and during the usual period of gall-stone formation. This period was comparatively short. He had never had a case of recurrence after removal by operation. The cases could be divided into two classes: those which should be operated upon and those which should not be operated upon. Among the latter were persons who had had attacks and obtained relief by passing small stones, thus demonstrating the likelihood of obtaining relief in a similar way again, for as a rule when a person passed small stones he did not have large ones. But when the doctor was called to a case which did not clear up in this manner, the patient having marked jaundice, pain, etc., he should call the surgeon early, and an operation should be performed before the development of cholæmia, referred to by the readers. The operative dangers related to cholæmia and tendency to hemorrhage consequent thereon, to sepsis, which was also more liable to occur in cases of delay, and to adhesions. It was to the prevention of these conditions that attention should be directed, for all depended in large measure upon tardy operation. Cases which required an operation certainly must have a period when it was best to operate, and it was likely that, as in most surgical conditions, it did not last very long.

The President said with regard to recurrence of gall stones after operation that a man had recently consulted him for the prevention of attacks, he having had one some years after a surgeon had removed a stone from the common duct by opening the duodenum.

Dr. G. G. Hopkins presented one hundred and ten gall stones, which he had removed in February from the gall bladder of a woman of forty-eight years. She made a good recovery. The largest stone was about the size of a filbert and was lodged in the cystic duct, and accounted for the immense distention of the gall bladder, which contained ten ounces of clear fluid.

The President was empowered to appoint a delegate to the centennial celebration of the Westchester County Medical Society.

Removal of Tumors from the Breast.—In the removal of benign tumors from the female mammary gland, one should not forget the method devised by Dr. T. Gaillard Thomas. He makes the line of incision correspond with the natural crease in the skin, seen when the patient is in the erect position. After incising the skin as freely as may be necessary (four or five inches being usually enough), the capsule of the gland is dissected from the muscles of the chest, and the gland turned up so as to expose the growth, which is then excised from beneath and the gland returned to its place. No milk ducts need be cut, nor will there be any hemorrhage to speak of. If there is much hemorrhage, drainage can be left in for a few hours. With care there will remain only a hairline cicatrix. This method of operating possesses great cosmetic value, especially in unmarried women.—*Columbus Medical Journal*, January 19, 1897.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SYPHILIS AMONG TROOPS IN INDIA—GOVERNMENT PLAN—NATIONAL MEMORIAL TO JENNER—INFANTILE PARALYSIS—STRICTURE OF ŒSOPHAGUS—BRAIN TUMOR—EXTRAVASATION OF URINE—LORD LISTER'S PORTRAIT—INFLUENZA.

London, April 2, 1897.

The sad results of the increase of syphilis among our European troops in India have to some extent opened the eyes of the public and induced the government to use its strength in an attempt to undo some of the evils of previous legislation. As the facts reported by the army sanitary commission and the departmental committee became known, it was felt something must be done. Even those who induced a former government to prohibit compulsory measures were many of them shaken in their views. On Monday the Royal College of Physicians discussed and unanimously adopted a report of a committee on the subject. This report contained some very serious statements, and was duly forwarded to the government. Whether it had much influence may be doubted, as the decision of the ministry has already been taken. Yesterday this decision was stated to Parliament in the form of a dispatch to the government of India.

This dispatch sets forth that in any measures which may be adopted there must be nothing that can be represented as an encouragement to vice; there must be no registration, licensing, or compulsory examination, nor must women be allowed to reside in regimental bazaars or to accompany regiments on the march. Subject to these restrictions, the government considers that the cantonment rules in force in cholera, small-pox, etc., should be made applicable to all contagious and infectious diseases. It may be argued that examinations which may, but need not necessarily, be held under these rules is in effect compulsory, but the government does not admit this, and says if any degree of compulsion exist it is only such as has been accepted as necessary and enforced without objection in diphtheria, typhoid fever, etc. There is to be no obligation on diseased women to attend hospitals, but as an alternative they will be required to leave the cantonment, as an almost certain cause of disease to others. The dispatch expresses the opinion of the government that valuable aid in checking disease will be found in extended efforts to improve the moral and physical condition of the troops in India: to enlarge the means of their instruction, occupation, and recreation; and to warn newly arrived soldiers of their temptations.

On Wednesday there was an influential meeting of scientific men at the London University, to promote a national memorial to Jenner. It is hoped to raise a considerable sum and to place the British Institute of Preventive Medicine on a satisfactory basis, such as the Pasteur institutes. The most remarkable speech was that of Lord Herschell, who was president of the vaccination commission. He said he went into that inquiry without any prejudice, and came out of it "surprised at the force of the evidence in favor of vaccination." This from an ex-lord chancellor, who ought to know what evidence is, should suffice, especially as his lordship has heard more of the evidence tendered against it than any living man, as another speaker remarked.

Infantile paralysis has so much about it to stimulate to fresh investigations that no one can wonder at the suggestions made from time to time as to its being an

infective disease. It is not uncommon to find that a case of this disease is followed by another in the same family, and this fact naturally arrests attention and suggests infection. Dr. Pasteur brought the subject before the Clinical Society, and gave an account of a family of seven children, every one of whom was attacked in rapid succession within a space of three weeks. Though each began with feverishness and headache, the following paralytic symptoms were most variable; but as Dr. Pasteur thought he could certainly exclude diphtheria, influenza, and the exanthemata, he felt the diagnosis of infantile paralysis justified, and the cases confirm the growing impression that this disease is really an acute infective one. Dr. Ormerod observed that two of the cases almost suggested cerebro-spinal meningitis. Dr. Beevor said that one case resembled anterior poliomyelitis, another was of a cerebral type, and he seemed to think others were not free from doubt. Dr. Cayley remarked on the inappropriateness of the names applied to the disease. Dr. Buzzard quoted a Stockholm observer, who found twenty-seven cases of typical poliomyelitis out of forty-four cases he had met with. He suggested bacteriological investigations.

Mr. Lockwood brought before the Clinical Society a case of malignant stricture of the œsophagus treated by Symonds' tubes, and in which the safety string was swallowed, leading to gastrostomy being performed. Mr. Makins said that in one such case he had passed another tube to get rid of the first, and did not think there was much risk in doing so. Mr. Lockwood replied that in his case he did not think it practicable to push the tube down, and he was glad he had not tried to do so. It seemed the general impression that this accident was best met by gastrostomy.

At the same meeting Dr. Washbourn and Mr. A. Lane described a case of tumor of the brain, which had been successfully removed. It grew from the pia mater and deeply indented the brain without involving it, though on removal a minute portion of gray matter adhered to the under surface. The growth had shelled out easily, and measured two by one and one-half inches.

The president, Dr. Buzzard, would not have had the courage to recommend an operation until iodide of potassium, which had been given only for a fortnight, had had a longer trial. On this point Dr. Washbourn said that the iodide had not given the slightest benefit, and there was not the least suspicion of syphilis.

A case of extravasation of urine, which appeared one morning to the great surprise of the patient, a healthy man of thirty six, was then related by Mr. Barwell, who attributed the accident to coitus the night before, though nothing was noticed at the time. It was, however, remarked that there was no reason for such a supposition, as it is not uncommon to meet cases of extravasation without any obvious cause.

On Monday a portrait of Lord Lister was presented to the Royal College of Surgeons by some of his admirers. This portrait had been undertaken before the peerage was thought of, which afforded Lister an opportunity of saying how much he valued above all decorations the good-will of his fellow-surgeons.

The recrudescence of influenza is spreading, and we are threatened with a widespread prevalence of the disease. The deaths have increased again, but the mortality from all respiratory disease is much below the average.

Abortion of Bubo.—Pressure bandage, when suppuration is not too far advanced, by folds of cotton carefully adjusted and a cocoanut-sized wad of tightly compressed cotton placed over the whole and retained by a very tight spica, produced abortion of the process in nine out of twelve suitable cases.—GÆTHER.

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE BALNEOLOGICAL CONGRESS—A NEW REMEDY FOR TUBERCULOSIS—FERMENTATION AND YEAST-CELLS.

BERLIN, March 31, 1897.

THE German Balneological Congress took place, as it does each year, in the middle of March. As the winter begins to break, our balneologists come out like the feathered harbingers of spring, and this, their eighteenth annual convention, brought them in flocks to Berlin, to exchange experiences and to stimulate each other to new investigations.

The proceedings were opened by Neisser with a paper on the hydropathic treatment of syphilis. He believes that the beneficial effect of baths is due to aiding the general organism in its absorption of mercury besides increasing the metabolic processes. Under certain circumstances the elimination of mercury is accelerated, and it is possible that a remedy which is thus taken up and worked over rapidly and then eliminated from the system will act more effectively than one which stagnates in the tissues.

The set oration of the congress was delivered by Winternitz, of Vienna. He spoke with reverential words of the late Dr. Ernst Brand, a plain general practitioner of Stettin, to whom the world owes the cold-water treatment of typhoid fever. It was voted by the congress to send a telegram of condolence to the family of this benefactor of the race. The speaker then announced as the subject of his discourse, "Hydrotherapy in Graves' Disease." While organotherapy is powerless for the relief of this affection, there is not one of its symptoms, Winternitz claimed, which was not amenable to water treatment. Especially useful is this in the relief of the nervous symptoms, such as palpitations, tremor, sweating paroxysms, but the nutritional disturbances also, which find their expression in the progressive emaciation, are favorably influenced by a properly ordered hydropathic treatment. The speaker looked upon this as a means of true disintoxication, favoring the elimination of the poisonous products of metabolism formed in this disease.

Dr. Lindemann, of Heligoland, then read a paper on the curative action of sea baths in gastric disorders. The conditions of depression encountered in the course of these affections were bettered by sea baths, and further the appetite and the general strength were benefited by the sea air.

"Cure and Curability" was the title of an interesting communication by Dr. Hausemann. A true cure, he said, occurs only when there is a renewing of the cells of the diseased organs, and is met with therefore only in diseases which expend their injurious action on the superficial parts of organs, as the mucous layer of the hollow viscera, for example. The former belief, that all cells are in a condition of constant renewal, had been shown to be erroneous. In the case of many wounds a true cure is not possible, as, for example, in wounds of muscles or nerves, in which the parts destroyed are replaced by connective tissue. Where a lesion has existed there may take place a compensatory hypertrophy, as we see often in cases of cardiac disease. In this way a patient with heart disease may attain to old age with comfort.

Dr. Lahnsen read a paper on "Sleep and Sleeplessness." The important part which sleep occupies in our earthly existence is shown, if by nothing else, by the enormous commercial importance to which the trade in hypnotics has reached. In sleep there is a continuance of the functions of vegetative life, an interruption of the voluntary functions, and an exclusion of the conception of time. Dreaming is a phenome-

non of the waking state. Insomnia is one of the symptoms of neurasthenia. For acute insomnia the speaker advised the employment of neurotics, but urgently warned his hearers against their use in chronic cases. Such patients should be sent to some small quiet spa, where all causes of excitement are excluded. Hydrotherapy is also directly sleep producing, especially warm baths and cold sponging shortly before bed time.

Some skiagraphs were exhibited which showed the size and position of the stomach, a rubber sound with a copper stylet having been previously introduced into the viscus. In one cases some silver sutures, which had been left after an operation upon the stomach wall, were distinctly visible. Dr. Lindemann, who exhibited these pictures, predicted a constantly widening field of usefulness for the Roentgen rays in the diagnosis of doubtful cases.

Baginsky then reported the results of his bacteriological examination of the water in the public baths of Berlin. Mendelsohn read a paper on the treatment of renal and vesical calculi by mineral waters, and Schubert one on the treatment of skin diseases by venesection. The latter held that the composition of the blood varied greatly according to the locality, and said that an examination of the blood abstracted from one part gave us no certain information as to the composition and condition of this fluid in general.

Finally, of the great number of papers we can mention only one more, that of Ziegelroth upon the "Significance of the Doctrine of Autotoxins in its Relation to Hydrotherapy." By means of hydrotherapy the autotoxins are either more quickly eliminated or else more promptly oxidized and so rendered harmless. The speaker prophesied a speedy end to orrhotherapy. Some of those who took part in the discussion said that we know nothing further of hydrotherapy than that it is effective, but an explanation of how it was effective had not yet been made. It was suggested also that we had better not talk learnedly about autotoxins until their existence had been proven.

Dr. Robert Koch comes to the front again with a new remedy for tuberculosis, in the shape of a new preparation of tuberculin. He has been pursuing his investigations in this field quietly and persistently since 1890, but has taken care not to keep the public informed of the progress of his investigations. He has now succeeded in elaborating two preparations, which he distinguishes as tuberculin-O and tuberculin-R, and regards the latter as capable of conferring immunity against the action of tubercle bacilli. An examination of tuberculous guinea-pigs treated with tuberculin-R showed the presence of regressive changes in the affected organs, and patients with incipient phthisis and lupus were without exception benefited by injections of this remedy. Many of these cases would, by the ordinary rules of judgment, be regarded as cured, but Koch hesitates to pronounce the word "cure" until after a longer period than has yet elapsed in the case of the patients upon whom his experiments were made. No untoward symptoms of any kind were provoked by the use of the remedy. The preparation is given subcutaneously, beginning with very minute doses (one-five-hundredth of a milligram) and gradually increasing. Professor Koch speaks with reserve of his new remedy and he evidently is restrained by a fear of arousing exaggerated hopes of an infallible remedy in all stages of the disease. Let us hope that a second tuberculin debauch will not be followed by a second expiatory headache.

We can here merely hint at another probably epoch-making discovery, concerning which Professor Buchner has made a report to the Biologico-Physiological Society of Munich. He has succeeded in demonstrating that fermentation is not caused directly by the action of cells, but that it is brought about by certain substances which are produced by the yeast cells. A fluid, free from cells but containing the active substance, will quickly split up sugar into alcohol and carbonic-acid gas. This discovery, if correct, will compel a fundamental change in our views concerning fermentation, sepsis, and infection.

DISINFECTION OF THE HANDS.

To the Editor of the Medical Record.

Sir: In a previous number of your journal is an article on the "Disinfection of the Hands," which is both entertaining and instructive, written by Dr. Robert F. Weir. There is much attention paid at present by the profession to antiseptics, germicides, etc., which to an old physician bears the earmarks of "red tape" and when boiled down to the real and true prophylactics amounts to nothing more than cleanliness. If we go back forty years and compare the treatment then in vogue with our present treatment, we will find there is not such an advance as seems apparent in the treatment of surgical cases. We know, or think we know, the why and wherefore of the benefits derived from the antiseptics now, while forty years since we used them from purely clinical experience. Take, for example, bichloride of mercury, which we all use as the most powerful germicide; from the experiments of Dr. W. it is as unreliable in disinfecting the hands as some others. Mercury was used forty years since as a germicide, but it was not understood in what manner it acted. I remember an old surgeon in Petersburg who was sent for from great distances to operate, and I do not know any surgeon now who can show better statistics of success under the many disadvantages. He was often called upon to operate for stone in the bladder, and he told me that he never lost a case. I assisted him in amputating an arm just below the elbow, which had been caught in a threshing machine and very much lacerated. Before leaving the patient he directed broken doses of calomel to be given every two or three hours, until the gums were sore. He said he did this in all his important operations, and had never had cause to regret it. In those days doctors thought calomel and Dover's powders would cure almost every ailment. Soon after graduating I met an old physician who had quite a reputation and was sent for in consultation far and wide; in fact, if any died after Dr. Field saw them, the friends were satisfied nothing more could have been done. He said to me: "You are now about starting out in your profession and you have enough medicine in your saddle pockets to open a drug store; you will soon have a sore-back horse, and have got medicine you will have no use for as long as you live. You examine my saddle bags and you will find nothing but calomel and Dover's powders. I give these, and if patients die I conclude they would die any way." I know another physician who got quite a reputation in the successful treatment of diphtheria, and he attributed all his success to the use of calomel until the gums were sore. I mention these cases to show the confidence the profession had from clinical experience in the use of mercury forty years since. I do not pretend to say it is taken up into the system and acts as a germicide, but we do now know that mercury locally applied is a germicide.

When I was a boy there was in the neighborhood always some one who would be sent for to spay all sow pigs and castrate the boars, colts, and yearling calves. He would have the pigs penned up for twelve hours before the operation, so that they would become gaunt and that one could better find the ovaries.

He would open the abdomen between the hind legs about four inches, so that the fingers could readily be introduced to find the ovaries and bring them out to be cut. After this was done he sewed up the opening with some strong twine which had previously been waxed with shoemakers' wax; then he would put on the wound tar and hog lard mixed in equal proportion, and turn the pig out into the field. The same process was pursued on the boars, calves, and colts as regards local treatment. The hogs would go to the first mud hole and lie in it, perhaps all day, and it was rarely the case that any of the animals died which were operated upon. The question arises whether this tar and grease acted as a germicide. We know the tar has in it creosote, which is a germicide, and I have seen grease put on chickens to kill the vermin on them, and must conclude this is also a germicide. I would suggest to Dr. Weir to try to make some mild and pleasant wash for the hands with creosote, which would be better understood by the laity than other preparations mentioned. There is one more germicide I would mention, used forty years since, which, perhaps, could be utilized at this time. In slavery times I well remember that if any animal had a running sore (ulcer), in which maggots had gotten, the old negroes would get the tender sprouts from the common elder, bruise them, and apply the juice to the sore. This would kill the maggots and prevent a further deposit of eggs from the flies. Possibly a hand wash could be made in this way which, with a little perfume added, would be pleasant and satisfactory.

So much for forty years back; now allow me to say something of our present system in operating. I do not pretend to be a surgeon, nor to have performed any important operations, but I have done some minor surgery and often assisted others in grave cases. Hospital facilities are now so convenient and expenses so very light in these "charitable institutions" that outside doctors have a poor show for their skill. It looks very nice to an old mountain doctor to visit these city institutions with all their paraphernalia, and see how clean everything appears and what precaution is used for antiseptic purposes, and then to read the statistics of the many successful operations performed by Dr. ——, with charges only for board. These things are enough to deter the country doctor from attempting to operate in an important case, without the trained nurse, the tiled floor, the operating table, the antiseptics, the uniform, etc. But if these things are requisite for success, why is it that so many do well and go on without them to a speedy and successful termination? A short time ago I assisted in removing a testicle weighing twenty-seven ounces from a mechanic (tinner), and our assistants were a carpenter and a tinner. Neither, so far as I saw, washed their hands or used any precautions whatever. The patient recovered speedily and is at his daily post at work. I might cite many cases of similar character, but have, perhaps, said already too much.

B. P. Reese, M.D.

Staunton, Va.

ASEPSIS OF THE HANDS.

To the Editor of the Medical Record:

Sir: A late issue of the Medical Record contains the report of a discussion before the Practitioners' Society of New York on the best method of rendering the hands aseptic, in which Dr. Beverley Robinson alluded to the fact that in his student days he had seen Nélaton wash all his amputation wounds with alcohol. During the past twenty-five years I have in nearly all cases washed all my amputation and other wounds with dilute alcohol, and kept them constantly wet with the same during the process of healing, and have in no case had cause to regret such a course. I also bathe my hands and immerse my instruments in pure alcohol before operating. All wounds heal readily without suppuration, inflammation, or soreness if so treated, and I do not believe that blood poisoning need be feared under such circumstances. It is important that the wound be thoroughly cleansed and kept constantly wet with the alcohol to insure the best results.

Some twenty years ago I wrote an article for the *American Practitioner* on this subject, and experience since then has only confirmed the favorable view I then entertained as to the good effects of alcohol as a surgical dressing.

L. J. Woollen, M.D.

Vevay, Ind., April, 1897.

MIDWIVES AND THE HEALTH BOARD.

To the Editor of the Medical Record:

Sir: My attention has been called to an editorial which appeared in the Medical Record in your issue of the 10th inst., entitled "Medical Practice on the East Side."

The alleged facts are apparently based upon a report made by Mr. Reynolds, superintendent of the University Settlement Society of this city. I desire to call your particular attention to that part of the article which reads as follows:

"Midwives are another class of medical attendants of inferior grade. The board of health seems not to be posted regarding their number, or else to be unwilling to give the list. As there is no system of licensing them, these women are unreliable and unworthy. Their chief hold upon the people is the smallness of their charge. The legal requirement that a certificate of recommendation from some physician be secured amounts to nothing, as such recommendations are easily obtained, and need not be preceded by an examination."

You will perceive that the author of the foregoing report unjustly criticises the board of health in assuming that the board is not informed regarding the number of midwives of the inferior grade or else is unwilling to make public the registered list. The duties of the health department seem to be clerical, so far as the same apply to midwives, as section 5 of the sanitary code provides that midwives shall be registered in the bureau of records of the health department "in a manner according to the regulations prescribed by the board of health." It is also provided by section 603 of the New York City consolidation act that a professional midwife shall keep a register of births.

Pursuant to section 5 of the sanitary code, a register is kept in the office of the register of records of the board of health, for the registration of midwives. This book is open for public inspection.

I am informed by Mr. Steinert, the attorney for the board of health, that there is no legal requirement for the practice of midwifery in this city, nor is there any law requiring a midwife to procure a "certificate of recommendation" from some physician, as stated by Mr. Reynolds. The law requires only that a midwife shall be properly registered. It seems to me very unfortunate that the board of health has no power or authority to inquire into the qualification or competency of a person who practises midwifery in the city of New York.

Repeated efforts have been made to secure the enactment of a law similar to the one now in operation in the city of Rochester in this State, and known as chapter 842 of the laws of 1895, entitled "An Act Regulating and Restraining the Practice of Midwifery in the City of Rochester, by others than legally Au-

thorized Physicians." If this or a similar law could be enacted to apply to the city of New York, the practice of midwifery, as characterized by Mr. Reynolds' report, and the abuses arising from the same would cease to exist.

GEORGE B. FOWLER, M.D.,
Health Commissioner.

THE "WATER-BORNE" THEORY OF MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the editorial in the MEDICAL RECORD for April 3d, discussing the question as to whether malaria is a water-borne disease, you say: "The burden of proof distinctly lies on those who endeavor to show that the commonly accepted theory is incorrect." As it looks to me, the burden of proof is exactly the other way. Is there anything in the form, size, vital properties, or anything else of the plasmodium of malaria that shows that it is capable of living in the air or of being conveyed in the air? Has it ever been detected in any shape or form in the atmosphere? I find one author (Manson) who has discovered that it can be carried by mosquitoes. To this extent, at least, there is proof that it is borne through the air in the bodies of its winged hosts. It is capable of being inoculated from one person to another by direct transference of blood containing the parasite. Further than this, all that is known is that it lives in the soil and water under conditions comprehensively summed up under the term undrained. If water from such sources known to be infected cannot convey it, there is no use in discussing the purely hypothetical question as to its being taken into the body through the medium of air. In other words, if it will not live when taken into the mouth with water, it will not live when taken into the mouth with air. But, further, I think that I have very good clinical proof that those who would escape malaria may do so by using only water that has been boiled. In fact, I have had this experience in my own person, when all my family were suffering from the disease and I was more exposed to night air and the like than any of them.

M. A. VEEDER, M.D.

LYONS, N. Y., April 5, 1897.

X-RAY DERMATITIS.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: I would like to add another to the twenty-two or more recorded cases of superficial burning due to the *x*-ray, showing that it is not alone through prolonged but through short exposures as well, frequently repeated, that these effects are produced. While working in Roentgen photography I have often looked through my own hand as a matter of curiosity, and as usual observed no ill effect. Recently, however, my hand was exposed more frequently—half a dozen times a day perhaps, but only for a few moments on each occasion. The result was that the skin became quite red and tender, with itching and burning pain, simulating almost exactly the effects of a sunburn: and later the pain became deeper seated and aching in character. The redness of the integument soon turned to a darker color, followed by considerable exfoliation.

I am sure that the few cases of burns that have been reported, some certainly of considerable severity, ought not unduly to prejudice against this valuable diagnostic method, but should simply put us on our guard and suggest a greater caution. Close proximity to the tube should be avoided as far as possible. In looking through the fluoroscope, the tendency is to approach the hand to be examined as close as possible to the source of the ray, and in my own case I think the part would have escaped injury had it not been held so many times almost touching the tube. In a recent issue of the *Bulletin of the Johns Hopkins Hospital*, Mr. T. C. Gilchrist, in an article on the *x*-ray and its effects upon osseous structure, reports the first case in which the radiograph has demonstrated a distinct osteoplastic periostitis, due to frequent and long-continued exposure to its influence. In this case, following the first superficial symptoms of burning, came deep-seated aching and throbbing pains, showing the deleterious effects of the ray upon the harder tissues. In my own case, too, the very positive though not very severe aching in the wrist and arm that followed and persisted for several days would seem to indicate that not only was the skin affected, but to a slight degree the deeper-seated structures also.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 17, 1897:

	Cases.	Deaths.
Tuberculosis	149	110
Typhoid fever	6	0
Scarlet fever	228	14
Cerebro-spinal meningitis	2	2
Measles	211	7
Diphtheria	238	20
Laryngeal diphtheria (croup)	10	9
Small-pox	3	0
Chicken-pox	36	0

The Humorous in Medicine.—The practice of medicine is not of its nature humorous, but even in the more or less tragic record of cases, usually completed by post-mortem examination and the handing around of specimens, the comic often finds utterance. The reports of discussions never do justice to this aspect of the meetings. Surgeon X——, for example, relates a particularly brilliant surgical escapade of his own, and insists upon the fact that the success of the operation was all that could be desired, adding, after a pause, that the patient died a few hours later. An instance is related of a man who had been fitted with a glass *à la Mule*, the movements and appearance of which were so perfect that he eked out a precarious existence after his discharge by making six-penny bets that his interlocutor could not guess which was his artificial eye. Medical students are familiar with phenomenal cardiac murmurs which are audible at some distance from the patient, and Charles Dickens has vulgarized the rattling of sonorous foreign bodies within the alimentary canal: but we have just heard of a policeman with paroxysmal tachycardia, who, during the attacks, developed a musical murmur so loud that the patient in the next bed complained of his rest being disturbed. It is hard to beat the following: A girl came to the hospital, complaining of worms, adding, in support of her diagnosis, that one had wriggled out of her nose that very morning. The physician naturally asked what had become of it, when she explained that her terror elicited a scream, and the ascaris availed itself of the opportunity to regain its domicile in the stomach via the open mouth.—*Medical Press*, January.

CATHETERISM OF THE URETERS IN THE MALE WITH THE HELP OF THE URETER CYSTOSCOPE—A REPORT OF SEVEN CASES.[1]

By WILLY MEYER, M.D.,

NEW YORK,

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

In my paper read before the section on general surgery of the New York Academy of Medicine, on November 11, 1895, entitled: "Catheterism of the Ureters in the Male and in the Female with the Help of Casper's Ureter Cystoscope,"[2] I purposely abstained from adding illustrative cases. The reason was that none of the diagnoses of renal disease in the male established by me with the help of separate collection of the secretion of each kidney, without a cutting operation, had, up to the time of reading and publishing the paper, been verified by operation or further manifestations in the course of the disease.

To speak at this date of the immense value, nay, of the necessity of performing cystoscopy and catheterism of the ureters in trying to clear up an obscure urinary disease, is rather a superfluous undertaking. The importance of the work is generally recognized. Since Kelly's method of viewing the bladder and draining the kidneys in the female has come into more general use; since special cystoscopic instruments, imported from the other side, are not needed to carry out this work, this method of cystoscopy has been more widely employed, and now seems to be resorted to by operators everywhere when treating female patients. If the same method of ballooning the bladder with air, and inspecting its interior through straight tubes introduced through the dilated urethra, could be utilized in the male, the whole matter would be very simple. But this can and will never be the case. The anatomical features of the male urethra, its limits to dilatation, the fact of its being surrounded by the prostate gland in its posterior part, will forever exclude Kelly's method from being used in the male. In very exceptional cases it may be successful. But it can never become a method that deserves recognition and recommendation. In the male it will never compete with Nitze's method. We are therefore justified in the assumption and can state the dictum: Cystoscopy and catheterism of the ureters in the male will forever be best carried out with instruments the principles of which have been laid down by Nitze.

That the problem of draining the kidneys of the male through catheters that are handled in front of the external meatus of the urethra, and introduced into the ureteral opening under the guidance of our eyes—that this problem, I say, has been actually solved is an established fact. Yet it seems there is still a doubt, yes, even a mistrust in the mind of many with reference to the feasibility of the procedure. Only a short time ago a colleague of high standing in the genito-urinary specialty wrote me, stating that he wanted to send a male patient to me in order "to test the efficiency of ureteral catheterization for diagnostic purposes."

Mr. Chairman and gentlemen, there is no longer such a thing as testing the efficiency of this procedure. Let it be generally understood that to-day the ureters of the male can be catheterized and the kidneys drained without a previous cutting operation. But the method has its limitations, as cystoscopy has when carried out with Nitze's instrument. The method will and must be a failure whenever the three cardinal conditions which permit cystoscopy cannot be fulfilled, viz.:

1. If the calibre of the urethra is not sufficiently large to allow the passing of the instrument.
2. If the bladder has not a capacity of at least four or five ounces.
3. If the fluid within the bladder cannot be made and kept transparent.[1]

Now and then these cardinal conditions are fulfilled, and yet the method proves unsuccessful owing to the fact that the mouths of the ureters cannot be found, or that they cannot be approached, or that they are too small to allow the entrance of even the finest of catheters.[2] Sometimes the catheter has well entered the ureter, but it soon becomes plugged by descending blood or pus.

To prove by illustrative cases that catheterism of the ureters is a feasible procedure in the male, and can be carried out even in patients with hypertrophy of the prostate, and that therewith our capabilities of distinctly diagnosing an obscure renal disease in the male are at last also very greatly enhanced, is the object of this paper.

Case I.—F. M——, twenty-eight years of age, married, experienced a sudden, sharp pain, a little above and to the left of the symphysis, about eight months ago. At the same time micturition became very frequent (sometimes every ten minutes), but was not painful; the urine never contained blood. In spite of proper medical treatment the pain remained persistent, so that the patient had to quit work. After a few weeks he was again able to attend to business in comparative comfort. He had almost considered himself cured when, five weeks ago, the former pain returned in the same place as before, and with equal severity. Soon after it also appeared on the opposite side. One month before there had been another obstinate attack of frequent micturition. History with reference to tuberculosis negative. Specific infection eleven years ago; as far as known no secondary symptoms. Urine macroscopically clear; left epididymis slightly painful to the touch and infiltrated; prostate normal.

Examination of bladder urine:[3] Acid; specific gravity, 1.026. Amount of urea, 0.023 in 1 c.c. Chlorides (approximate), 0.01 in 1 c.c. Faintest trace of albumin.

[1] See for particulars the author "On Cystoscopy," in "A System of Genito-Urinary Diseases, Syphilology, and Dermatology," edited by Prince A. Morrow, vol. i., pp. 455 and 456.

[2] I lately had such a case in the female; see later on.

[3] All examinations of urine in the cases here reported have been made at the laboratory of Dr. Fred. E. Sondern, of New York City.

Microscopic examination:[1] A few cells of blood and pus: fair amount of mucus; few hyaline casts: many cells of the superficial layer of the bladder: few cells of the renal pelvis; marked deposit of phosphate-of-calcium crystals.

Diagnosis, based on the result of the urinary analysis: Slight renal hyperæmia, with slight irritation of the pelvis. Fairly marked vesical irritation with congestion; suspicion of stone.

Question: Does the amount of crystalline deposit descend from one kidney only, or from both? With other words: Is the clinical probable diagnosis of gravel or stone in the left kidney corroborated by actual facts?

October 25, 1895, cystoscopy and catheterism of the ureters with Casper's ureter cystoscope at my office. (This is the first case in which I ever used the instrument.) Cocaine anæsthesia. Bladder normal; a few disseminated spots injected, especially so the trigonum. Mouth of left ureter is first approached; catheter enters at first attempt without difficulty and without pain. It is pushed forward for about one and one-half inches. Then the tiny mandrel is withdrawn. After a few seconds urine begins to flow, drop by drop, first at intervals, then almost continuously; it is slightly turbid. To comfort the patient, the catheter is lifted out of the groove of the instrument with the help of the straight metal mandrel and the cystoscope is withdrawn from the bladder.[2] The kidney drained rather fast: 10 c.c. were collected in a small tube, marked "Left," in twelve minutes (I had ordered the patient to take two cups of coffee for his breakfast, and a few tumblers of water before coming to my office). After this amount had been gathered the catheter was pulled out of the left ureter, the cystoscope introduced for a second time into the bladder, and the manœuvre repeated at the mouth of the right ureter with the same ease and rapidity. The discharge from the right kidney was still more copious. Almost without cessation 11 c.c. flowed off in eight minutes. During this time the cystoscope was left *in situ;* then it was removed with the catheter. Both specimens thus obtained were submitted to Dr. Sondern for analysis. I cite from his report specially interesting points:

Reaction, L. and R., acid. Specific gravity, L., 1.011; R., 1.013 (at 15° C.). Amount of urea in 1 c.c., L., 0.015; R., 0.017. Chlorides (approximate), L., 0.005; R., 0.0075 in 1 c.c. Albumin, L., present: amount according to Esbach's test (approximate), 0.25 per cent. by weight; R., negative.

Microscopic examination: Blood, L., fair amount: R., few cells only.[4] Pus, L., few cells; R., none. Casts, L., few hyaline and epithelial-studded casts: R., none. Bacteria, no tubercle bacilli, no gonococci, on either side. Epithelium, L., many cells of ureter and renal pelvis; R., few cells of ureter and renal pelvis. Crystalline and amorphous deposit, L., considerable uric-acid crystals; R., some uric-acid crystals.

Diagnosis, based upon this examination: R. kidney, parenchyma normal; moderate excess of uric-acid crystals, with possible slight irritation of the renal pelvis. L. kidney, hyperæmia of the parenchyma with catarrh of the renal pelvis, both probably due to the presence of a stone. Bladder, marked vesical irritation and congestion.

As the patient could not leave his work at that time and did not suffer materially, an operation on the left kidney was deemed inadvisable, but proper medical treatment was begun. The man did well for the following three weeks, when he went back to his former home in Germany. I have not heard from him since.

Case II.—M. L. Y——, thirty-four years old, seen by me in consultation with Dr. A. H. Fridenberg, of this city, December 6, 1895. Patient had scarlet fever in his early youth with following kidney trouble, which lasted several years but was ultimately cured. In 1884, gonorrhœa; discharge for several months; no complications. In 1888, urine contained pus and a corresponding amount of albumin; no casts; amount, two quarts per diem; specific gravity, 1.016. In the fall of the same year the patient was suddenly taken sick with a chill and fever, and general malaise. During this time the urine appeared much clearer. With decreasing temperature the turbidity returned. Afterward pus was permanently present, about one-tenth volume. In April, 1890, the patient, then being in the South, again had a severe attack; three consecutive chills with following high temperature; he had to stay in bed for a week; quinine did not relieve his condition. Once he had also moderate transient pain in the left lumbar region. Patient lost in weight. November, 1891, third attack with a temperature of 106° F.; one year later a fourth and last one, much milder in character. After that the patient was much better, but the urine remained turbid. He has seen many physicians in this city and in the South; so far a definite diagnosis could not be made.

Status præsens: Micturates three or four times a day, nights not at all; slight tenesmus. Prostate somewhat enlarged, soft: on massage per rectum, no discharge from urethra. Kidneys not palpable; no pain on pressure in either lumbar region. Urine turbid, acid, odor slightly offensive; amount, 1,520 c.c. in twenty-four hours.

Urinary analysis, December 7, 1895: Specific gravity, 1.017; amount of urea, 30.6 in twenty-four hours; chlorides (approximate), 15.3; trace of albumin.

Microscopic examination: Moderate amount of pus, forming the bulk of the deposit; also a few tubular plugs of the same; some hyaline casts; no tubercle bacilli; no gonococci: numerous cells of the superficial and middle layers of the bladder; few cells from the renal pelvis; rather large amount of oxalate of lime and uric acid

Diagnosis based on urinary examination: Catarrh of the renal pelvis, probably a very moderate pyelitis and the cause of a very moderate renal hyperæmia: moderate chronic cystitis: excessive crystalline deposit, allowing suspicion of renal stone.

December 11, 1897: Cystoscopy and catheterism of the ureters with Casper's instrument, under cocaine, in the presence of Dr. Fridenberg: bladder contains six ounces of sterilized two-per-cent. boric-acid solution. It shows the symptoms of some chronic cystitis. The manœuvre of engaging the catheter in the ureteral mouth is again easy and successful at first attempt; the catheter is introduced about one and one-half inches. Kidneys work rapidly: patient had taken more fluid than usual before coming to my office, according to my orders.

Amount of urine passed: L., 6 c.c. in 19 minutes; R., 10 c.c. in 8 minutes. Color, L., pale; R., light yellow. Odor, L., offensive; R., characteristic. Reaction, L. and R., acid. Specific gravity, L., 1.008 at 15° C.; R., 1.015 at 15° C. Amount of urea: L., 0.009 in 1 c.c.: R., 0.016 in 1 c.c. Chlorides (approximate), L., 0.005 in 1 c.c.: R., 0.01 in 1 c.c. Albumin, L., good trace: R., trace.

Microscopic examination: Blood, L. and R., small amount: pus, L., very small amount: R., none. Mu-

[1] The sediment of the specimens was in each case obtained by centrifuging the urine for eight minutes at twenty-five hundred revolutions.

[2] For particulars see author, *Am. Medical Journal.*

[3] L., left; R., right.

[4] The few cells of blood, or the small or fair amount of the same (nearly all the specimens of renal urine collected through the ureter catheter, are due to the slight mechanical lesion of the tender ureteral mucous membrane by the instrument. For this reason I lately have not saved the first ten or twelve drops which escape through the catheter. They often appeared brown, or even red. We may assume that blood which appears later on, especially in a larger quantity descends from the kidney

cus, L., small amount; R., none. Casts, L., some hyaline and epithelial-studded casts; R., none. Bacteria, L., no tubercle bacilli, no gonococci; many pyogenic cocci; R., none. Epithelium, L., some cells from ureter, numerous from renal pelvis; R., some cells from ureter only. Crystalline and amorphous deposits, L., some uric acid and oxalate of lime; R., none.

Extract from remarks made by Dr. Sondern: "Left kidney: The lower specific gravity and diminished amount of urea and chlorides excreted, with a little more albumin than the blood present would account for; the presence of hyaline and epithelial-studded casts, a little pus and mucus, and epithelial cells from the renal pelvis, with an offensive odor, would indicate a very slight pyelitis with fermentation in the pelvis, and some nephritis, chronic in character. The affection of the parenchyma seems out of proportion to the slight inflammatory lesion of the pelvis.

"Right kidney: The relatively normal excretion of urea and chlorides, no more albumin than the blood present would account for, and the absence of renal elements on microscopic examination, would exclude any renal lesion. The presence of the small amount of blood and epithelial cells of the ureter is due to the introduction of the catheter."

Diagnosis, based on the urinary examination: Left kidney, some chronic nephritis with very slight pyelitis. Etiology, probably stone. Right kidney, normal.

The result of this examination speaks for itself. After seven years of existence, an obscure urinary trouble, with an almost entire absence of clinical symptoms for the last three years, is clearly diagnosed beyond doubt and dispute.

So far the patient has not submitted to an operation, as his subjective condition is rather good. I shall not fail to report at a future time whether this strictly laboratory diagnosis has been corroborated by direct inspection.

Case III.—B. B——, fifty years old, seen by me in consultation with Dr. Fred. E. Sondern. Previous history negative. In October, 1894, he had a very acute attack of pain in the region of the right kidney, radiating into the right testicle and the penis; tenesmus and frequent desire to urinate; nausea and vomiting. Duration three hours.

Analysis of urine (first passed after attack): Acid: 1.025; some albumin, but not more than the blood present accounts for.

Microscopic examination: Small amount of blood, some groups of epithelial cells, from the renal pelvis presumably; large quantity of uric acid in crystals. Also amorphous urates, some bladder cells. No stone was passed.

During the following two months the patient had several attacks of right renal colic; pain was usually greatest at a point midway between the umbilicus and the anterior superior spine, radiating from there into the penis and scrotum. Duration varied from one-half an hour to four hours. In the early part of 1895 there were frequent, at times daily attacks of pain more or less severe, radiating downward from the point above stated.

March 15th, a very severe colic, lasting three hours. Urine: 1.015, albumin, considerable blood, some hyaline casts, no crystalline deposit. From the end of April to October no symptoms referred to the genito-urinary tract. Then again there was constant pain in the region previously mentioned. Urine, 1.020; chemically and microscopically negative. For the following month the patient was under the care of a neurologist, at the suggestion of a surgeon whom the patient had consulted. Both gentlemen looking upon the condition as a neurosis, the previously ordered and strictly followed medication and diet were discarded.

December 14, 1895: Severe renal colic on right side; duration four hours. Urine, 1.029, albumin and considerable blood, some hyaline casts, epithelial cells of the renal pelvis and bladder, large quantity of uric-acid crystals and amorphous urates. Subsequently much pain and burning referred to the glans penis for some days. Several days after the last attack a small particle which consisted of mucus was found in the urine, in which there were also some blood and pus, numerous epithelial shreds, presumably from the renal pelvis, numerous hyaline casts, and crystals of uric acid.

First few days of 1896, colics almost daily. January 4, 1896, patient came with Dr. Sondern to my office for ureter catheterism. Cocaine anæsthesia; six ounces of a sterile two-per-cent. boric-acid solution were injected into the bladder. Cystoscopy showed marked uniform hypertrophy of the prostate; mouths of ureters easily approached. The right side, being the one presumably diseased, was catheterized first. Eight cubic centimetres were collected within twenty minutes, during which time the cystoscope had been left *in situ*. Then the ureter catheter, which had been pushed up for about two inches, was removed from the right side, and a new one introduced through the channel of the instrument, which had been left in place, into the bladder. After having entered the left ureter, I wanted to save the patient the little annoyance of the further presence of the cystocope, and, contrary to my rule, which is to leave the tip of the catheter within the lower three inches of the ureter, I pushed the catheter quickly up toward the kidney for about twenty centimetres, in order to be sure that it would not slip out of the ureter back into the bladder when pulling out the cystoscope. I then liberated the catheter and removed the cystoscope. Now I pulled out the mandrel. No urine escaped. I pulled and pushed the catheter, and aspirated with a powerful syringe; no urine. I pulled the eye of the catheter down into the lower third of the ureter, aspirated, and waited; no urine. I then injected a few drops of a sterilized saline solution in order to clean the tiny lumen of the catheter, thinking it might have become clogged; as I had expected, a vehement renal colic was the result; but not one drop of urine appeared. I had to remove the catheter entirely, and then learned to my disgust that the tip of the latter had bent a little at the eye, and that within it a small shred of coagulated blood had been caught. In spite of a perfectly successful catheterism of both ureters, the whole procedure was thus, in part at least, a failure. I had the urine of the right kidney only (the probably diseased one), and none from the left for comparison. The patient's condition did not admit of my again introducing the cystoscope to catheterize the left ureter for the second time. I regret to-day that I did not at once withdraw the tip of the catheter from the ureter back into the bladder, wash it through with the syringe attached to the outer funnel-shaped end, and then reintroduce it into the ureter. With my present experience I should certainly have done so. Of course, for this purpose I should not have removed the cystoscope from the urethra and bladder. It is certainly of great importance not to withdraw this instrument until the urine has begun to drain through the catheter. With the cystoscope still within the bladder, one generally has no difficulty in pulling the catheter back into the vesical viscus, cleaning it there, and then reintroducing it into the ureteral mouth.[1]

[1] On January 4, 1897, when catheterizing the ureters of a lady who evidently had a pyonephrosis, I pulled the catheter out of the ureter three times and then washed it through, its tip being within the bladder. When I had catheterized the ureter for the fourth time urine at last began to flow. I could collect fifteen cubic centimetres in ten minutes. Examination was in every way successful.

Analysis of urine from right kidney: Acid; 1.020; albumin, trace; amount of urea, 0.02 in 1 c.c.

Microscopic examination: Some blood, probably due to the introduction of the catheter; few pus cells, an excess of mucus, numerous groups of epithelial cells from the renal pelvis; exceedingly large amount of uric acid in small crystals and also large aggregations, apparently broken.

After the catheterism of the ureters the patient claimed to be much better. Besides being put on large quantities of water and a general régime, he was given urotropine, fifteen grains three times a day. In a subsequent consultation held with two colleagues, it was, therefore, decided to keep the patient under observation and medical treatment. So far, he has been free from further attacks of renal colic.

Case IV.—J. S——, twenty-eight years, of Rochester, came under my care through the courtesy of Dr. S. L. Elsner, of that city, January 31, 1896.

Four years ago patient noticed blood in the urine and experienced great pain in his left lumbar region; had to stay in bed for three days. Hæmaturia ceased after a few weeks; pain, however, has persisted ever since; is much worse since the last six weeks. Urinates at times three and four times a day; now and then very frequently, every hour or even half-hour. He then has pain in the glans and at the neck of the bladder. Bladder large, holds easily three pints of fluid. History of tuberculosis and gonorrhœa negative. Chancre twelve years ago, but no secondary or tertiary symptoms.

Objective examination negative. Urinary analysis, February 3d: Acid; specific gravity, 1.024; marked deposit; amount of urea, 0.026 in 1 c.c.; chlorides (approximate), 0.01 in 1 c.c.; trace of albumin.

Microscopic examination: Moderate amount of blood; very moderate amount of pus, few tubular plugs of the same; moderate amount of mucus; few hyaline casts; no tubercle bacilli, no gonococci; numerous cells of the superficial layer of the bladder; some of the renal pelvis; exceedingly large amount of uric acid and oxalate of calcium, forming the greater bulk of a considerable deposit.

Extract from remarks made by Dr. Sondern, accompanying the report: "The exceedingly heavy deposit of oxalate of calcium and uric acid are most worthy of note, allowing the strong suspicion of renal stone. I believe the amount of gravel found in the bottom of each of the two bottles sent, if continually excreted, would alone be sufficient to cause the lesions above stated, and would account for the blood present."

Diagnosis based on urinary analysis: Very moderate pyelitis with but slight secondary affection of the renal parenchyma; strong suspicion of renal stone; moderate secondary chronic cystitis.

February 7th, cystoscopy: Symptoms of moderate chronic cystitis; no calculus; no ulcer; mouths of ureters injected, projecting considerably into the bladder on either side.

February 12th, catheterism of ureters (Casper's instrument), 650 c.c. of fluid in bladder. Manipulation not so easy as in the previous cases, in which 150 to 200 c.c. of boric-acid solution had been injected. Discharge through ureter catheter as noted during the examination:[1] L. kidney drains 12–13 drops every 20–34 seconds—in all, 10 c.c. in 9 minutes; R., 16–32 drops every 3–5 seconds—in all 12 c.c. in 5 minutes.

Analysis: Odor, R., characteristic, not offensive; L., possibly slightly offensive. Reaction, R. and L., acid. Specific gravity, R. and L., 1.004 at 19° C. Amount of urea, R., 0.009 in 1 c.c.; L., 0.008 in 1 c.c. Chlorides (approximate), R. and L., 0.0025 in 1 c.c. Albumin, R., negative; L., trace.

[1] Patient had taken much fluid before coming for the examination.

Microscopic examination: Blood, R., few cells only; L., small amount. Pus, R., none; L., very small amount. Mucus, R., none. L., small amount. Casts, R., none; L., few hyaline casts only. Bacteria, R. and L., no tubercle bacilli. Epithelium, R., some cells of ureter only; L., some cells of the ureter and some of the renal pelvis. Crystalline and amorphous deposit, R., very few uric-acid crystals; L., considerable uric-acid crystals.

Extract from remarks made by Dr. Sondern: "Right kidney: As the specimen shows no albumin, an absence of renal elements microscopically, and the very few blood cells or epithelial cells of the ureter being accounted for by the introduction of the catheter, a renal lesion on that side can be excluded.

"Left kidney: There is a slight diminution in the relative excretion of urea, more so when one considers the diminution in the amount of urine voided in a given time, a trace of albumin and few hyaline casts, the whole indicating a moderate chronic nephritis; together with few pus cells, few epithelial cells of the renal pelvis, some mucus, a possibly faintly offensive odor, but no tubular plugs of pus, which would indicate a catarrh of the renal pelvis. There is beyond doubt a much larger quantity of uric acid voided by the left kidney than by the right; the whole amount does not, however, nearly approach that found in the specimen of February 3, 1896. This may be accounted for by the dilution of the urine by ingestion of water prior to examination, as the specific gravity of the above is 1.004, compared with 1.024 of the previous examination. There must, however, remain the suspicion of uric-acid stone in the left kidney. It is also possible that such a condition as above described might be caused by a long-continued passage of large amounts of uric-acid gravel."

Provided all urine was collected from each kidney in the time specified, the proportion of work done would be as follows: Right kidney, seventy per cent.; left kidney, thirty per cent.

Diagnosis, based on urinary analysis: Right kidney normal; left kidney, very moderate chronic nephritis with catarrh of the renal pelvis; suspicion of renal stone, or possibly only gravel.

In view of this result, I advised the patient not to undergo an operation right away, but, in spite of having been under medical care for a number of years, to once more try a strict régime for lithæmia. This was faithfully done at the patient's home, under Dr. Elsner's supervision. Six weeks later the patient came back to New York, ready to submit to whatever operation might be found necessary. Internal medication and dieting had not relieved his suffering. On the first of June, at the German Hospital, I cut down on the patient's left kidney by the longitudinal incision; the pelvis and upper portion of the ureter were easily exposed. There was no palpable concretion. Then the kidney was bluntly freed from its surroundings (a manœuvre which proved somewhat tedious on account of manifold adhesions, especially to the lower surface of the diaphragm) and pulled in front of the twelfth rib. The organ was large and hyperæmic, more curved around the hilus than is usually seen, as if enclosed by too tight a capsula propria. Careful palpation of the pelvis and parenchyma, also multiple needling, did not prove the presence of a concretion.

Having in mind the negative operative result of Case VI. (May 15th), I did not make the section-cut of the kidney, but opened the rather small pelvis and probed upward into all the renal calyces, and down toward the bladder. There was no stone. The wound of the pelvis was at once closed by a few catgut sutures which avoided the mucosa. Suspecting that the rather tight capsule might possibly play a rôle as an etiological factor in the clinical symptoms, I

split it at its convexity, stripped it off the kidney anteriorly and posteriorly, and resected it down to the pelvis. Then the kidney was replaced, the subdiaphragmatic space drained by a gauze strip (for forty-eight hours), and the rest of the wound closed by sutures. The patient made a good recovery. During the first few days his urine was bloody, but it soon cleared up. An irregular temperature which suddenly appeared on the twelfth day after operation was broken by quinine. A report received from Dr. Elsner in reply to my inquiry of April 10th states: "The patient has gained ten pounds; he looks well, but claims to have considerable pain in the left side of the epigastrium, and in the back in the region of the fixed kidney. This pain is more marked upon change of posture, and on deep inspiration. He admits being better for the operation. His urine still contains a little pus and débris, and becomes alkaline almost immediately after voiding."

The case strikingly demonstrates, as does also Case VI., that crystalline deposits found in the urine may be unequally produced in the kidneys. That renal concretions and gravel are often found unilaterally cannot be explained in the same way. We know that the nucleus of a calculus of the kidney, even one of smallest size, has an organic structure as its basis. With it the uric-acid salts are very strongly united. Around this centre the salts dissolved in the urine rapidly deposit, making the stone. It is different with the uric-acid crystals, which are contained free within the urine.

Of course, the conclusion drawn from this irregular discharge of crystalline deposit in the renal urine found by catheterism of the ureters is open to the objection that the suspected renal stone, although not found during the operation, may nevertheless have been present somewhere in the organ.

Case V.—M. P——, forty-four years old, sent to me through the kindness of the late Dr. Charles Milne, of New York, on November 15, 1895. Had gonorrhœa twice at the age of nineteen and twenty-three respectively. Ten years ago he sustained an injury to the perineum followed by swelling and abscess formation in the right testicle. During the last year there has been slowly increasing frequency of micturition, polyuria. March, 1895, painless hæmaturia, twice on same day in succession: blood thoroughly mixed with urine; no tenesmus. After that urine clear. The following night, sudden call for micturition; passing impossible; then a discharge of a larger amount of pure blood, once only. Two weeks later another single marked attack of hæmaturia beginning with right lumbar pain. In May a small quantity of blood passed for the third time; between that time and November, two more slight attacks.

Status præsens: Micturates four or five times a day; at night once or twice, without tenesmus. Now and then there is pain in the glans. Occasionally he finds small pieces of coagulated blood in the chamber; the last drops are never colored. Of late he has frequently had colicky pain in the region of the right kidney, radiating down to the right testicle; he has lost twenty pounds during the last six months. One brother died in Florida of phthisis (?); otherwise history negative. No specific infection. Palpation of kidneys negative; prostate slightly enlarged, painful to the touch.

Urinary analysis: Amount of urine passed in twenty-four hours, 1,920 c.c.; reaction acid; specific gravity, 1.015; marked deposit. Amount of urea in twenty-four hours, 26.88. Chlorides (approximate), 9.6 in twenty-four hours. Albumin present, 0.1 per cent. by weight.

Microscopic examination: No blood; considerable pus, also tubular plugs; considerable mucus; few hyaline and epithelial-studded casts; no tubercle bacilli, no gonococci; many cells of the superficial and middle layers of the bladder and of the renal pelvis; some indican.

Abstract of remarks made by Dr. Sondern: "The presence of the albumin, hyaline and epithelial-studded casts, with a practically normal excretion of urea, pus and tubular plugs of the same, and many epithelial cells of the renal pelvis, would indicate a pyelonephritis, the affection of the parenchyma being but moderately marked. The normal excretion of urea is surprising, and would most probably indicate that only one kidney is affected. The large number of bladder cells of the superficial and middle layers, much mucus, pus, etc., would indicate a rather severe chronic cystitis with probably small ulcerating areas. As to the etiology, repeated search failed to show any tubercle bacilli or gonococci, and there are no evidences of stone. The specimen gives no clew as to which lesion, that of the kidney or that of the bladder, is the original and which the secondary."

Diagnosis, based on urinary examination: Chronic pyelo-nephritis (the affection of the parenchyma being but moderately marked); normal excretion of urea, indicating probably that but one kidney is affected. Rather severe chronic cystitis with probably small ulcerating areas. Etiology obscure.

November 21, cystoscopy: Prostate enlarged, easily bleeding; chronic cystitis; left ureteral mouth normal, presents a narrow slit, expels apparently transparent urine; above and inward of the same, toward the fundus, is an irregularly shaped small ulceration. Right ureteral opening wide, gaping, highly injected; its immediate surroundings markedly hyperæmic; jets of urine here purulent.

On the ground of this cystoscopic result I asked Dr. Sondern to search once more for tubercle bacilli. I had found in my experience with the cystoscope that one mouth of ureter healthy, the other and its immediate neighborhood inflamed or ulcerated, generally means: "Descending (unilateral) renal tuberculosis." The search for tubercle bacilli was taken up carefully, but with negative result. The report of November 27th reads: "In a sediment obtained by centrifuge and composed of elements as previously reported, I could not find any tubercle bacilli after repeated search over specimens prepared and stained by different methods." That of December 5th states: "In many specimens, composed of elements the same as previously reported and stained by various methods, I am still unable to find any tubercle bacilli."

The patient, dissatisfied at not getting a definite answer at once, then left my observation, and I lost track of him for a time, he having declined catheterism of the ureters. On February 21, 1896, he returned to my office, ready to submit to any further examination necessary definitely to diagnose the lesion. He had had a great deal of renal pain of late and was very despondent. The question to be decided was: Provided the trouble is tuberculosis of the right kidney, is its fellow also involved, and, if so, how far?

February 21, 1896, catheterism of the ureters (Casper's instrument) under cocaine: four and one-half ounces in bladder; manipulation easy. Amount of urine passed, L., 12 c.c. in 5 minutes, 150 drops without interruption; R., 10 c.c., in 9 minutes, 36–41 drops in one stretch; interval, 3 minutes.

Analysis: Reaction, L., faintly acid; R., alkaline. Specific gravity, L., 1.007 at 16° C.; R., 1.003 at 16° C. Deposit, L., slight; R., more marked. Amount of urea, L., 0.01 in 1 c.c.; R., 0.005 in 1 c.c. Chlorides (approximate), L., 0.005 in 1 c.c.; R., 0.0025 in 1 c.c. Albumin: L., faint trace, fully accounted for by the small amount of blood present; R., present, 0.5 per cent. by weight.

Microscopic examination: Blood, L., small amount; R., very small amount. Pus, L., none; R., considerable, forming bulk of deposit; also tubular plugs of same. Mucus, L., none; R., small amount. Casts, L., none; R., some hyaline and few granular casts; also pus casts as above. Bacteria, L., no tubercle bacilli; R., few single bacilli, presumably tubercle, no gonococci. Epithelium, L., some groups of cells from the ureter only; R., some cells from the ureter; numerous groups from the renal pelvis. Crystalline and amorphous deposit, L. and R., very few crystals of uric acid.

Abstract of remarks: "Left kidney: The specimen derived from the left kidney by the ureter catheter shows absolutely nothing abnormal, either chemically or microscopically. The presence of a little blood and the epithelial cells of the ureter being accounted for by the introduction of the instrument; the little albumin is fully accounted for by the blood.

"Right kidney: The excretion of less urea and chlorides than from the left kidney, the presence of albumin and hyaline and few granular casts, together with considerable pus, tubular plugs of the same, and epithelial cells of the renal pelvis, would indicate a rather marked chronic pyelo-nephritis. The small amount of blood, a little less than on the other side, and the epithelial cells of the ureter are probably due to the introduction of the instrument.

"As to the etiology: A few single bacilli were found, generally only one or two on each specimen made, which I take to be tubercle bacilli. I am always very sceptical in pronouncing a result on any single organism, but the fact that there were several, considering all the slides gone over, I do not hesitate to state that the process is presumably tuberculous. Much time was spent without avail in the endeavor to find the characteristic groups. The proportion of work done by each kidney, as estimated by the excretion of urea in a given time, provided all urine from each kidney was collected during the time stated, is as follows: Right kidney, twenty per cent.; left kidney, eighty per cent."

Diagnosis: Left kidney normal, no tubercle bacilli; right kidney, a fairly marked chronic pyelo-nephritis, presumably tuberculous.

In view of these facts, the condition was explained to the patient and his family, and an operation on the right kidney, nephrectomy if necessary, advised, and that as soon as possible. As far as I know, the operation has not yet been performed.

Case VI.—George McL——, M.D., forty-four years old, first seen by me on February 27, 1896. In 1887, when riding horseback, the patient sustained an injury to the left testicle, which was followed by traumatic epididymitis. In 1893, when in London, he had left renal colic, lasting four days and a half; hæmaturia; left testicle again became inflamed; extirpation. In the fall of 1894, after an extensive trip on a train, again pain; two days later, passage of a uric-acid stone, about one-half inch long and one-sixth inch thick; he felt much better afterward. Six months ago, moderate pain in region of left ureter; no more marked attack since then; almost constant, heavy, dull ache in left lumbar region. For the last two years the patient is also conscious of a slight pain over the right kidney. At present, the patient does laboratory work in New York; he has found in his urine casts and a large quantity of uric acid with some pus; he has always taken a great deal of albuminoids, about two-thirds of his nourishment consisting of meat.

Status præsens: Stout, short man; nothing palpable in region of kidneys; prostate normal; patient worries a great deal over his trouble, which has lately prevented him from attending to his practice. With a view of determining which kidney most probably contained the suspected stone, I advised catheterism of the ureters. At that time the patient had to go home; he returned early in May, very despondent on account of the continuous, unabated trouble.

Urinary analysis, May 4th, revealed the following status: Amount of urine passed in twenty-four hours, 1260 c.c. Reaction, acid. Specific gravity, 1.025 at 15° C. Amount of urea in twenty-four hours, 35.28 grams; chlorides (approximate), 12.6 grams. Phosphates (approximate), some excess. Albumin, trace.

Microscopic examination: No blood. Very moderate amount of pus, also few tubular plugs of the same; small amount of mucus; some hyaline casts; no tubercle bacilli, no gonococci; some groups of cells from the renal pelvis, also numerous cells of the superficial layer of the bladder; very little uric acid.

Diagnosis based on this examination: Slight pyelitis with a moderate secondary renal hyperæmia; moderate secondary cystitis. Etiology, possibly renal stone.

Catheterism of ureters with Casper's instrument, May 6, 1896, under cocaine; procedure easy.

Amount of urine passed by right kidney 19 c.c. in 10 minutes; by left kidney, 15 c.c. in 10 minutes. (Patient had taken a great deal of fluid before examination as per my orders.) Reaction, R. and L., acid. Specific gravity, R., 1.003; L., 1.004, at 15° C., Westphal's balance. Amount of urea, R., 0.006 in 1 c.c.; L., 0.007 in 1 c.c. Chlorides (approximate), 0.0025 in 1 c.c. from either side. Albumin, R., trace; L., negative.

Microscopic examination: Blood, R., small amount; L., none. Pus, R., moderate amount, and few tubular plugs of same; L., none. Mucus, R., small amount; L., none. Casts, R., few hyaline casts only; L., none. Bacteria, no tubercle bacilli, no gonococci on either side. Epithelium, R., numerous cells from the ureter; also some groups from the renal pelvis; L., some cells from the ureter only. Crystalline and amorphous deposit, R., small amount of uric acid; L., none.

Extract from remarks: "Specimen obtained from the left kidney: The absence of albumin and all renal elements, no pus, etc., would allow the conclusion that this kidney and its pelvis are normal. There is no blood in this specimen, and the epithelial cells of the ureter are the result of the introduction of the catheter. It may be of interest to note that there is no crystalline deposit from this kidney.

"Specimen obtained from the right kidney: The small amount of albumin, some pus, and a few tubular plugs of the same, little mucus, few hyaline casts, and some groups of epithelial cells from the renal pelvis, together with a polyuria, and at the same time normal relative excretion of urea and chlorides, would indicate a moderate pyelitis, with but slight secondary hyperæmia of the parenchyma.

"As to the etiology, the fact that there is some uric acid in the deposit obtained from the right kidney and no crystalline deposit from the left kidney would allow a strong suspicion that the lesions above mentioned are the result of uric-acid stone or gravel."

Diagnosis, based on analysis of separately collected urine: Left kidney, normal; right kidney, moderate pyelitis, with but slight secondary hpyeræmia of the parenchyma. Etiology, justified suspicion of uric-acid stone or gravel.

With such a vague diagnosis in hand, I was naturally opposed to an operation. But the patient wanted relief at all hazards; he was very much depressed, even thought and spoke of committing suicide. He pressed for operation and asked me to perform the same. I yielded, because I thought an operation might, perhaps, reveal the presence of a calculus, if not in the pelvis then in the parenchyma; and under aseptic precautions the interference is, furthermore, void of danger.

Before proceeding I had to promise the doctor to

exhaust all the means at my disposal to find the suspected concretion in his kidney. For the same purpose he, personally, had made arrangements with Dr. William James Morton, professor of Electro-therapeutics at the Post-Graduate School, to take an *x*-ray picture of his kidney when exposed, and I had to bind myself to make the section cut of the kidney, if the *x*-rays, palpation, and needling should fail to reveal the presence of a stone. On May 15th, I exposed the right kidney by Simon's incision at the Post-Graduate Hospital. A palpable concretion could not be detected. To bring the kidney in front of the twelfth rib, a transverse incision, parallel to this rib, had to be added. There were some quite firm adhesions between the kidney and its fat capsule: they were bluntly divided. The organ when before us for inspection and palpation appeared normal throughout; there was no palpable resistance anywhere within its pelvis nor in the parenchyma, that pointed to the presence of a calculus.

According to his promise, Dr. Morton now proceeded to take the radiograph. For this purpose the kidney was surrounded by a compress of sterile gauze and the sensitive plate wrapped in two sterile towels. Then the assistant took the plate and pushed its border into the transverse wound, while I, gently fixating the kidney with the second and third fingers of both hands a little below its pelvis, tried to steady the organ as much as possible. By taking special care to keep the patient well narcotized, an exposure of nine minutes to the rays sufficed, and Dr. Morton, within ten further minutes, developed a very good negative of the kidney. It presented very beautifully the entire kidney except its pelvis (which had been shadowed by one border of the wound) in the shape of a uniformly white area. Comparing this negative with others, which Dr. Morton had taken with the *x*-rays from cadaver-kidneys containing larger and smaller calculi, it seemed evident that a stone of even moderate size was not present in the parenchyma. But our experience with the *x*-rays in this respect is of rather recent date and limited. Furthermore, I had faithfully promised to proceed in my search. After an intermission of twenty minutes, I therefore continued the operation, rather unwillingly. Following my directions, the house surgeon, Dr. Chas. L. Ogden, now took hold of the organ's pedicle. He compressed the renal artery and vein between the pulpæ of the second and third fingers of both hands, while I with two rapid incisions divided the organ from its convexity down into the pelvis, thus splitting it into two equal halves (section cut). The doctor did his part of the work so thoroughly and cleverly that the operation was almost bloodless, and we had a full view of the pelvis and pyramids, and could probe the calyces in all directions. There was no stone. The doctor continued his compression a few moments longer, until four deep catgut sutures and five more superficial ones, all traversing the parenchyma, had brought into apposition the two halves of the kidney. Now the assistant's fingers were removed from the renal vessels. The slight hemorrhage from the stitch channels and from the wound at the convexity was easily controlled by a short compression. The kidney was replaced, the wound partially drained by gauze, partially closed by sutures.[1]

The doctor's recovery was uninterrupted. Of course, at first the feeling that the stone had not been found created some worry and more mental depression. However, the absence of pain during his stay at the hospital, and the rapidly closing wound cheered him up and made him forget that he had in vain gone through all the phases of this complicated operation. On July 6th he left the city, with the wound almost closed. He emptied his bladder every two or three hours: the urine showed slight turbidity. The latter was due to some muco-pus, which evidently still came down from the right kidney. As the doctor advised me by letter, under date of November 3, 1896, this discharge was still present, intermittently; the former pain had very much improved. There was evidently an exacerbation of that moderate right pyelitis which I had found by ureter catheterism before the operation. During the winter months the patient was in southern California. About his present condition I cannot state anything, as I have not yet received an answer to my letter of inquiry, sent a few weeks ago. Excluding, for a moment, the possibility that a stone within the parenchyma of the right kidney had not been found during the rather thorough operation of May 15th, this case seems to teach, as also does Case IV., that a microscopically crystalline deposit in the urine can descend from one kidney alone, and thus enter the bladder urine. This finding struck me as probably something new. Being unable to find in the current literature any remarks bearing upon it, I asked Dr. Howard A. Kelly, of Baltimore, regarding his experience in this respect. On April 15th, I received his answer, from which I extract, with the doctor's kind permission:

"Baltimore, April 13, 1897.

"Dear Dr. Meyer: . . . I have never observed uric acid on one side and none on the other, or any difference in this respect between the two sides. Your finding is certainly an interesting and important one. I will try to verify it on some of my patients.

"Sincerely yours,

"Howard A. Kelly."

Hitherto we have generally believed that the increased amount of uric acid (not gravel) in the urine is excreted by both kidneys.

Case VII.—W. D——, sixty-two years of age, seen by me in consultation with Dr. L. Stieglitz, of New York City. Eight years ago, biliary colic; stone found in stool. Four years later, very sharp pain in left side, lasting four to five hours, and extending down to bladder and left testicle; slight fever: no stone passed. Then well for three years. November, 1894, persistent dull ache in right lumbar region. Examination by competent physicians proved negative. In the summer of 1895 extremely severe pain in same spot: slight fever; remained in bed for one week. November, same year, similar attack. Urine shows large amount of uric acid, but is otherwise negative. Within the last month and a half patient has had fully six attacks of colicky pain in the region of the right kidney, disappearing in from two to eight hours. Pulse never over 80; temperature 100° to 101° F. Within the last week more or less pyuria; urine is more turbid after the renal colic; no gravel. History with reference to tuberculosis and specific disease negative. Mother's parents may have died of phthisis; one child has Pott's disease.

Status præsens: Urinates every hour or two, nights once, never less than eight ounces. Prostate hypertrophied. Lumbar regions not painful on pressure; kidneys not palpable.

Urinary analysis, May 7, 1896: Amount, 1860 c.c. in twenty-four hours. Reaction acid. Specific gravity, 1.009 at 15° C. Amount of urea, 27.9 grams in twenty-four hours. Chlorides (approximate), 9.3 in twenty-four hours. Phosphates (approximate), slight excess. Albumin, good trace.

Microscopic examination: Very small amount of blood: fair amount of pus, forming bulk of deposit; also tubular plugs of same: small amount of mucus, moderate number of hyaline casts: no tubercle bacilli, no gonococci; some cells from the superficial layer

[1] In October, 1895, I had also done the section cut of the kidney in a man of twenty-nine years. The patient recovered.

of the bladder, also some groups from the renal pelvis. Considerable amount of uric acid.

Diagnosis based on urinary examination: Moderate pyelitis, with but moderate renal hyperæmia. Slight secondary cystitis. Etiology, probably uric-acid stone or gravel.

In view of the clinical history, one had to diagnose right suppurative pyelitis, most probably due to a stone. To find out the health or disease of the left kidney as a preliminary to a probable operation to be done on the right, Dr. Stieglitz brought his patient to me for catheterism of the ureters. This was done three days later, on May 10th, at my office, as usual under cocaine anæsthesia. In spite of the hypertrophied prostate, the ureteral mouths were easily entered.

Amount of urine passed: Right kidney, 4.5 c.c. in 7 minutes. The catheter became clogged after seven minutes; attempts (lasting one-half hour) with catheter *in situ* were made to remove the obstructing plugs, but without success. After removal of the catheter the plugs were found within its eye and farther down in the lumen of the same. They were pressed out with some sterile water, and added to the amount collected. To facilitate examination, the specimen obtained from the right kidney was diluted by Dr. Sondern with an equal amount of distilled water. Left kidney, 15 c.c. in 15 minutes.

Reaction acid on both sides. Specific gravity, R., 1.002; L., 1.012 at 15° C., Westphal's balance. Amount of urea, R., 0.004 in 1 c.c.; L., 0.018 in 1 c.c. Chlorides (approximate), R., 0.0025 in 1 c.c.; L., 0.0075 in 1 c.c. Albumin, R., present, one-quarter per cent. per mille by weight; L., slight trace.

Microscopic examination: Blood, R., very small amount; L., small amount. Pus, R., fairly marked, some necrotic in character, also tubular plugs; L., none. Mucus, R., fairly marked; L., none. Casts, R., numerous hyaline and few granular casts; L., none. Bacteria, R., no tubercle bacilli, no gonococci, many pyogenic organisms; L. none. Epithelium, R., many cells from the ureter and groups from the renal pelvis; L., numerous cells from the ureter. Crystalline and amorphous deposit, R., considerable uric acid and its salts; L., none.

Remarks based on this examination: "Specimen from the left kidney: The small amount of albumin present being accounted for by the blood, a relatively good excretion of urea and chlorides, and the absence of all renal elements, allow the conclusion that this kidney is normal. The blood and epithelial cells of the ureter are, as proved by former experience, probably due to the introduction of the catheter. I may note that there is no crystalline deposit from this kidney.

"Specimen from the right kidney: The very low specific gravity as compared with that of the other specimen, a marked diminution in the excretion of urea and chlorides, with the presence of albumin, numerous hyaline and few granular casts, pus, much of which is necrotic in character, tubular plugs of pus, considerable mucus, and many groups of epithelial cells from the renal pelvis, would indicate a pyelonephritis, with, I think, an abscess cavity somewhere. The plugs which occluded the ureter catheter, as before described, tend to substantiate the above. (They consisted of pus, tubular plugs of the same, few hyaline and granular casts, all of which were embedded in mucus.) The small amount of blood and epithelial cells of the ureter is probably due to the catheterization.

"As to the etiology: The presence of a considerable deposit of uric acid and its salts, and considering the fact that there was no crystalline deposit from the other kidney, would allow the strongest suspicion that uric-acid renal stone or gravel constitutes the etiological factor."

Diagnosis based on this analysis: Left kidney normal; right kidney, rather marked pyelo-nephritis, with probably an abscess cavity. Etiology, probably uric stone or gravel.

In view of the continuous presence of some rise of temperature, and also of the fact that Mr. D—— intended soon to leave for his country residence in the northern part of the State, we proposed, after having carefully weighed the pros and cons as to the safest way, to have nephrotomy done on the right side in order to find and remove the stone. Before giving his consent, the patient decided to ask a number of prominent physicians and surgeons to give their opinion, submitting to them the analysis of the separately collected renal urine. The greater number of these gentlemen favored temporizing, especially as not long after the examination made by myself the fever disappeared. In the latter part of May, Mr. D—— left for his country home in charge of a trained nurse. Our agreement was that if the carefully outlined general treatment and the internal medication should not improve his condition, especially if the temperature should again rise and remain high, he should return to the city at once, ready for surgical interference.

Early in July, after a few days with marked vesical irritation, he passed an irregular stone per urethram, which, upon analysis, proved to consist entirely of uric acid. Soon after that the urine began to clear up. In August it was absolutely transparent, and the patient was in a splendid condition. He has remained well since that time.

This case nicely illustrates that the treatment of nephrolithiasis belongs to the domain both of internal medicine and surgery. Mr. D—— was lucky that in continually flushing his kidneys with a large volume of water, according to our orders, the stone entered the uterer with its longitudinal axis parallel to that of the ureter, and also that it was not too large to travel down. Had this not happened, an operation would have had to be done sooner or later. For such an operation it certainly would have been a very welcome assurance to the surgeon to know that the opposite kidney was healthy.

In perusing the history of these seven cases, Mr. Chairman and gentlemen, it may seem rather queer that my last case of this kind should date May 8, 1896. But as I have stated in my previous paper (*loc. cit.*) and would like to emphasize here once more, I have catheterized the ureters according to strict indications only. I have never introduced the catheter into a ureteral orifice for the sake of gaining personal practical experience in this kind of work, and shall not do so in the future. As will be seen, I have done catheterism in the male only when a renal lesion had to be localized, when health or disease of its mate had to be determined, and, furthermore, when an operation on the kidney seemed urgent and would probably have had to be done sooner or later.

By a singular coincidence, all patients who needed catheterism of the ureters since that time have been female, and in every one of these I drained the kidneys at my office with the help of Casper's instrument. Of course, I have had under my care, within the last eleven months, quite a number of male patients with renal disease, but in none of them did I find the indication for nor did I carry out ureteral catheterism.

I might here mention a few of these cases for illustration: In a young man in whom the cystoscope showed a marked ulcerative unilateral vesical catarrh, the mouth of the left ureter in the centre of an irregular sore, and in whom no tubercle bacilli could be detected, the first indication was to make a suprapubic opening into the bladder in order to scrape and cauterize the ulcerations and drain the viscus. Through the su-

prapubic opening a small catheter was then introduced into the ureter of the seemingly healthy side and fixed in front of its orifice by a catgut stitch. The urine collected in twenty-four hours proved the respective kidney to be healthy.

In a man of forty-seven, I had, in 1894, removed a papilloma of an apple's size from the right side of the bladder, which had been diagnosed by the cystoscope, resecting at the same time the vesical end of the ureter for a distance of two inches. In 1895, after repeated cystoscopy and a second suprapubic incision, from fifteen to twenty tumors of larger and smaller size were removed. In 1896, I successfully crushed a stone in his bladder, which I had seen through the cystoscope, notwithstanding the presence of a number of recurrent growths. Now, spring, 1897, his bladder is again full of recurrent tumors, and he has frequent pains in the left lumbar region. Analysis of the urine proved the presence of a pyelitis and the cystoscope showed a number of papillomata crowded around the left ureteral opening. In this case catheterism of the ureters would be impossible, because the mouth of the probably diseased side cannot be approached. The indication is suprapubic cystotomy for the third time, with catheterism of the ureters, provided this is found to be feasible.

In a man of fifty-three, with hypertrophy of the prostate, vesical catarrh, and occasional pain over the left kidney, urinary analysis showed a pyelitis but no crystalline deposit whatever. The patient feels comfortable, has very little residual urine. An operation certainly is not indicated at present. I did not catheterize his ureters. More cases could be cited.

With reference to the work itself, I can to-day repeat what I said a year ago: I consider the manipulation here in question an easy one, in the male as well as in the female. I have not changed my views since then. To approach the ureteral mouth and engage the tip of the tiny catheter in the same is not a bit more difficult in the male than it is in the female.

Of course, in order to be successful, a perfect familiarity with cystoscopic work is required. He who thinks that for catheterism of the ureters in the male it is merely necessary to buy Casper's or Nitze's instrument and then to proceed, is very much mistaken, and will no doubt be disappointed in his attempts, surely in his first ones. I had practised cystoscopy with Nitze's instrument in the male and female for fully eight years, before I catheterized the ureters in the male for the first time. The reason for this was not that such a long preparation is needed, but simply because a useful instrument was not to be had sooner. Such was not for sale before 1895. But during these eight years I had learned in many hundreds of cases how to find the ureteral openings, even under adverse and difficult conditions. I had learned how to approach them, even in such cases. For half-hours at a time and longer did I, in a great number of instances, uninterruptedly watch the ureteral jets for the sake of determining the transparency or turbidity of the descending urine. I had carefully timed the outflow with a view to finding the working coefficient of the respective kidney. Often did I do this for so long a time that I was forced to stop because of the running of my eyes due to the severe strain. If the cystoscopist knows how, I might say, to "handle" the ureteral openings, he will surely enjoy this kind of work, as I have done from the very beginning.

But he who does this sort of work in the male should always have made up his mind to proceed with patience and perseverance; he must not be in a hurry. My patients come on special appointment. It has taken me at times fully two hours before I got through, and then I had, in one instance, to be satisfied with the collection of 4.5 c.c. from the one kidney (Case VII.); in another case the catheter did not give exit to any fluid whatever on the one side (Case III.). But the reason for this annoyance was not the difficulty of the procedure, but some mechanical obstruction of the catheter's eye or lumen. Plugs of descending pus, the smallest amount of coagulated blood, with some pushed-off epithelial cells of the ureter, may easily obstruct the eye of the tiny catheter.[1] If repeated aspiration with a powerful syringe attached to the outer funnel-shaped end of the ureter catheter does not soon make the urine flow through the catheter, one ought to pull back the catheter's tip into the bladder, then wash the canal out with sterilized boric-acid solution, the eye of the ureter catheter being within the vesical fluid, and then reintroduce the instrument. As mentioned above, I did this manœuvre in the case of a lady three times. At the fourth reintroduction urine at last began and continued to flow through the catheter.

I further wish to mention the necessity of good assistance when catheterizing the ureters. I believe it is impossible to do good ureteral work in the male without a trained hand at one's side. I have so far always had and needed the help of my office nurse. She thoroughly knows what I want, how to fix the cystoscope and the catheter when I pull out the mandrel, how to steady the instrument when the catheter is *in situ*, etc. All these points to be observed when carrying out the work may at first glance seem cumbersome and superfluous, yet I deem them absolutely essential for successful ureteral work in the male.

In summing up these remarks I should say that repeated disappointment in the early time of ureteral work in the male should not discourage the cystoscopist. On the contrary, it should stimulate him to further trials (efforts). The reason for his failure should be sought rather in lack of experience in intravesical cystoscopic work, and also perhaps in lack of proper assistance, than in the imaginary defect of the instruments used for this purpose. Both of the ureter cystoscopes now in our hands are useful and do not need special improvement.

In order to be successful in using Casper's instrument, one will do well, I believe, to follow the rules I have laid down in my former article, repeatedly referred to, rules which I have found practical by personal experience. They are, briefly repeated and revised, and extended after my additional experience, as follows:

1. Wash and cocainize the bladder according to well-known rules.[2]

2. Fill the bladder with from five to seven ounces of clear fluid.

3. Introduce the instrument. For this purpose the ureter catheter should be pushed down to the internal opening of the canal of the cystoscope; the lid of the latter should be pulled out about one-third inch.

4. As soon as the beak has entered the bladder the catheter should be gently pushed forward into the vesical cavity by about one-half to three-quarters of an inch, and then the lid should at once be pushed back into place, *i.e.*, it should be fully closed.

5. After the interior of the bladder has been satisfactorily inspected and the ureteral openings have come into view, approach one of them.[3]

6. Let the ureteral opening appear at the very end

[1] The conclusion that in such a case the introduction of the catheter into the ureter has produced a mechanical reflex anuria of the kidney is, I believe, an erroneous one. We know this to appear even in the opposite kindney in consequence of ureteral (partial or complete) obstruction by a calculus. But I do not believe that the catheter which only partially fills out the lumen of the ureter can bring forth this phenomenon.

[2] See author in Morrow's "A System of Genito-Urinary Diseases," etc., vol. i., p. 456.

[3] For particulars I refer those interested to my previous article.

of the cystoscopic picture, farthest away from the middle of the bladder, but keep it under your direct inspection, with the prism as near to it as possible.

7. Push the catheter gently forward: if the beak's direction is a proper one, *i.e.*, if it is parallel with that of the lower end of the ureter, I am sure the ureteral catheter will almost invariably easily enter the mouth, when conducted by a trained hand.

8. Allow the catheter to proceed not more than one or two inches into the ureter, and withdraw the wire mandrel. Then, as a rule, urine will begin to flow drop by drop at intervals or continuously.

By faithfully adhering to these rules in my work, I have invariably been successful. Of course, the number of patients thus treated is not yet very great. But, so far, I can repeat conscientiously that whenever, whether in male or female, I have been able to see and approach the ureteral opening, I have also succeeded in introducing the catheter into the same. I have specially added the words "so far," because I have no doubt that I may probably encounter cases in the future in which my attempts will not be crowned by success, although the ureteral openings can be well seen and approached. But up to date there has been only one among all my cases, male and female combined, that of a lady, a patient of Dr. E. F. Cushier and Dr. Robert F. Weir, of this city, in which I have failed in my repeated attempts, although I saw the opening very distinctly before me. However, in this patient I afterward also failed with Kelly's method in repeated sittings. There was no catheter or probe small enough, metal or flexible, to enter the mouth. The reason for this was partially, as had been primarily well ascertained with the cystoscope, that the ureter emerged, not as is usually the case, at the innermost end of the ureteral intravesical fold, *i.e.*, nearest the trigonum, but about one centimetre away from it upwardly. The consequence was that the ureter catheter, in order to pass on, would have had to turn in a sharp angle right after its entrance into the ureteral mouth. This seemed not feasible. Besides, the mouth of the ureter was constricted, evidently congenitally. Such strictures we have to put on a basis with the congenital narrowness of the external meatus, so often found in the male. By chance, I nevertheless succeeded in determining the question at issue, viz.: Is the opposite kidney healthy? I may add this here, because the case really was a perplexing one. There had been an intermittent renal pyuria for the last two years. The right kidney was large, easily palpable, slightly painful to the touch. At the third sitting it struck me at once that, when washing out the bladder, the water returned clear from the beginning. I concluded that on this day the ureter of the diseased side was most probably temporarily obstructed. Cocainization of the bladder was somewhat prolonged on account of making preparations for the following work. It may have taken in all about six or seven minutes. During this time the patient, who had taken a great deal of fluid before coming to my office, discharged five ounces (!) of urine into the bladder. Instead of drawing off 50 c.c. of the cocaine solution and perhaps 10-20 c.c. of meanwhile admixed urine, I measured 200 c.c. (50 c.c. of a two-per-cent. solution of cocaine had been injected by me). On viewing the bladder after Kelly's method, I saw that the ureter of the presumably diseased side, which emptied within the centre of an irregular ulceration, did not discharge a drop of fluid. Examination of the 200 c.c. of mixed cocaine solution and urine proved the latter to be perfectly normal. In other words, there was a well-working, healthy opposite kidney. Dr. Weir successfully removed the diseased kidney. The operation, as well as the specimen thus obtained, proved to be of unusual interest.[1]

Whether we should advise patients to take a large amount of fluid before examination is still a mooted question. In the male I believe it is a wise plan. As explained in my former article, in the male we must drain one kidney after the other; if possible, of course, always in the same sitting. That is to say, we can generally not leave the catheter first introduced into one ureter in place; liberate it; catheterize the opposite side, leaving the catheter there also *in situ;* remove the cystoscope. There will be few urethræ found in the male of sufficiently wide calibre to allow properly moving the cystoscope with the catheter at its side within the urethra. It may often be possible under general narcosis. The latter, however, it seems to me, should, for obvious reasons, be avoided as much as possible in this procedure. We drain the kidneys separately for renal disease. And ether as well as chloroform is detrimental to the renal tissue. So far, I have never used or needed general anæsthesia for my ureteral work. This, as mentioned above, has been office work throughout.

In the male we are, therefore, limited in the time. The sooner the patient gets through the better. The more fluid he has taken before the examination, the more rapidly his kidneys will work. Of course, due weight must be given this point in drawing conclusions from the urinary analysis. However, as both kidneys have been subjected to greater work at the same time, mistakes can be avoided by a competent analyst.

In the female the case is different. Both kidneys may be drained for hours, provided we do the work at the patient's home or at the hospital. The urine from each can be separately collected in proper bottles put into the bed. We certainly can state the fact: Urinary analysis will be more satisfactory without diluting the renal secretion too much by previously ingested fluids.

With reference to finding out the amount of work done by each kidney within a given time, I formerly counted the drops that were discharged through the ureter in a certain number of seconds, and also counted the intervals between the different discharges. I have discarded this method since I have distinctly seen jets of urine at the ureteral opening enter the bladder with the ureter catheter *in situ*. The urine evidently often drains alongside the catheter besides passing through its lumen. The catheters which accompany Nitze's ureter cystoscope are of more use in this respect than those of Casper's instrument. The former have an end hole behind a scoop-shaped lengthening of the material of which the catheter is made, the whole thus forming a sort of bougie. The latter carry the eye at the side. Nevertheless I believe that timing the number of drops discharged through the ureteral catheter is an unreliable observation.

My whole ureteral work with a cystoscope according to Nitze's principles has, so far, been done with Casper's instrument—this for the simple reason that the first specimen of Nitze's reached me in a damaged condition. Before it was exchanged by the factory, more than half a year elapsed. I shall certainly try it the first opportuniy that offers.

Whether in the female one should make use of a cystoscope constructed on the Nitze plan, or of Kelly's

[1] This is a very important rule. Lately I received a letter from a gentleman in Boston who is interested in this work and studied in Berlin under Nitze and Casper. He possessed the latter's instrument. He complained of not having succeeded so far, a single time, in entering the ureteral mouth with the catheter. He wanted to come to New York and see me do the work. I wrote him to proceed according to Rule 6. Five days later I received another letter. The colleague was delighted. At his first attempt he had accomplished the task.

[1] *Cf.* Report of New York Surgical Society, meeting of March 10th, "Annals of Surgery," 1897.

instruments, is really a matter of taste. The manipulation with the imported ureter cystoscope certainly is a very gentle one; it is also very comfortable for the patient. She rests on her back in the position used by us for biamanual vagino-abdominal palpation.

A trained cystoscopist should, in my opinion, be master of all methods "that have proved useful and can be made use of for this purpose." In many instances he may, even in the female, succeed with the one method or instrument when the other failed for certain reasons.

In the male we have no choice. As explained at length above, Kelly's method for catheterism of the ureters is here a technical impossibility. We need instruments which carry the electric light into the bladder, and enable us at the same time to inspect and catheterize the ureteral openings by looking through a telescope and guiding the catheters through a separate channel.

With regard to the indication for catheterism of the ureters, it is, in my opinion, our duty to try and separately collect and analyze the secretion of each kidney "*in the male as well as in the female*" in all so-called obscure urinary diseases, provided the analysis of the bladder urine points to a renal lesion. It becomes our solemn duty to establish the presence, the health or disease, if possible also the working power, of the opposite kidney if nephrectomy has to be done.

If physicians will come to appreciate the importance of this now feasible examination, and make it a point to have cystoscopy and catheterism of the ureters in the male as well as in the female added to the other means at their disposal for arriving at a definite diagnosis, then the so-called obscure urinary diseases will at last become a thing of the past also in the male, and our diagnosis in the majority of such cases will from mere guesswork be put on a strictly scientific basis.

EXTROVERSION OF THE BLADDER TREATED BY LEFT NEPHRECTOMY AND TRANSPLANTATION OF THE RIGHT URETER THROUGH THE LOIN.[1]

By REGINALD HARRISON, F.R.C.S.,

SURGEON TO ST. PETER'S HOSPITAL, LONDON, ENG.

THE subject of the treatment I am about to describe is a boy, now aged fifteen years. He is the victim of a congenital exstrophy of the bladder and an epispadiac penis with the pelvic cleft. He first came into St. Peter's Hospital in July, 1895, for the deformity I have mentioned. There was a considerable protuberance of the posterior wall of the bladder, upon which the orifices of the ureters were distinctly visible. The exposed mucous membrane was very sensitive, and readily bled upon being touched either by the hand or by the clothes, and the thighs and legs were much excoriated by the constant dripping of urine from above. The patient's condition was a very miserable one, and he was much emaciated on his admission to the hospital. Shortly after his reception he showed signs of having contracted scarlet fever, and was consequently removed to an infectious hospital. For some weeks after this his urine remained slightly albuminous.

On his readmission, after satisfying myself that both kidneys were in good working order and the urine healthy, on January 17, 1896, I removed the left kidney by lumbar incision. The patient recovered rapidly and completely from this preliminary operation. With the view of allowing ample time for the purpose of enabling the remaining kidney to grow and to provide for the entire urinary excretion, the patient went home for some months, occasionally returning for observation.

He was again admitted to the hospital in November, 1896. His legs and thighs were still much excoriated by the constant dripping from the single ureter, and the protruding mucous membrane of the posterior wall of the bladder remained scarlet and sensitive. Having satisfied myself by repeated examinations that the excretion of urine had been effectually carried on by the solitary kidney during the period of nearly eleven months which had now elapsed since the preliminary nephrectomy, the right ureter was transplanted on December 5, 1896, in the following manner:

I first passed a flexible bougie up the solitary ureter so as to serve as a guide for finding the canal as it crossed the brim of the pelvis. I then made a small incision in the right loin on the same lines as if for a lumbar colotomy. By a little deep dissection and with Mr. Fenwick's assistance, the ureter was readily found and exposed. A arbolized silk ligature was placed upon it just below where it crosses the common iliac artery, and the tube was then cut across on the kidney side of the ligature and brought out into the loin wound. To the latter it was attached by one fine silk suture. There was very little bleeding and the whole proceeding occupied only a few minutes. The loin wound was partly closed by a suture at either end, but not so as to occlude the ureter. Before the patient left the operating-room, urine was seen issuing from the transplanted ureter, so that it was at once evident our object had been attained. A pad of absorbent material over the wound completed the dressing. It was noticed that, as the ureter was being transplanted, retching and attempts to vomit became continuous. Mr. Braine, who administered ether, called my attention to this.

The patient also vomited at frequent intervals for twenty-four hours after the operation. This immediately ceased at the expiration of this period, when in the course of my usual visit to the hospital I removed the little suture which attached the divided end of the ureter to the loin wound, and which had evidently been keeping up some tension on the former. The now disused and protruding posterior wall of the bladder was covered with lint and vaseline, and the patient was placed on a light but nutritious diet.

For ten days after the operation the patient's condition was in all respects most satisfactory, the discharge of urine from the loin wound being, as far as I could judge, free and normal. Then followed a series of high temperatures, which continued from December 16th to January 29th. On December 23d the temperature was 105.3° F., while on December 24th it fell as low as 97.4° F. These variations continued up to January 29th, when the normal level was again maintained. No rigors were noticed, though there were sweating and occasional vomiting. At times the patient was evidently drowsy, but he seldom complained of feeling ill and was generally in good spirits and took his food with appetite. On January 7th he was allowed to get up on a couch, and since this date he has steadily improved in every respect.

Different causes were assigned for these variations in temperature. At first it was thought that they were due to influenza. Then it was suggested that some suppuration was going on. But the evidence was insufficient. The urine as collected from the ureter was clear and contained only a slight trace of pus, which was probably derived from the external wound. It seemed more likely that either the eliminating function of the kidney had been disturbed, or that these variable temperatures were due to changes directly connected with the absorption of the unused mucous

[1] Read before the Medical Society of London, April 12, 1897.

membrane of the bladder, which was now rapidly going on. I regretted that at this stage no qualitative examination of the urine was made, which might have thrown some light upon the point.

That the boy has greatly benefited by the change in the mode of urination, there can, I think, be no doubt. He is now able to maintain the erect position, and moves about comfortably, being quite free from excoriations about his thighs and legs. His general condition has also much improved. I am indebted to our house surgeon, Mr. Pardoe, for the notes of this case, as well as for the following analysis of the urine, which was made on February 27, 1897, when the patient was convalescent: Specific gravity, 1.014; reaction neutral; no albumin; urea, 1.3 per cent. No casts or crystals present. As he is growing, he is provided only with an absorbent wool pad for the loin, which he changes every four hours and by means of which he keeps himself comfortably dry. Later on he will be fitted by Mr. Hawksley with an apparatus for collecting the urine as it escapes from the loin fistula. Nothing has yet been done to close in the posterior wall of the bladder, as it appears to be undergoing slowly a process of cicatrization. It would, however, be quite easy to effect this by a plastic operation, now that the surface of the bladder wall is no longer in contact with the urine.

I would ask your attention to the difference in the condition of the urine trickling from the ureters in these deformities, mixed with the abundant glairy excretion of mucus from the surface of the exposed membrane of the fissured bladder, as compared with the excretion that escapes from the artificial fistula in the loin, as in this case. In the former instance the excretion is irritating and offensive, with a strong tendency to form phosphatic calculi upon nuclei provided by the pubic hairs; while in the latter these characteristics are absent, and the presence of the patient ceases to be in these respects a cause of offence to others.

Though in this instance the treatment I have described was undertaken solely with the object of ameliorating the patient's condition, it is possible that a similar proceeding, or some modification of it, might be utilized in connection with the treatment of other forms of urinary disease. I refer more particularly to the extirpation of the entire bladder for malignant as well as for some advanced forms of suppurative diseases. Cases are occasionally met with in which, if it were possible to dispense with the bladder as a receptacle for the urine, its total removal might be safely and advantageously undertaken.

As over four months have now elapsed since the completion of the operation, I have thought this a favorable opportunity for submitting to the fellows of this society a proceeding which, in its application to this most distressing deformity, is, so far as I can gather, the first recorded example of its kind.

Carcinoma of the Rectum.—From an extensive statistical and analytical study of the subject, Tuttle (*Journal of the American Medical Association*, March 27, April 3, 1897) concludes that carcinoma of the rectum can be cured in over ten per cent. of the cases. The mortality from the radical operation, though still considerable, is not alarming and is decreasing with every year's experience. The radical operation prolongs life on the average over one hundred per cent. As a palliative measure, excision is far more successful and beneficial than any other measure. The sequences, though numerous, are not at all intolerable, and should weigh little in the consideration of a question so serious as carcinoma of the rectum.

ON THE CURATIVE TREATMENT OF TIC DOULOUREUX.

By CHARLES L. DANA, M.D.,

NEW YORK.

At the meeting of the Association of American Physicians, held in Washington, in May, 1896, I reported eight cases of tic douloureux, which had been treated by me according to a method described at the time. Of these eight cases, six were relieved and two were not relieved, although in one of them the method was not fully carried out. Since that time five other cases have been treated by me personally or under my direction, four with successful results. The claims which I made at the time that this plan of treatment was the best one with which I was acquainted—seem to me to be established by later experience. It is now three years since Dr. Elliott and I began to use this method, but I still find that many persons do not know anything about it, and that others have tried it in a perfunctory way and have failed. I therefore feel that I am justified in referring again to the matter and publishing further results.

It must be understood that this plan of treatment applies only to that form of trigeminal neuralgia which is known as tic douloureux or epileptiform tic. This disease is a typically degenerative neurosis, occurring almost always in persons who have reached or passed middle life, and is associated usually with considerable arterio-sclerosis. The malady is very typical and distinctive in its origin and course. The pains from which the patients suffer are sharp and agonizing, and are accompanied often with secretory and vasomotor disturbances, such as sweating, lachrymation, nasal discharge, or puffing and flushing of the face. There are few diseases which cause more suffering or make life more intolerable.

In recent years surgeons have turned their attention especially toward it, and new and ingenious operations have been devised for its cure. In many cases these operations do afford relief, usually for a period of time varying from six months to a year and a half, and this relief is often quite sufficient to justify operative interference. I have, however, seen many relapses following surgical operations, with failures attending the second operation, and I have in some cases seen the pains aggravated, apparently, by surgical interference. On the other hand, in cases that have been seen early by me, the relief by the strychnine and rest treatment has been very prompt, as compared with that in the old cases or in those in which operations have been performed. So that I am led to think that surgical interference is unwise until other measures have been exhausted, for it has happened that in some instances surgery has finally made the patient worse.

In estimating the value of any method of cure for a disease like this, I have taken into account the fact that this disease has periods of intermission, naturally, though these are not ever very long—never more than a few months, and usually less. I also have borne in mind the fact that the disease sometimes ceases of its own accord, though this rarely occurs before at least four or five years have passed.

With these introductory remarks, I will proceed to relate the histories of my later cases.

Case I.—Mrs. C——, aged fifty-six. This patient had been a healthy woman until the onset of the present disease. This began in March, 1895, with intense darting pains in the lower jaw on the left side, the pain extending up into the upper jaw. In September, 1895, she was operated upon and a small portion of the inframaxillary nerve was removed. This gave her relief for several months. The pain then returned, involving the same nerve, and, in addition, the left superior maxillary branch and the left side of the

tongue, so that speaking and swallowing became very difficult. She was obliged to live on liquid food largely, owing to the pain caused by mastication. She was operated upon a second time, in June, 1896, and one and one-half inches of the inferior dental nerve were removed. This operation gave her no relief. She was sent to me by Dr. William F. Whyte, of Watertown, Wis., and I saw her September 15, 1896.

On October 3d she was placed on the strychnine and rest treatment, this being carried out with great care and patience by Dr. Whyte. The treatment was continued for ten weeks. During this time the injections of strychnine reached, as a maximum dose, one-fourth of a grain hypodermatically, and she was kept in her room all this time. On November 8th Dr. Whyte wrote me that she was practically free from pain and was feeling very well, but had lost some flesh and was somewhat weakened by a lack of exercise and a light diet. On January 5th the patient reported that there had been a slight relapse, the pain returning in the tongue only. Upon my advice she was again put to bed and was given injections for four weeks.

On February 16th Dr. Whyte wrote me that she was free from pain and was feeling practically well. During the second course of treatment the injections were increased to only one-eighth of a grain daily. Dr. Whyte's summary of his treatment of the case presents its main features so well, that I insert it here: "We began the treatment by injections of nitrate of strychnine on October 3d, and at her own request kept it up until November 25th. The largest doses, one-third of a grain, produced some discomfort, with decided trismus and increase of the pain. We then kept it up with a smaller dose until October 23d, when there was another exacerbation, and I gave her three-twentieths of a grain for some time. When I stopped the injections she still had some pain, although she was much better. This improvement kept up until January, when an attack of bronchitis seemed to cause a return of the symptoms; she then decided to undergo four weeks' more treatment, which we completed day before yesterday. The pain gradually left her after she went to bed, and now she says that she feels only a slight disagreeable sensation occasionally in her tongue while eating. The treatment caused no increase of the pain this time, so that the aconitine was not necessary. I did not give her more than three-twentieths of a grain except once, when she took four-twentieths, with some discomfort."

I should add, in concluding this case, that since the first treatment she had never suffered anywhere near so much pain as had been the case previous to the treatment.

A letter from Dr. Whyte, dated April 10, 1897, says: "Mrs. K—— is entirely free from pain, and regards herself as cured. When she received her last injection, February 14th, she had still a slight occasional tingling in the tongue, but that is gone now."

Case II.—Mrs. S——, widow, aged fifty-six. The patient had always been a strong, active woman, but had worked very hard teaching and writing. A short time before the onset of her neuralgia she had had some severe uterine hemorrhages. The pain began in the fall of 1895, with pain in the lower jaw of the right side. This soon became intense and distressing, and extended to the tongue of the same side and to the upper jaw. The attacks were accompanied by sensations of numbness and a feeling of paralysis of the throat. She could not swallow food, and would often be for hours in the greatest agony, unable even to move. The teeth of the affected jaw were gone. She received all kinds of antineuralgic treatment—aconitine, potash, quinine—and finally resorted to morphine. Even this did not relieve her pain. At the time the injections were begun she was suffering intensely though using morphine. Treatment was given by her physician, Dr. Washburn, of Chatham, N. Y. After four days the morphine was stopped, and at about this time the pain subsided. She was treated for six weeks, the full course being given.

I saw Mrs. S—— in April, 1897, and she assured me she had had no pain since.

Case III.—Mrs. L——, aged sixty-seven. This patient had been a vigorous and healthy woman up to the time of her present trouble. The neuralgia began two years before she consulted me. It affected the left side of the face, beginning in the lower jaw, involving the tongue, and extending into the upper jaw on the left side. There were no associated spasms. The patient was referred to me by Dr. Robert Abbe. He had proposed an operation, but the patient had refused to submit to it. I saw her in June, 1896, and proposed that she undertake the treatment. She disliked the idea of going to bed, and delayed matters until the early part of July, 1896. She had, during the past two years, tried various remedial measures, without any effect. She finally consented to go to bed, and the treatment was carried out by Dr. Edwin B. Tefft, of New Rochelle, to whom I am indebted for my notes as to the progress of the case.

The treatment was carried on during the hot weather of July and August, and under the most depressing conditions possible. For the first four weeks she did not improve. After that, when the large doses of strychnine were stopped, the pain gradually left, and she was free from it until November. She then had a slight relapse, and was again treated for a short time, with relief, until February 1, 1897. Another short treatment was given her.

In April, 1897, Dr. Tefft wrote: "Mrs. L——'s condition remains about the same as when I last wrote you some weeks ago. I put her to bed for three weeks and gave her the strychnine injections as suggested, but she did not get so much relief as she had by the two previous treatments. She still has a great deal of pain, and complains more particularly of a burning sensation over the course of the nerve. She is very much better than she was last June before she had any strychnine, but still suffers at times very much."

I saw the patient later, and found her as stated above. She was much better generally, but still suffered from the neuralgia. She had, as sometimes happens, a great deal of the hypochondriasis of old people.

Case IV.—This patient I have never seen. The circumstances of her case were laid before me by her physician, Dr. Charles A. Church, of Millbury, Mass., who applied the treatment. She was a woman, sixty-five years of age, with no history of rheumatism, gout, or malaria. She had always led an active life, and had never been sufficiently ill to require the services of a physician, except at childbirth, until five years ago, when she began to have neuralgic pains in the fifth nerve, attended with flushings of the face. These pains and spasmodic twitchings came on about three times a year, lasting, at first, a few days. The attacks increased in severity and duration, until they finally became practically continuous. They were associated with pharyngeal and masseteric spasms, so that feeding became difficult. She had been given quinine, salicylate of sodium, colchicum, phenacetin, antifebrin, caffeine, cannabis indica, and finally morphine. Locally, all kind of anodyne liniments had also been employed.

Dr. Church consulted me regarding the case, December 24, 1896. At that time she was suffering daily from intense and agonizing pains, and was taking morphine hypodermatically to relieve them. I advised putting her upon the special treatment, to which plan

Dr. Church immediately assented, and began injections on January 1st. On the tenth day of treatment he had reached a daily dose of one-tenth of a grain of strychnine. He wrote me that she had shown no effects from it, except that it "braced her up a little for about half an hour after the injection, and quieted the pain a little." At that time her bowels were obstinately constipated, and she was passing only six or eight ounces of urine in twenty-four hours, the specific gravity being 1.040; no albumin or sugar. The tongue and jaws were so sensitive that she could take but little food. She was still taking, in addition to the strychnine, from three-fourths to one grain of morphine a day, hypodermatically. On the twenty-first day of treatment the maximum dose of one-fifth of a grain had been reached, and this was repeated for three days. The morphine had been gradually discontinued, but on the twenty-eighth day she was still taking from one-eighth to one-sixth of a grain daily. She was then passing urine in normal amount, but the mouth was still so sensitive that she could take only liquid food, and not very much of that. She still had considerable pain. She had lost twenty-five pounds since the commencement of the treatment, owing to the difficulty experienced in swallowing food without intense pain. Her present weight was one hundred and forty pounds. She did not sleep well, and complained of nausea. Aconitine had given her no relief, although as much as a forty-fifth of a grain had been given in one day. I had previously advised that the morphine be entirely stopped, and had assured Dr. Church that the patient would not get well unless this was done.

On February 19th (fiftieth day) Dr. Church wrote me that the patient had shown marked improvement. The strychnine had been stopped for three weeks, and the patient was taking small doses of iodide and tincture of iron. She had slept well, was taking nourishment, had a good appetite, and had had no pain for two weeks. The morphine had been entirely stopped. Dr. Church wrote me at this time that he was greatly pleased with the results of the treatment, but "especially so after reading the report of a case of the same kind in the adjoining town, who was a physical and mental wreck from the use of opiates." On April 11th he wrote that she was free from pain.

These four cases are perhaps not such brilliant illustrations of therapeutics as one would wish, but, in connection with the others, they do illustrate a certain efficacy in the method beyond doubt. Two of these patients have had slight relapses, but they have been speedily brought out of them, and are practically safe from severe attacks of their disease as long as they are willing to fight against it. When one considers that this malady is a degenerative one, that it affects people whose vital powers have been lowered by advancing years, and when one considers, further, the inefficacy of other medicinal measures, it seems to me that we can regard the results with considerable satisfaction.

Of my previous patients, I know that four of them are still well; one of them has had two slight relapses, but has been kept practically free from severe pain. Two of them have had no relapses at all.

In my previous article I have discussed the other methods of treating tic douloureux. It is certainly a fact that we occasionally find a patient who is relieved or made comparatively comfortable by the use of aconitine. At other times they are relieved by the iodide of potassium or gelsemium, or by simple tonics and rest; but these are exceptional cases, and the relief is often not permanent.

A form of medicinal treatment, which has been recommended by so high an authority as Trousseau and by other French physicians, is the use of opium. This drug I have seen produce such disastrous results in a number of cases that it seems to me most unwise to recommend its use. Opium will, of course, stop the pain for a time, but in a great many instances it results in producing the opium habit, and that often without curing the neuralgia.

I went into the technical details of this treatment in the article referred to in the beginning of this paper, and which was published in the *Post-Graduate* for July, 1896 ("Neurological Reports"), and also in the Transactions of the Association of American Physicians for 1896. I shall refer readers, therefore, to this article for these details.

I must, however, in conclusion, insist upon the absolute necessity of undertaking the treatment in all its details, if good results are to be expected. I would not consent to treat a case unless the patient were willing to submit to at least three months, and perhaps four, of treatment. Patients who prefer a surgical operation or their neuralgia to the unpleasantness of a tedious therapeutical procedure, can, of course, exercise their choice.

REMOVAL OF FOREIGN BODY FROM THE ŒSOPHAGUS BY ŒSOPHAGEAL FORCEPS, GUIDED BY THE AID OF THE FLUOROSCOPE.

BY H. BEECKMAN DELATOUR, M.D.,

SURGEON TO THE NORWEGIAN, LONG ISLAND COLLEGE, AND ST. JOHN'S HOSPITALS, BROOKLYN, N. Y.

WHILE the use of the Roentgen rays to locate and picture the presence of metallic substances in the human body has become so common as hardly to attract notice, yet the use of these rays in conjunction with the fluoroscope to remove them has not been practised, to my knowledge, until employed by myself, on February 15th, in the following case:

F. B——, aged four years, applied at the Norwegian Hospital, on February 13th, for treatment. The mother gave the following history: On the 9th of February, while playing with some iron washers (nine-sixteenths of an inch in diameter), he swallowed one. Since that time he had been unable to swallow any solid and only very little fluid food. The boy was made to swallow some water, and by auscultation the disc was located as about opposite the fourth dorsal vertebra. It was then decided to locate the washer by means of the *x*-rays. Accordingly, on the 14th, at my request and in my presence, Mr. Frank Perret examined the boy with the fluoroscope, and plainly saw the foreign body. He then made a two-minute exposure and obtained the skiagraph here presented (Fig. 1). While looking through the fluoroscope the distinctness of the picture impressed me, and I at once thought of the possibility of passing a pair of œsophageal forceps, guided by the fluoroscope, and grasping the washer from above. Accordingly I made arrangements to operate with the aid of the light on the following day.

On February 15th the patient was chloroformed, and after being turned on his side was moved into a position before the tube. The fluoroscope applied to the back showed the disc to be at the same point as at the previous examination. A pair of flexible bullet forceps was then passed into the œsophagus, and was visible in the fluoroscope. The forceps grasped the washer and had withdrawn it about one inch, when efforts at swallowing by the child dislodged it from the grasp of the forceps and it slipped back to its former position. After a further administration of chloroform, a second attempt was made with a pair of slender alligator forceps, and with the same results. In the third attempt a pair of œsophageal forceps (Fig. 2) was

passed until they were seen to be half an inch below the washer; they were then opened and closed, and seen to grasp the foreign body, the tips of the forceps remaining separated by about one-eighth of an inch when the handles were closed. The forceps were then withdrawn, without any obstruction whatever, holding the washer in their grasp.

The total time consumed was about twenty minutes. In order to pass the forceps the head was thrown well backward, so as to bring the mouth on as near a line with the œsophagus as possible.

With the recovery from the anæsthetic the boy was well. He has had no difficulty in swallowing, and no soreness of the throat since.

In several cases foreign bodies lodged in the œsophagus have been located by means of the x-rays, notably those of J. William White (jackstone) and of M. Péan (a coin).

In all the cases the foreign body has entered the œsophagus and caught about opposite the first dorsal vertebra. This is the narrowest part of the tube, and represents its point of entrance into the chest.

The operation of choice for removal of foreign bodies located in the œsophagus is external œsophagotomy, but in children with short and particularly fat necks this is very difficult.

M. Péan, in his case, cut down, and it was only with much difficulty that he could find the œsophagus. After locating the coin he did not open the tube, but by gentle manipulation forced the coin into the pharynx, from which it was easily removed by forceps. M. Péan considered it a great step in advance not to be compelled to open the œsophagus.

Dr. White abandoned any attempt at external œsophagotomy because of the short fat neck of the child. He made several attempts with œsophageal forceps and failed. He then resorted to gastrotomy, and by means of threads passed through the œsophagus finally succeeded in drawing the "jackstone" into the stomach and then removing it. The child made a good recovery.

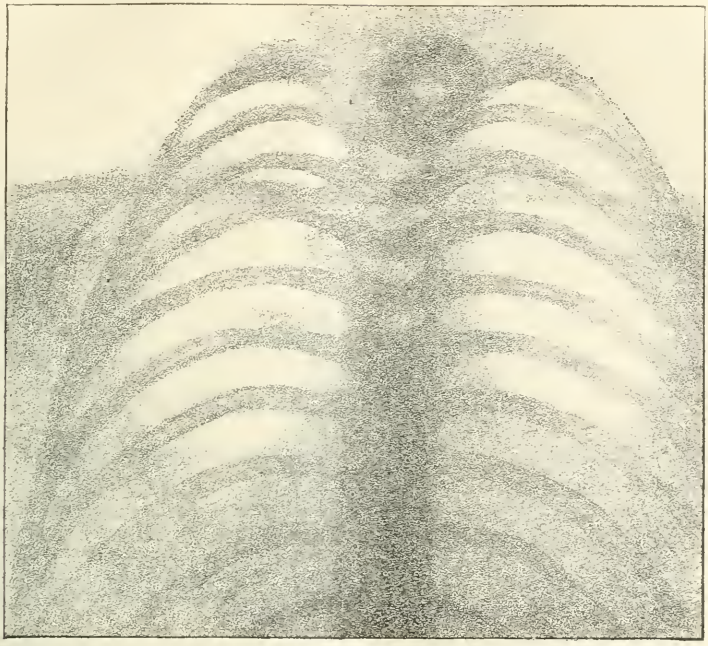

Fig. 1.

Attempts at removal of foreign bodies from the œsophagus by forceps, unguided, are quite likely to be failures, as it is impossible to know when the body is reached and grasped. Any successful cases are the results of chance.

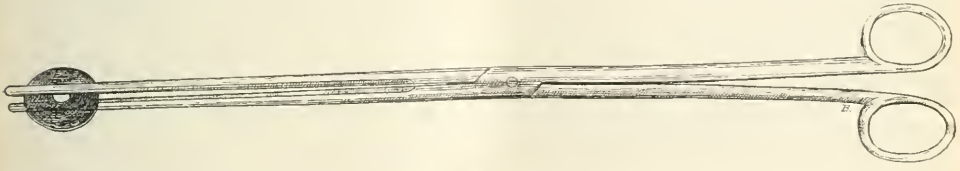

Fig. 2.

My first idea was to attach the œsophageal forceps to the telephone in place of the probe, so that by hearing one would know when the body was grasped; but after viewing the washer in the fluoroscope, I was convinced that "seeing was better than hearing," and so made the successful attempt above described.

Eighth Avenue.

Antipyrin and Calomel are found to produce a reaction when given simultaneously, forming corrosive sublimate in dangerous amount, even in ordinary medicinal doses.—Werner, *Pharmac. Zeitung.*

Progress of Medical Science.

Consciousness in Epilepsy.—Prof. E. Siemerling (*Berliner klin. Wochenschrift*, Nos. 42 and 43, 1895), in a paper on "The Transitory Disturbances of Consciousness in Epileptics in their Forensic Relations," draws the following conclusions: 1. In the epileptic psychoses a dream-like altered condition of consciousness is probable, and not by any means total or partial amnesia. 2. The most various transition forms occur between the different forms of so-called acute and chronic epileptic psychoses. Epileptic and epileptoid conditions and psychoses must alike be reckoned as symptoms of cerebral disease. 3. The transitory, dreamy states are characterized by the rapidly recurring, apparently orderly, indifferent, and inconspicuous manifestations, and by unusual, unexpected, often violent acts. 4. There is no epileptic or epileptoid psychosis without epileptic or epileptoid antecedents. Epileptoid conditions are more frequent than is commonly supposed, especially vertiginous attacks. 5. With the lack of epileptic or epileptoid manifestations, all other symptoms, such as amnesia, similarity of attacks, peculiarity of action, sensory hallucinations, will serve to make the diagnosis of epilepsy most probable.

How Long is Syphilis Contagious?—Dr. Drennen (*Cleveland Medical Journal*, January, 1897) says that there are no well-authenticated cases on record of syphilis occurring in the second generation as a result of heredity; there are no cases on record in which vaccino-syphilis has been transmitted from children over eight months of age; hence, no matter what condition may confront us in acquired syphilis, it is almost certain that in hereditary syphilis its power of transmission is lost by the end of the first year of infection.

Sloughing Myoma of the Uterus.—Findley (*Journal of the American Medical Association*, April 3, 1897, p. 637) reports a case of sloughing myoma of the uterus, and expresses the conclusion that in the majority of cases uterine myoma is the cause and not the result of sterility. Uterine myomata complicating pregnancy are especially liable to infection. The gangrenous process begins in the periphery of the tumor, invades the interior of the growth, and may penetrate the uterine wall. Myomata usually grow rapidly during pregnancy. Submucous, less frequently interstitial, myomata may so distort the uterine canal as to render impossible the delivery of the placenta: such growths should be enucleated when possible, the retained placenta extracted, and the uterine cavity thoroughly sterilized and packed with sterilized gauze. If the growths cannot be enucleated and the symptoms of sepsis do not yield to antiseptic douches, no time should be lost in performing hysterectomy. In every case of abortion or labor complicated by myoma, the first indication of sepsis should be carefully looked for, and in the event of septic infection operative interference is imperative.

The Influence of Anæsthetics upon Circulation and Respiration.—As the result of an experimental investigation conducted in the pharmacological laboratory of the University of Pennsylvania, Wood and Carter (*Journal of Experimental Medicine*, March, 1897, p. 131) arrive at the conclusion that lowered arterial pressure has a comparatively feeble effect upon the respiration: but, when the pressure falls sufficiently, respiratory depression does occur. Even excessive lowering of blood pressure primarily stimulates the vasomotor centre, the sensibility of which is evidently necessary to the automatic regulation of the circulation. The circulation recovers itself more slowly after profound etherization than after a like chloroform narcosis. It is possible for ether, as well as chloroform, to produce death some hours after the cessation of its administration, at a time when the cerebrum has long freed itself from distinct evidences of the narcotic, so that consciousness and intellectual action have been restored. In applying these conclusions to the subject of practical anæsthesia, it is evident that the depression of the circulation produced by chloroform has effect upon the respiratory centres only when the pressure has fallen very low: and, while it may be a factor in the production of respiratory failure during chloroformization, the failure must be chiefly due to the direct influence exercised by the drug upon the respiratory centres. Clinical experience shows that nausea and general depression are more pronounced after the use of ether than after the use of chloroform. This research confirms this observation and experimentally shows that the depression of the circulation caused by ether is more permanent than that caused by chloroform, the reason probably being the large amount of ether necessary to induce profound narcosis, with lowering of the arterial pressure—an amount so large that it can be neither burned up in the system nor yet eliminated in the time that would be necessary for the much smaller amount of chloroform to be gotten rid of after chloroformization.

Pathogenetic Cutaneous Eruptions.—In a study of the differential diagnosis of medicinal eruptions, F. Guirand (*Arch. Clin. de Bordeaux*, January) concludes: (1) It is possible to observe medicinal eruptions exclusively limited to the face, of almost symmetrical distribution, whose objective characters simulate in their onset an attack of erysipelas. (2) Unless we have to deal with true intoxications, due to the ingestion of large doses, the eruptions are not accompanied by general symptoms. This absence of general symptoms is usually sufficient for the differential diagnosis from microbian or infectious toxicodermas. (3) The change in the aspect of the eruption is, so to speak, pathognomonic of their medicinal nature. This feature is of great diagnostic value when the ingested drug belongs to the group of balsamics. (4) Eruptions occasioned by balsamics taken in small dose have a rapid course. Most frequently their symptomatology is confined to the objective signs furnished by the skin surface, and their evolution is at times so discrete that they often pass unnoticed.

Hypertrophic Pigmentary Alcoholic Cirrhosis.—Dr. Letulle (*Le Bulletin Méd.*, February 7th) believes that we should place the above along with the pigmentary cirrhoses of diabetes, malaria, tuberculosis, cancer, and those of still undetermined cause. He has recently seen three examples of the alcoholic variety. All cirrhotic pigmentary cachexias are characterized by a certain number of material disorders, almost constant, which may be stated as follows: (1) We recognize at least three kinds of pigment: (*a*) the ochre pigment (ferruginous), which is the most frequent; (*b*) a yellowish-brown pigment, whose ferruginous nature cannot be determined by the chemical reagents at our command; (*c*) the melanic pigment of the skin normally elaborated in the deep cells of the mucous layer of Malpighi. (2) All the visceral lesions of diabetic pigmentary cirrhosis are found in the alcoholic form. (3) The distribution of the ochre pigment is almost generalized, but with predominance very marked in the glands (absence in the kidney). (4) Almost absolute integrity (from a pigmentary point of view, of the covering epitheliums, external (epidermis) as well as internal, and of the canals. (5) Great fixation of the ochre pigment, whose elimination is extremely difficult.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUBLISHERS

WM. WOOD & CO., 43 45, & 47 East Tenth Street.

New York, May 1, 1897.

HARD LINES IN MEDICAL PRACTICE.

WHEN the physician with shrunken income reverts to the palpable fact that practice is not what it used to be, there are many etiological factors which claim his consideration, and there is much melancholy comfort during his forced leisure hours in discussing their relative merits. There is some satisfaction in recognizing the causes of a malady, even if no cure may be in sight. We can usually bear the burden of our ills more philosophically when we balance them with a becoming interest in the study of their pathological conditions. This knowledge of the reasons why gives that discipline to resignation which enables the latter to conform itself to the working of natural laws, and to bow becomingly to the decree of an inevitable fate. Thus the doctor finds that he must necessarily fit himself to a new environment. His work is supplemented by many conditions for success which did not exist half a century ago. The community has grown in knowledge, and the doctor has become a mere incident to such a condition. In times gone by, legitimate medicine was a restrictive science; now every clerk prescribes for his fellow, and most of the fashionable drugs are on the bargain counters of the department stores. The ordinary druggist of commerce, although forbidden by law to prescribe, can sell the prescription of any physician he chooses without being strictly amenable to the law. The only limit to such a practice appears to be in the case of poisons, which always require a physician's order. The patients make their own diagnoses, use grippe remedies on themselves, and there is hardly a young man or young woman about town who cannot, while in need of it, buy a gonorrhœa mixture over most of the drug counters without a question. Quinine appears to be no longer a medicine, but an article of food, and the rise and fall in its price is of as much interest to the general public as that of sugar, coffee, or flour. The druggist, too, has his own little mixtures for headache, cough, malaria, or constipation, and is ever ready with a sample for his many customers. If the ordinary self-prescribing patient is in doubt as to the real character of his ailment, the free dispensary is ever ready for his desirable custom, and he can go from one department to another and have all his organs examined by experts, with possibly clinical lectures in the bargain. Then, again, there is another class of patients, who are the natural patrons of the quacks, who believe everything they read, and who float from one sharper to another, until they land in a hospital bed, with no money left, no health, and no hope.

All these conditions are the natural results of so-called medical education of the people, and which can easily be understood to act so disastrously upon the conscientious physician who aims to make an honest living.

Still, again, the very systems of dispensing public charity, of affording aid to the injured, and even of preventing the spread of diseases, always so necessary in large communities, have markedly curtailed paying practice with a large majority of emergency cases. All acute surgery, minor or greater, is rapidly transported to the hospital, and the chance accident cases for the convenient doctor are no more. The health department gives free vaccination, and, of course, has something more important to think of than the fee taken from a doctor. The latter dares not in decency complain, sacrifices himself on the altar of expediency, and complacently turns to figure his chances on his unpaid bills.

All this time, however, the medical colleges are urging men to study medicine, promising them great futures, lucrative business, and the like. There may be plenty of room at the top, but the bottom just now is very full.

CAMPHORIC ACID IN NIGHT SWEATS.

ONE of the many remedies for the night sweats of phthisis, which is not so well known as it apparently deserves to be, is camphoric acid. It has been strongly recommended by many continental writers, and the first number of the *Edinburgh Medical Journal* for the current year contains an article by Dr. Stockman, in which the drug is spoken of as one of great value in the control of this distressing symptom.

In this country Dr. H. A. Hare has for a number of years advocated the use of camphoric acid as an efficient antisudorific. His first experience with it was in the wards of St. Agnes' Hospital during 1890–91, where he found that it controlled the sweats of tuberculosis in the great majority of cases and did not produce any such disagreeable symptoms as are usually caused by atropine. He also spoke of the value of this drug in the first edition of his "Text-Book of Practical Therapeutics," published in 1891, and has since referred to it in other articles. In a paper in the *Therapeutic Gazette* for March, 1897, he writes that a continued large employment of camphoric acid during the past six years has still further confirmed his high opinion of this drug. Like every other remedy, it will fail in some cases, but nothing has been met with which in his hands so universally succeeds. As the drug is slowly absorbed, it should be given an hour or two before the time at which the sweat usually comes on. A dose of twenty grains is usually quite sufficient to control the sweat, provided it is given early enough, but as much as sixty grains may be given, if necessary, without deleterious effect.

DIAGNOSIS BY THE ROENTGEN RAY.

That the *x*-ray has passed through its infancy and is now well started in upon that second period which precedes adolescence is evident from the reports which multiply on every hand. The location of bullets and other foreign bodies in various regions of the body; the determination of union in fractures, as well as their diagnosis at the time of injury, with the relative position of the fragments, are all twice-told tales.

It is no longer a novelty to see radiograms of coins, jackstones, or false teeth stuck fast in some portion of the alimentary or respiratory tubes. Even renal calculi have been shown in the kidney's pelvis, and Seiffert disclosed a hairpin in the bladder, which the young lady claimed to have swallowed by accident. The aid in diagnosis of these conditions alone far surpasses anything that an ordinarily sanguine man could have hoped for at the time Professor Roentgen's discovery was announced.

Still in this short time much more surprising things have happened, and to-day it may be claimed that the rays have a much wider field of usefulness. Aneurisms of the arch of the aorta can be made out; shadows of the heart and diaphragm in motion can be shown, so that a diagnosis of adhesion between the costal pleura and diaphragm can be established, as well as thickening of the pleura.

At a recent meeting of the Vienna Medical Club Dr. Wassermann exhibited shadows of diffuse lung infiltration, and in a second case an impulse seen in an aneurism in the left mediastinum was accepted as a sufficient differential diagnostic point from other variety of tumor.

Dr. Willard has demonstrated before the American Orthopædic Association that by skiagraphy one can determine whether deformities of the feet can be corrected without tarsectomy, and in an instance of clubfoot subcutaneous section of the contracted tissues permitted replacement and proved the correctness of what was shown by the rays. The obstacles to be overcome in correcting varus of long standing can thus be made clear and the relations of all the bones be satisfactorily demonstrated. Experimenters are gradually coming to secure images of the soft tissues, and hypertrophy of the heart has been repeatedly made out. Jeanselme has recently demonstrated that organs surcharged with ochre or ferruginous pigment are much less permeable to the rays than similar organs weak in iron. Experiments were made with liver tissue, pancreas, and lymphatic ganglion from a subject of bronzed diabetes.

This and similar experiments may lead to valuable diagnostic data, while Grunmach, Macintyre, and others have already shown in a satisfactory way that certain growths, infiltrations, and thickenings of the softer tissues can be seen by the aid of the rays. We are thus in a position to hope for certain definite practical results in the near future, which will be of immense benefit to medicine and surgery. There is a reasonable promise also that with the perfection of methods skiagraphy will eventually become a widely extended method of diagnosis in both branches.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the U. S. navy for the week ending April 24, 1897. April 19th.—Surgeon D. O. Lewis ordered to Annapolis as member of the medical examining board, May 17th.

The Association of German Naturalists and Physicians.—The sixty-ninth annual meeting of this association will be held at Brunswick, from September 20th to 25th. The work will be distributed among thirty-three sections, being an increase of three as compared with previous years. One of the new sections is apportioned to anthropology and ethnology, another to scientific photography, and the third to geodesy and cartography.

The French Society of Otology and Laryngology will hold its annual meeting in Paris on May 3d. The questions proposed for discussion are: (1) Treatment of ozæna; (2) recurrent paralyses; (3) the ear, nose, and larynx from the medico-legal point of view.

Surgeons Wanted.—The hospitals of the Greek army in Thessaly are reported to be overcrowded. A despatch to *The Sun* from Larissa says that the nurses and surgeons employed in the hospitals are completely exhausted by the vast amount of work they have been called upon to perform, and it will be impossible for them to stand the strain much longer. An urgent appeal has been sent to the Government at Athens to send more surgeons and nurses to aid those already here. There are so many wounded there that it is impossible to give them the care and attention they should have. So pressed are the surgeons for time and so urgent is the necessity for their work that operations are being performed without the use of chloroform or other anæsthetics.

Yellow Fever.—The steamer *Finance* arrived at Quarantine from Colon on April 22d with a passenger ill of yellow fever on board. He died a few hours after being removed to hospital. The vessel was disinfected and allowed to come up to her pier in the city. There is said to be considerable yellow fever on the Isthmus of Panama.

Middlesex County (N. J.) Medical Society.—At the annual meeting of this society held in New Brunswick on April 22d the following officers were elected: J. G. Wilson, of Perth Amboy, *President;* C. M. Slack, of New Brunswick, *Vice-President;* David Stevens, of New Brunswick, *Secretary;* D. C. English, of New Brunswick, *Treasurer.*

Pennsylvania Hospital.—The Walter Garrett Memorial Building of the Pennsylvania Hospital at Philadelphia was opened on April 23d with appropriate ceremonies. Addresses were made by the president of the board of managers, Mr. Benjamin H. Shoemaker, and by Drs. Thomas G. Morton, J. M. Da Costa, and J. B. Chapin. The new building includes an operating-pavilion, receiving wards, and children's wards. On the ground floor are a receiving ward for

men and one for women, together with a small operating-room, where dressings are applied and minor operations performed. There is also a "quiet" ward, containing twelve beds in which patients are undressed, bathed, and put into condition for transfer to other portions of the hospital. There are, besides, rooms for the storage of patients' clothing, a room containing a steam and a hot-air sterilizer for the disinfection of clothing, and also a diet-kitchen. Provision has been made for the treatment of cases of sunstroke in the basement or in tents on the lawn. On the second floor is an operating-amphitheatre, 45x46 feet in size, lighted by a large glass dome and many windows. The hall has a seating-capacity for two hundred students. Around the amphitheatre are communicating rooms in which patients are anæsthetized and otherwise prepared for operation. There are, besides, dressing-rooms, rooms for sterilizing instruments, a room for keeping the instruments, and a private operating-room. Ample facilities for microscopic work, for photography, and for skiagraphy have been provided. The third floor of the building is given up to the children's ward, with twenty-five beds, nurses' room, pantry and diet-kitchen, baths, isolation ward, and playroom.

The Woman's Medical College of the New York Infirmary was burned on April 22d, all the specimens in the museum, the scientific apparatus, and the library being destroyed. The college building only was burned; the adjoining infirmary, in which there were at the time about sixty patients, being saved by the firemen. The building was erected only about seven years ago, but the trustees will now put up a larger and fireproof structure in its place, and they hope to have the new building ready for the opening of the college in October next. The infirmary was the oldest hospital for women in the country, having been founded in 1854 by Drs. Elizabeth and Emily Blackwell. The latter is now dean of the college.

The Cumberland Co. (N. J.) Medical Society.—The District Medical Society of Cumberland County, N. J., held its annual meeting at Bridgeton, April 13, 1897, and elected the following officers: Dr. H. W. Elmer, *President;* Dr. A. R. Judson, *Vice-President;* Dr. Jos. Tomlinson, *Treasurer;* Dr. Hamilton Mailly, *Secretary;* Dr. J. C. Applegate, *Reporter.*

The Western Pennsylvania Hospital celebrated on April 20th the fiftieth anniversary of its foundation at Pittsburg. New hospital buildings have been proposed and attractive designs have already been prepared.

Cape May County (N. J.) Medical Society.—The twelfth annual meeting of the Cape May County Medical Society was held at Cape May, N. J., on April 20th. The following officers were elected for the ensuing year: *President*, Dr. Wilson A. Lake: *Vice-President*, Dr. A. L. Leach. *Secretary*, Dr. Julius Way; *Treasurer*, Dr. Randolph Marshall; *Censors*, Drs. V. M. D. Marcy, B. T. Abbott, and W. S. Leaming. Drs. Leach and Way were elected delegates to the American Medical Association.

The Microbe of Mumps.—The Berlin correspondent of the *British Medical Journal* writes that Professor von Leyden has discovered a new diplococcus in the parotid-gland secretion of persons suffering from mumps, which he takes to be the mumps bacterium. It is distinct in appearance, and can be cultivated on the usual media. Attempts to inoculate animals proved unsuccessful. The diplococcus has been found, not only in the parotid-gland secretion, but also in the pus of the inflamed gland.

Medical Fees in Vienna.—The following is published as the fees charged by Vienna physicians: A day visit, 3 gulden (about $1.20); an evening visit, 4 gulden ($1.60); a night visit (without carriage), 6 gulden ($2.40); a consultation, 10 gulden ($4); one hour, 5 gulden ($2); a visit at a time fixed by the patient, 5 gulden ($2); for each additional patient seen in a house, 1 gulden (40 cents).

The American Laryngological, Rhinological, and Otological Society will hold its third annual meeting in Washington on May 1st and 3d, just prior to the meeting of the Congress of American Physicians and Surgeons. The sessions will be held in the Columbian University building, corner of Fifteenth Street and H Street.

Bequests to Hospitals.—The late Andrew J. Garvey, who died in Southampton recently, left in his will bequests of $10,000 each to St. Luke's Hospital, the Presbyterian Hospital, St. Vincent's Hospital, the Woman's Hospital, Mount Sinai Hospital, and the German Hospital, for the endowment in each hospital of two beds in memory of his mother, Elizabeth Jeffries Garvey, to be known as "the Elizabeth Jeffries Beds." He made also a further bequest of $15,000 to St. Luke's Hospital, to found three beds, two of which are to be in memory of his brother, John Garvey, and are to be known as "the John Garvey Beds." The third bed is in memory of George W. McLean, and is to be named "the George W. McLean Bed."

The Medical Society of the State of Pennsylvania will hold its forty-seventh annual meeting in Pittsburg on May 18, 19, and 20, 1897. A one and one-third rate has been granted to delegates by the railroads. Dr. E. E. Montgomery, of Philadelphia, is president, and Dr. William B. Atkinson, of Philadelphia, is secretary. There will be plenty of business before the society in addition to the scientific work, as there are a score of proposed amendments to the bylaws to be voted on.

A Clinical Observation.—Dr. Cantrell stated that the ordinary bedbug was capable of causing much local distress. He had noted one case in which there had formed grave abscesses at the site of the bite.—*The Philadelphia Polyclinic.*

Deaf-Mutes.—Norway has nearly one deaf-mute per 1,000 inhabitants, and thus occupies an intermediate position between countries like Holland and Belgium with 0.43 per 1,000, and Austria with 1.31, and Switzerland with 2.45 per 1,000. England and Scotland have 0.51 and 0.53 respectively.

Suicides in the United States.—It is stated that the number of suicides in this country has risen from two thousand and forty in 1890 to six thousand four hundred and twenty in 1896. The *Medical Examiner* says that by those who have considered the subject, the incontestable life insurance policy is blamed very largely for this enormous increase in self-destruction.

The Kansas Medical Society has a rule that all papers presented and read at its annual meetings must be type-written.

The Widow of the Late Professor Charcot has resigned the annual pension of 2,000 francs which she received from the state, in favor of other widows and children of professors of the faculty of medicine of Paris who have died without leaving provision for their survivors. Madame Charcot has also refunded all the money that she has received from the pension since the death of her husband.

Columbus, Ohio, wants the next meeting of the American Medical Association. We have not learned who in Columbus has the presidential bee in his bonnet—perhaps no one.

Vital Statistics of Philadelphia.—For the week ending April 17th there were reported to the Philadelphia board of health 419 deaths, 66 less than during the previous week, and 108 less than during the corresponding week of the preceding year. One hundred and fifty-nine occurred in children under the age of five years. The more important causes of death were as follows: Pneumonia, 66; pulmonary tuberculosis, 43, bronchitis, 19; convulsions, 19; heart disease, 18; marasmus and old age, each 16; diphtheria, 15. There were further reported during the week 94 cases of scarlet fever, 84 of diphtheria, and 37 of typhoid fever.

Delaware County (Pa.) Medical Society.—A stated meeting of the Delaware County Medical Society was held on April 16th at Rosedale Inn, Essington, Pa., followed by a planked-shad dinner. Delegates were elected to the American Medical Association.

Northampton County (Pa.) Medical Society.—The forty-eighth annual meeting of the Northampton County Medical Society was held at Easton, Pa., on April 16th. The following officers were elected for the ensuing year: *President*, Dr. E. W. Evans, of Easton, Pa.; *Vice-Presidents*, Dr. W. Freeman, of Freemansburg, and Dr. Kate De Witt Miesse, of Easton; *Secretary*, Dr. Charles McIntire, of Easton; *Corresponding Secretary*, Dr. H. T. Edwards, of South Bethlehem; *Treasurer*, Dr. Amos Seip, of Easton; *Censors*, Drs. J. S. Hunt, of Easton, H. Keller, of Bangor, and E. D. Schnabel, of Bethelehem. Delegates were elected to the Medical Society of the State of Pennsylvania and to the American Medical Association.

Pathological Society of Philadelphia.—At the annual conversational meeting of the Pathological Society of Philadelphia Dr. Ludvig Hektoen, professor of morbid anatomy in Rush Medical College, delivered an address entitled "Segmentation and Fragmentation of the Myocardium." He showed that these lesions may be present under many conditions, both of health and disease, and he contended that sudden death may result in consequence. In fact he asserted that it is probable that in many cases of sudden death in which other obvious cause was wanting, these lesions would be found.

A Medical Health Commissioner in Chicago.—The platform of the supporters of the recently elected mayor of Chicago declared that the health commissioner should be a physician, and now the medical men of that city are expecting the fulfilment of this pledge by the appointment of one of their number.

Dispensary Investigators.—The St. Louis Medical Society recently appointed a committee of three to investigate the various free clinics in that city in the attempt to remedy the abuses of the system.

Dr. John Welsh Croskey has been elected attending surgeon to Wills Eye Hospital of Philadelphia, in succession to the late Dr. Peter D. Keyser, recently deceased.

The Fifth International Congress of Criminal Anthropology will be held in Amsterdam in August, 1901.

Obituary Notes.—Dr. Le Roy McLean, of Troy, died in that city on April 23d, of apoplexy. He was born in 1831 and was graduated from the Albany Medical College in 1855. He served during the civil war as surgeon to the Second New York Volunteers. At the close of the war he took up practice in Troy and until 1877 served as surgeon of the Third Division of the National Guard. He had a slight apoplectic stroke ten years ago, but recovered and continued in practice until six months ago, when a second attack incapacitated him.—Dr. Frank Abbott died suddenly at his home in this city on April 20th. He was born in Maine in 1836 He began the practice of dentistry in Johnstown, N. Y., but in 1863 came to this city and attended lectures at the University Medical School, where he obtained a medical degree. He had been connected with the New York College of Dentistry since its foundation in 1866, and was dean of the faculty from 1869 until his death. He was a member of the County Medical Society, the Academy of Medicine, the American Dental Association, and many scientific and other societies.

The Results of School Inspection.—Dr. Blauvelt, chief of the medical school inspectors, in his report to the health board of the work of the school inspectors for the week ending on April 23d, stated that out of 4,599 examined, 243 children were excluded. There were 4 cases of measles, 4 of diphtheria, 1 of scarlet fever, 2 of croup, 13 of mumps, 8 of chicken pox, 28 contagious eye diseases, 160 cases of parasitic diseases of head and body, and 13 skin diseases.

The Small-pox Outbreak in New York appears to have been gotten under control by the board of health. The largest number of cases in any one locality was on Randall's Island, where thirteen cases were discovered within a week.

Dr. Hermann M. Biggs, of New York, will deliver the address on public medicine before the British Medical Association in Montreal.

Nature Study for Public Schools.—The College of Agriculture of Cornell University has, under the Nixon or agricultural extension bill, undertaken to assist, free of expense, all teachers who wish to introduce nature study into their schools. All parents and teachers interested in this work may obtain detailed information by addressing the chief clerk, College of Agriculture, Ithaca, N. Y.

Osteopaths in Michigan.—It is stated in the *Medical Age* that "osteopathy" has received legal sanction from the legislature of Michigan, and in a way, moreover, that entirely excludes it from being interfered with or in any measure brought under subsequent medical acts.

Castration of the Feeble Minded.—A bill has been introduced into the Michigan legislature by Dr. W. R. Edgar providing for the castration of all inmates of the Michigan Home for the Feeble Minded and Epileptic before their discharge; also for that of all persons convicted of a felony for the third time, and of those convicted of rape. The advocates of castration are too mild in their measures of prevention. The attempt to asexualize the vicious and the unfortunate may fail through faulty operation, especially in the case of women. A much safer remedy is decapitation. It is equally effective as a means of preventing the propagation of the unfit and it is far more certain. Besides, it is not only a prophylactic but a curative method. Half-way measures are foolish.

Prof. Max von Pettenkofer, of Munich, has been invited by Lord Playfair, president of the Society for Public Hygiene in London, to come to England in order to receive the Harben gold medal.

The American Public Health Association.—The twenty-fifth annual meeting of the American Public Health Association will be held at Philadelphia, Pa., October 26, 27, 28, 29, 1897. The executive committee has selected the following topics for consideration: 1. The Pollution of Water Supplies. 2. The Disposal of Garbage and Refuse. 3. Animal Diseases and Animal Food. 4. Car Sanitation. 5. Steamship and Steamboat Sanitation. 6. The Prevention of the Spread of Yellow Fever. 7. The Transportation and Disposal of the Dead. 8. The Relation of Forestry to Public Health. 9. Nomenclature of Diseases and Forms of Statistics. 10. Cause and Prevention of Infectious Diseases. 11. Public Health Legislation. 12. Cause and Prevention of Infant Mortality. 13. Transportation of Diseased Tissues by Mail. 14. River Conservancy Boards of Supervision. 15. The Period during which each Contagious Disease is Transmissible, and the Length of Time for which each Patient is Dangerous to the Community. 16. Sanitation, with special reference to Drainage, Plumbing, and Ventilation of Public and Private Buildings. 17. Some Method of International Arrangement for Protection against the Transmission of Infectious Diseases. 18. Disinfectants. 19. Existing Sanitary Municipal Organizations of the Countries belonging to the Association, with a view to a Report upon those Most Successful in Practical Results. Upon all the above subjects, special committees have been appointed. Papers will be received upon other sanitary and hygienic subjects also.

An Impudent Forgery.—A Brooklyn correspondent writes us that a prominent resident of that city died while under the care of an unregistered quack, and that the latter in issuing the death certificate signed to it the writer's name. A warrant was issued for the forger's arrest, but there was so much red tape necessary that the man got wind of what was going on, and escaped. He was subsequently captured, however, and was convicted of practising medicine without a license and of forgery.

Sterilized Water in the French Army.—An experiment with the use of sterilized water in some of the barracks in France has proved so successful that these barracks, previously the frequent scene of typhoid fever, are now reported thoroughly healthy. Sterilizing apparatus is now being generally introduced in all military centres in France where the drinking-water is not undoubtedly pure.

A Candidate Quarantined.—The mayor of a Wisconsin town was surprised recently to find himself a prisoner in his own house by order of the health officers. His son was suffering from diphtheria, and the health commissioner issued an order that the mayor should not be allowed to leave his house, and a police officer was stationed at the door to see that the order was not disobeyed. The town was in the midst of its municipal campaign, and the mayor, who is a Democrat, was a candidate for re-election. The health officer is a Republican, and possibly his very laudable zeal may have been quickened somewhat by the happy chance which its exercise afforded him of keeping his opponent housed until the election was over.

The New Gouverneur Hospital.—The sinking fund commission opened bids a few days ago for building the new Gouverneur Hospital. There were twelve bidders. The lowest bid was $116,000, but the contract could not be awarded on account of a technical error in the bid. The next lowest bid was $129,400. The contract will be awarded later.

Inspection of Pupils in the Industrial Schools.—It is the intention of the board of health in this city to have the six thousand three hundred and fifty-four pupils in the twenty-three industrial schools of the city looked after by the special inspectors recently appointed with a view to stamping out contagious diseases in the public and parochial schools.

Hog Cholera.—The agricultural department has taken steps looking to the extermination of hog cholera, and as an initiative has sought the co-operation of the States of Tennessee and Iowa in an experiment to determine how economically the malady which is devastating swine interests can be stamped out. If the governors of these States will co-operate in the

work, it is the intention of the department to send representatives of the bureau of animal industry to one or two counties which the governors have been asked to designate as particularly subject to an outbreak, in order to study the disease and discover, if possible, some effective means of prevention.

Dr. A. W. de Roaldes, of New Orleans, has recently received the decoration of a knight of the French Legion of Honor.

Excellent Advice.—A forlorn "British exile," in a letter to *The Lancet*, containing some more or less accurate information concerning the medical-practice laws in this country, concludes with one word of good advice to the English medical man who has ideas of coming out here to heal the sick—"Don't."

Extreme Poverty of a Medical Man.—It is reported from Hazelton, Pa., that a physician holding a diploma of the University of St. Petersburg and indorsed by the Michigan board of medical examiners, was recently arrested for practising without being properly registered. On investigation it was found that the man and his family were destitute in the most extreme degree.

Lycoming County (Pa.) Medical Society.—At the annual meeting of the Lycoming County Medical Society, held at Williamsport on April 6th, Dr. Thomas J. Mays, of Philadelphia, read a paper entitled "The Treatment of Consumption." The following officers were elected for the ensuing year: *President*, Dr. William B. Konkle, of Montroseville; *First Vice-President*, Dr. G. M. Adams, of Williamsport; *Second Vice-President*, Dr. G. W. Metzger, of Hughesville; *Secretary*, Dr. W. W. Hull, of Williamsport; *Treasurer*, Dr. B. H. Detweiler, of Williamsport; *Trustees*, Drs. C. W. Youngman and John Klump; *Censor*, Dr. J. S. Bell, of Williamsport. Delegates were elected to the Medical Society of the State of Pennsylvania and to the American Medical Association.

The Hospital of St. Francis is the name chosen by a collection of antivivisectionists for a hospital they propose to build in London. The institution is to be named after St. Francis of Assisi, whose love for animals was the source of so many beautiful legends. Forgetting that St. Francis also loved his fellow-men, these people purpose to treat the patients of the hospital after antivivisection principles, returning therefore, if they are consistent and honest, to the guesswork methods of the darkest ages. Of course such consistency would be as impossible as it would be criminal, and we shall therefore see patients treated by antivivisectionists according to principles discovered through vivisection. A vegetarian butcher would be no greater an absurdity.

Atlantic City (N. J.) Academy of Medicine.—At a meeting of the physicians of Atlantic City, N. J., held April 9, 1897, a medical society was organized under the title of the Atlantic City Academy of Medicine. The purposes of the society are the interchange of medical thought and opinion, and the fostering of debate and consideration of medical matters, and the consideration of matters of public good that may properly come within the province of the medical profession. The officers elected for the ensuing year are: *President*, Dr. W. M. Pollard; *Vice-President*, Dr. W. Blair Stewart; *Secretary*, Dr. E. C. Chew; *Treasurer*, Dr. Walter Reynolds; *Reporter*, Dr. Joseph F. Edwards; *Governors*, Drs. Boardman Reed, E. A. Reilly, and the president of the society.

Medical Degrees for Women in Austria.—The correspondent of the *Medical Press* writes that for the first time in Austria the degree of doctor of medicine was conferred on April 2d, in Vienna, upon a woman, in the person of Baroness Possaner von Ehrenthal. She matriculated in Vienna, and studied later in Zurich, where she obtained the M.D., but she had to pass another examination in order to have that degree confirmed in her native country. The rector of the university, in congratulating the new doctor, remarked that when women occupying thrones can, by their wisdom, obtain immortal fame in history, the time had certainly arrived for considering the sex eligible for university degrees.

The Episcopal Eye, Ear, and Throat Hospital was dedicated recently in Washington. It occupies a building at the corner of Seventeenth and L Streets, which has been remodelled to suit its present purpose. In the basement are the kitchen, dining-room, and office. The first floor will be devoted to the dispensary service. There are four rooms on this floor, including a waiting-room, consultation room, refraction room, and ophthalmoscope room. The second floor contains the room of the superintendent, and three private rooms for pay patients. The third and fourth floors are taken up by the free wards, the third floor for white patients and the fourth floor for colored patients. There are bathrooms on each floor above the first, and on the third floor is an operating-room.

Jefferson Medical College.—The trustees of Jefferson Medical College have decided to inaugurate a system of summer laboratory work in the department of pathology and bacteriology, partly undergraduate and partly post-graduate.

The Commencement of the Johns Hopkins Medical School will be held in June, at the same time as that of the other departments of the university. There are one hundred and twenty-seven students in the medical school, of whom twenty are women, with seventeen students in the graduating class; one is a woman. This is the only medical school in the country that requires an academic degree for admission to its school. Harvard will make the same requirement after 1899.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on April 14th. Dr. Joseph Price read a paper on some of the common causes of mortality in abdominal surgery. Dr. Mordecai Price read a report of a case of laceration through the sphincter ani, with remarks on suits for malpractice. Dr. A. Ferree Witmer read a paper entitled "Is There a Daily Rhythm in Epilepsy?"

Clinical Department.

A CASE OF NOMA.

By W. M. CUMMINGS, M.D.,

TRINIDAD, COL.

In the MEDICAL RECORD of March 20, 1897, Dr. Alexander McKenzie Campbell reported a case of noma. In reading his report I am reminded of a case occurring in my practice nearly twenty years ago, the clinical history of which is very similar to that reported by Dr. Campbell, the cause of the disease in my case being, however, quite different. I have preserved a few notes of the case, and will report it, chiefly because of the favorable termination and because I have reason to think that the treatment adopted conduced to the favorable result.

"E. G——, female child, aged five and one-half years, of healthy parentage; both parents advanced in years, mother past fifty, and father near sixty. Child appears anæmic, ill-nourished, cachectic. The mother states that the child has always been well until two months ago, when she had fever for two weeks (presumably remittent), and since then has had 'the chills.' She noticed four or five days ago something wrong with the child's mouth; it seemed to her that the right cheek was swollen a little, and, as she expressed it, the child 'drools' all the time.

"There is a swollen, livid, shining appearance of the right cheek, which to the touch is hard and resistant; the breath has a marked gangrenous odor, and inspection of the cavity of the mouth shows a grayish-colored ulcer in the right cheek, and also upon the gums of both upper and lower jaws, opposite the ulcer in the cheek. The teeth in the affected gums were so loose that I removed three of them with my fingers."

I began the treatment with four-grain doses of quinine, to be repeated every fourth hour, which were continued for six days, and after that two-grain doses were given three times daily for ten days longer. Locally I ordered the following.

℞ Cupri sulph. ..... ℥ iv.
Pulv. cinchonæ rub.,
Pulv. cinnamomi cort. ..... āā ʒ i.
Aquæ ..... ℥ vi.
M. S. To be applied to the diseased parts on a cotton swab every six hours.

This was applied faithfully for five days, after which it was used only twice in the twenty-four hours for three or four days longer. By this time, the slough having pretty well separated and the sore having a healthy look, this wash was discontinued. All the molars and alveoli on that side were removed. The ulcer slowly healed, and under administration of citrate of iron and quinine the child regained her health.

I think the favorable result in this case may be attributed in no small degree to the free use of quinine. I gave it because of the pronounced malarial cachexia, but I have since observed a very marked beneficial result in several cases of severe ulcerous pharyngitis, in which there was no reason to suppose there was any malarial poisoning. I have upon more than one occasion observed that in pharyngitis of that character treated locally with antiseptics and astringents, as carbolic acid and Monsel's solution, not only has there been no improvement, but, the patient growing worse, the administration of four or five ten-grain doses of sulphate of quinine, repeated every four or six hours, has acted with the best result, promptly changing the condition, lessening the swelling, and limiting the ulcerated area. So I am inclined to think that it was of importance in the case above, aside from its value as an antidote to the poison of malaria.

APPENDICITIS VERSUS GRAPE SEEDS.

By GEORGE E. ABBOTT, M.D.,

CORONADO BEACH, CAL.

Although not in a position to report a long list of operations for appendicitis and peritonitis, I am in an exceptionally favorable position to speak negatively of a point in its etiology. I do not know to whom belongs the priority of refuting the grape-seed theory of appendicitis; but my attention was first called to the exceedingly small percentage of cases in which grape seeds are ever found by Dr. McBurney, at a meeting of the New York County Society, some years ago. Others have shown a much more probable etiology in constipation and catarrh. In this paper I hope to show that whenever seeds of fruit are found, it is in all probability a matter of coincidence and not the cause of the intestinal trouble. I shall also show that in grape countries children and adults eat from one hundred to three hundred grape seeds and from four hundred to five hundred guava seeds every day for months at a time, without any intestinal trouble whatsoever. Notwithstanding these facts, that the large proportion of cases of appendicitis are due to constipation and catarrhal conditions of the bowels, and that comparatively few cases are due to grape seeds, the old theory that they were the cause of all cases still dominates the majority of people, and one often meets patients or friends who are in mortal fear of grape seeds and cherry pits, and their life is made miserable thereby, while they deny themselves the pleasure of many healthful and refreshing foods on account of their unnecessary fear. It is to allay this unwise anxiety and to give confidence to those who need to enjoy and be benefited in health by the seed fruits that I send you this article.

I am at the present writing spending a vacation in El Cajon Valley, one of the most noted of California, famous for its Muscat grapes and Valencia raisins. There are in this valley nearly two thousand inhabitants, of whom about one hundred and fifty are school children and a large number children from school age downward. All of these, adults and children, eat grapes and guavas (the latter fruit having more seeds than the grape) every day and many times a day, during the season—a period of three months and over.

I have just taken an average-sized bunch of these grapes, such as a man would select at the table, and carefully counted the seeds. There were from one to five seeds in each grape (average three or four) and ninety-five in the bunch. At a guava festival (similar to your Eastern strawberry festivals) a saucer of guavas will contain four hundred and thirty-three seeds. These vary from the size of a pin head to a grape seed, and are as hard as a stone. Seeds and all are swallowed by every one. I know that school children eat two and three times as many grapes as I took, so I said to one of the school boys, about fourteen years of age: "What is the 'dose' of grapes for you school boys—a bunch as large as this?" First a queer look of contempt came over his face, followed by a smile, as he said: "Why, doctor, we boys and girls eat grapes until we can't get another one down, and that just about lasts us until recess." "Well! do you discard the skin and seeds?" "No; the teachers do, but with us boys everything goes except stems."

The next day I drove past the high school, located at the edge of a very large vineyard. The bell had just rung for the close of recess, and the children came running in from among the vines, grapes in hand, munching away for dear life, proving the boy's statement.

It is entirely within bounds to state that the average school child will swallow from one hundred to three

hundred grape seeds daily (one to three teaspoonfuls), for weeks at a time, during the grape season, and the rest of the population will eat in proportion.

Now, what is the practical outcome of this? I drove over to Dr. C. M. Johnson, formerly of New York State, who for many years has had all of the medical and surgical practice of the valley, and asked him, in a casual way, how many cases of appendicitis he had had of late years. He said that there had been none. I then asked for cases of peritonitis—because formerly cases of appendicitis were considered as cases of peritonitis—but to this again came a negative reply. Then followed a careful conversation with Dr. Johnson, and it was most evident that not only had there been no cases of appendicitis or of peritonitis in this grape-eating community for many years, but that the health of the valley was unusually good during the three or four months of the grape season. This report was also confirmed by two well-educated ladies of the valley, who were conversant with most of the cases of sickness here.

Now these statistics, gathered in this practical way, ought to relieve all anxiety and allow the free use of the desirable seed fruits, which add so much to the general health.

A CASE OF FRACTURE OF THE CRICOID CARTILAGE.

By GEORGE B. STORY, M.D.,

PORTLAND, ORE.

On December 22d, I was called to see S. E. O——, a mill hand, aged thirty-two years, who while at work about fifteen feet distant from a large circular saw had been struck on the right side of the neck by a piece of wood projected from a log which was being sawed.

Arriving about thirty minutes after the accident, I found the patient sitting up in a chair, the breathing being difficult and stridulous in character. At frequent intervals he coughed up large quantities of frothy mucus and blood. The countenance was extremely pale, and there was distinct emphysema of the neck and lower portion of the face. When first seen he was able to speak in a weak but very high-pitched tone of voice, but complete aphonia quickly supervened.

I was told that a splinter of wood had entered the neck, and after an exceedingly hasty examination I found a wound on the right side of the neck, from which there was but a trifling amount of hemorrhage. This wound was about an inch in length, and situated midway between the right clavicle and the right half of the inferior maxilla, over the sterno-cleido-mastoid muscle. It proved to be superficial and in no way connected with the larynx. The patient was then ordered to be removed to the hospital, with the view of doing either intubation or tracheotomy as soon as possible. He had been carried but a short distance toward the hospital before he expired.

A few hours after death an autopsy was performed, which revealed the wound of the neck to be only about one-quarter of an inch in depth. There was an area of ecchymosis extending along the lower border of the right side of the inferior maxilla. The entire body was emphysematous. The eyeballs protruded and the pupils were dilated. There were also bruising of the pneumogastric and recurrent laryngeal nerves and a fracture of the left side of the cricoid cartilage, extending through the attachment of the crico-thyroid muscle, or, in other words, a fracture of the cricoid cartilage by contrecoup. There were also emphysema, œdema, and a more or less hemorrhagic infiltration of the glottis. All of the viscera were in a state of acute congestion, the venous heart being enormously distended.

Asphyxia was the immediate cause of death, being induced by œdema, hemorrhage, emphysema, and spasm of the glottis, accompanied by shock. I was unable to determine which of these conditions was the most influential in causing the asphyxia.

A CASE OF DERMATITIS VENENATA DUE TO SNOW-ON-THE-MOUNTAIN.

By GEORGE THOMAS JACKSON, M.D.,

PROFESSOR OF DERMATOLOGY IN THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY.

Snow-on-the-mountain is defined by the Standard Dictionary as "a spurge of the western United States, sometimes cultivated for the curious, white-margined leaves around its flowers." Its botanical name is given as Euphorbia marginata. A great many of this family of plants are well known to possess acrid qualities, and to produce vesication and inflammation when applied to the skin. White ("Dermatitis Venenata," Boston, 1887) names several species as giving rise to dermatitis, but does not mention the one that produced the trouble in this case. So far as I have been able to ascertain, there is no report of this plant being dangerous to handle, and, as there seems no doubt that it did give rise to the inflammation of the skin in this case, it seems proper to report it. Gray, in his "School and Field Botany," describes the plant as follows: "It grows wild on the plains of the United States west of the Mississippi River. Leaves pale, ovate or oval, sessile, the lower alternate, uppermost in threes or pairs, and broadly white margined. Flower cups with five white petal-like appendages behind as many saucer-shaped glands."

The subject of the poisoning is a gentlewoman who is very susceptible to drugs of all sorts, whether applied to the skin or taken by the mouth, and had been poisoned often by both the poison ivy and the poison dogwood. The poisoning took place in the country where she resides in the summer, a place that is peculiarly free from poisonous plants. As she had not walked off her own grounds for several days before the dermatitis set in, and is positive that she had not come into contact with poison ivy or dogwood, both of which she knows well by sad experience, there seems to be little doubt about the sequence of events now to be narrated.

On a certain Tuesday in September of 1896, a neighbor presented to the patient a bouquet of snow-on-the-mountain, the stems of which were well wrapped up in paper. The donor said at the time that she had been told that the plant poisoned some persons, and therefore she brought the bouquet herself, rather than send it by one of the children of the patient. As the flower was beautiful, it was put in water and set on the mantelshelf. During the day, which was cool, a fire was burning on the hearth, before which the patient sat. She became warm and sweated freely. The next day her face felt hot and uncomfortable, and soon began to swell. From then on the swelling, redness, and vesiculation steadily increased. The eyes were closed, and the patient felt so ill that she thought of the possibility of erysipelas. Shortly after the face became swollen the same dermatitis showed itself on the hands and ankles, the swelling of the hands being so great that they could not be used, while the feet became so painful as to render walking difficult. The inflammation was at its height in about four days, and then subsided, but it was several weeks before the skin returned to its normal condition.

The patient asserts that there was far more pain associated with this form of dermatitis than with that due to rhus poisoning, and that the swelling and vesiculation were the worst she had ever experienced.

FACIAL PARALYSIS WITH NO LACHRYMATION.

By G. D. MURRAY, M.D.,

SCRANTON, PA.

Mary O'Neil, aged twenty-six, domestic, presented the following history: Four weeks ago she was taken with a severe pain in the neck, near the angle of the jaw, which continued several days. At the end of the third day she noticed the paralysis. The unusual feature of the case is that on the paralyzed side there is no lachrymation and the eye is dry. I believe this is the second case of the kind on record. Goldzieher has reported a similar case, with the exception that in his case the velum palati was paralyzed.

A FATAL CASE OF SANTONIN POISONING IN AN INFANT OF ELEVEN MONTHS.

By J. S. TAYLOR, M.D.,

ORANGE, N. J.

On the afternoon of March 20th I was called to see a baby suffering from "convulsions." The parents were Italians of the poorer class, and as I have several times seen convulsions in Italian babies under eighteen months, resulting from the gastro-intestinal irritation produced by the ingestion of macaroni, liver, and confections of different kinds, I was prepared for something similar in the present instance.

The infant was an unusually large, fat, healthy-looking boy of eleven months. Besides a promiscuous diet of bread, meat, soup, and potatoes (the baby showed especial predilection for the latter), the mother was in the habit of giving it a mixture of condensed milk and water, in the proportions of one to five, as her supply of breast milk was exhausted. There was a history of a convulsion accompanying indigestion six months before. With that exception the child had always been healthy. The present indisposition dated from two days before my first visit. The child had been fed freely on potatoes, and in the course of some hours became fretful, gave evidence of abdominal tenderness, and toward night had a convulsion. The mother administered santonin—"a little on the end of a teaspoon, ever so little"—and repeated it on the morning of the day of my visit, which was paid late in the afternoon. The child had a second convulsion after the first dose of santonin, but no more.

On examination I found great general abdominal tenderness, but rather more marked in the right iliac region, where there was distinct dulness on percussion. Lungs and heart normal. Respiration shallow and rapid; pulse full, tense, and slightly increased in rate; temperature normal. Patient unconscious. Slight icterus. Pupils normal. Convulsive movements of hands, arms and legs, and head on manipulation, especially on making slight pressure over the abdomen. The bowels had moved but twice from the santonin.

I prescribed a tepid bath every morning, absolute restriction to milk diet, and five powders one hour apart, containing each one grain of milk sugar and one-tenth grain of calomel.

I called early on the morrow, expecting to find the child better or else that something more definite had developed. The stools induced by the mercurial during the night were three, and of spinach color instead of yellow, as the first ones were. The abdominal tenderness had disappeared, and there had been no more convulsions. It had fed eagerly from the bottle and taken sips of cool water when offered, but at other times lay in a profound stupor, with eyes tightly closed and hands gripped. The temperature was now 102° + F., and the jaundice had increased somewhat, though it was not even yet conspicuous. There was profuse and constant flow of saliva from the mouth. The pulse had become rapid and weak, and the respirations continued shallow, labored, and rapid. On again examining the thorax, fontanelle, abdomen, limbs, pupils, nothing amiss could be discovered. I ordered a suitable amount of carbonate of ammonium in spearmint water as a stimulant, gave directions about the bath, fresh air in the overheated, unventilated room, and requested to be called at once if alarming symptoms appeared.

Without having been summoned, I called in the evening. The mother reported that while the amount of golden-yellow urine had been noticeably large up to the time of my morning's visit, the child had passed none since. It had sweated profusely all the morning, but the skin was now harsh and dry. I discovered slight puffiness of the eyelids. It no longer drank readily from the bottle, and lay perfectly still and showed no sign of consciousness when the mother, pursuant to my orders, changed the child's position from time to time as a prophylaxis against œdema of the lungs. I immediately put the infant in a hot bath, which was followed by a hot pack. When a handkerchief wrung out in cold water was laid over the infant's head, it opened its eyes and cried for the first time in twenty-four hours. After copious sweating had been produced, I began the administration of minute doses of digitalis, acetate of ammonium, and acetate of potassium. No urine was passed, and on the morrow, March 23d, at 8 A.M., the child died.

In the absence of any increase in the intracranial pressure as evidenced by the fontanelle, in the absence of vomiting, in the absence of bloody stools, serious cough, râles, dulness, and there being no paralysis in any limb, I made a diagnosis based on the following facts: History of incautious administration of santonin on two successive days, prolonged stupor, jaundice, increased flow of urine followed by suppression, profuse salivation, convulsive movements, elevation of temperature. In the three days of illness the child had lost no flesh, and, except for the icteric hue and the slight œdema of face at the close, might have passed for a healthy infant.

If this interpretation of the symptoms was correct, the lesson as to the danger of the administration of santonin to infants is emphatic, and druggists should sell it, and worm candy and vermifuges, of which it is an ingredient, with great caution, always specifying that it shall not be given to a child under three or four years old. The toxicity of the drug even in small doses is very great in infants of a year or more, as evidenced by the fatal result in this case, in which in favor of recovery was the fact that the child was robust, hearty, well developed, was soon relieved of pain in the intestines, that it took its nourishment well, and that it was able to survive for twenty-four hours a complete suppression of urine, and to survive for nearly three days the ingestion of two poisonous doses of santonin. It is to be regretted that the exact number of grains administered cannot be determined, but it could not have been less than two or three grains, to judge by the estimate the mother gave me by putting some sugar on the end of a spoon.

"The Practitioner," edited by Malcolm Morris, is one of the most pleasing examples of high-standard journalism that comes to our exchange desk.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL SURGERY.

Stated Meeting, April 12, 1897.

W. W. VAN ARSDALE, M.D., CHAIRMAN.

Lipoma Resembling a Tail; Spina Bifida.—DR. B. F. CURTIS presented a female baby three months old, a photograph, and the specimen removed, a lipoma of the shape of the appendix vermiformis and situated over the sacrum, presenting a resemblance to the fancied human beings with a tail. Further, there was a spinal bifida in the sacro-lumbar region, with the cord in the sac, and in the lipoma was a distinct mass of cartilaginous tissue, which, no doubt, was originally intended to close in the gap. The cord made a U-like bend into the sac just at the beginning of the cauda equina, and was attached to the sac by a rather broad mesentery. Its separation was somewhat difficult. No nerve symptoms were present before or after the operation.

Tuberculous Peritonitis Cured; Tuberculosis of Hernial Sacs Persisting.—DR. CURTIS presented a boy under ten years of age, who, five months ago, began to have symptoms which led to the diagnosis of tuberculous peritonitis, enlargement of the abdomen, loss of appetite, loss of weight, irregular temperature, fluid in the abdomen, etc. He was treated with guaiacol and creosote and the tuberculous peritonitis had seemed to disappear, and the general health had improved. But double scrotal hernia was present; the hernial sacs were evidently tuberculous, presenting hard masses at the bottom of the scrotum, while the testicles themselves were healthy.

Plastic Operations on the Face.—DR. CURTIS also presented two patients, showing to what extent gaps left by operations on the face could be filled by a flap of suitable shape, cut out on the face and shoved around into place, thus avoiding the necessity for skin grafting. One patient was a girl with a nævus, of the hairy, pigmented form, larger than a silver dollar, encroaching on the ala nasi. The other patient was an aged woman with epithelioma of the lower eyelid. In both the diseased area was removed, and the gap filled by circular flap brought in from the face.

Osteoplastic Resection of Sternum for Retrosternal Dermoid.—DR. WILLY MEYER presented a young man who, when sixteen years of age, had had intermittent pain in the right ear, neck, and sometimes in the shoulder. A swelling appeared above the clavicle, and when he was twenty-one years of age he visited a clinic in his country, Austria, where the tumor was aspirated and drainage was established above the clavicle. On a subsequent occasion an opening was also made below the clavicle. His pain returning and the opening continuing to discharge, the patient visited Dr. Meyer while in this country. Dr. Meyer recognized restrosternal dermoid, as had also been done in Austria; he made an osteoplastic operation in part, by dividing the sternum through the first intercostal space, and with the hook lifted the upper portion of the sternum and excised the accessible part of the dermoid. The main wound closed and the painful symptoms disappeared. Through the sinus in the sternum hair could still be withdrawn.

Radical Operation for Femoral Hernia.—Dr. Meyer also presented a woman on whom in November, 1896, he had performed Fabricius' operation for femoral hernia on the right side. There had been no recurrence, but a similar hernia existed on the left side. Dr. Meyer described the operation, said he had not found it difficult in any of the three patients upon whom he had performed it, and thought it was to be recommended. In introducing the sutures, one must feel the pubic bone with the needle in order to know that he had grasped periosteum.

Severe Injuries of the Spine; Recovery without Operation.—DR. PEARCE BAILEY presented four patients illustrating severe injuries of the spine without fatal issue and with partial disappearance of symptoms subsequently; no operation. The first was a man forty years of age, who, some years ago, had sustained a heavy blow on the back, causing dislocation in the lower dorsal region, paraplegia, loss of sphincter control. Two years ago he was still unable to walk, but had since recovered power of locomotion, being able to go about on crutches. There was still dropfoot. He could retain his water for the most part.

In the other three cases the injury was in the cervical region. One was that of a man of fifty who had sustained a stab wound just below the axis, partly dividing the cord and causing motor paralysis on one side and sensory paralysis in large degree on the other. The patient still had spastic paralysis, but was able to go about with a cane. The third was an old case, that of a man who had fallen from a wagon, striking the back of the head, causing unconsciousness and dislocation of the fifth cervical vertebra. He was unable to move the body, had no control over the rectum for a year: sensation had been markedly impaired, but had returned. The patient now had difficulty in getting about with crutches, and presented evidence of degeneration of both pyramidal tracts on both sides, with atrophy of hand muscles. The reflexes were exaggerated, as they were also in the other cases. The fourth case was that of a young man who had struck his head on diving from a height into shallow water, evidently causing hemorrhage in the upper cord. He did not lose consciousness, but lay abed three days, unable to move the limbs. He began to walk after four weeks. At present the right leg was normal: the left one was weak, and on walking showed spastic rigidity. The knee reflex was increased. There was some stiffness in the hands, most marked in the left hand: the little finger was nearly paralyzed. The evidence was strongly in favor of a slight hemorrhage in the region of the first dorsal vertebra, chiefly on the left side.

Result of Implantation of Bone Chips Five Years after Operation.—DR. CHARLES L. GIBSON presented the patient, a young man of eighteen, who, in 1891, was operated upon at St. Luke's Hospital, at which time the head of the diseased tibia was chiselled out and the cavity filled with bone chips, the soft parts being united over the wound by suture. After a time the patient acquired good use of the limb until the spring of 1896, when he entered Dr. Gibson's service with the old wound discharging. Cutting down, he removed a considerable amount of the old bone chips, which he found entirely unchanged, buried in loose tissue and detritus. He curetted the cavity freely. As it showed no signs of filling up after some weeks, he freshened it and nailed the soft parts to the bottom. The flap united to the bone and there had been no further trouble. Two nails had been used, one of which was removed after the fifth day to relieve dangerous tension, the other one after the tenth day. The cavity in the bone was now covered entirely by skin or cicatricial tissue. It was expected to become shallower as time passed. He believed general experience had been unfavorable to bone chips.

A Case of Successful Bone Grafting.—In the absence of DR. A. M. PHELPS, DR. WALKER presented his patient, a man who had fallen in 1888 and sustained fracture of the upper part of the humerus. Eleven months subsequently he entered a hospital, where an

incision was made down upon the fragments and they were wired together, but without successful result. He subsequently came under the care of Dr. Phelps, who took small bone fragments from the patient's patella, placed them in the gap, and put the arm up in a splint: bony union took place, and the man recovered with a strong arm.

Dr. Curtis said he had seen a case like Dr. Meyer's two years ago, it being evidently one of dermoid cyst behind the sternum. It occurred in a child, with a history of abscess, which had been opened two or three times, and a sinus remained in the sternum about the third rib. The microscopical examination showed one side lined with skin, the other with columnar epithelium. It was not connected with the bone.

Dr. Weir remarked that Dr. Meyer's case was another in the direction of opening up a new field in surgery. Very recently he had read an article by Milton on the splitting in two of the sternal cartilage, separating the edges, and introducing the fingers. In this manner he was able to reach the heart, feel the bifurcation of the trachea, palpate tumors, etc.

Dr. B. Sachs said with regard to the cases presented by Dr. Bailey that they were not cases in which it was at all certain that surgeons or neurologists would have recommended an operation. He thought we should distinguish between cases in which the injury had resulted only in the production of unilateral symptoms, and those in which it had been followed by bilateral symptoms. In the former the extent of the lesion in the cord must be quite limited, too limited to be found and successfully treated. In at least three of the cases presented by Dr. Bailey, he thought an operation was not indicated.

Dr. Weir said, with regard to use of bone chips, that he could recall cases in which, after three to five months the chips had come away, and were in as good condition for use in other cases as originally!

Antistreptococcus Serum; Report of Six Cases.—Dr. R. F. Weir read a paper in which he gave the histories of six cases of septicæmia treated by antistreptococcus serum, with but little if any benefit. He pointed out that in 1895 Marmorek, connected with the Pasteur Institute in Paris, reported four or five cases of virulent erysipelas which recovered under the use of serum. Other successful cases were reported in Paris, but Charpentier's conclusion from a study of forty puerperal cases was not in its favor. Probably there were no ill effects from the injections. The amount of the fluid injected had varied greatly, ranging from two to ten cubic centimetres, and in one case Dr. Weir had injected in the course of the day as much as one hundred and twenty cubic centimetres. His first case was one of ileo-lumbar abscess. The temperature when the abscess was opened was 99 F. A few tubercle bacilli were found in the fluid. The temperature rose on the fifth day, there was streptococcus and staphylococcus infection. Septic symptoms continuing, serum from Paris was used. It was concluded that the fall in the temperature, improvement in general condition, and recovery were due to making counteropening and freer drainage, and not to the antitoxin. The second case was one of chronic suppurative ostitis of the femur with secondary involvement of the knee. Operation in December, 1896. Only slightly turbid serum was found in the joint itself. After the operation staphylococci appeared in abundance, while previously only tubercle bacilli had been found. No impression was noted from serum injections. The thigh was amputated in January. The third case was one of carcinoma of the breast; amputation by the Halstead method, septic infection, treatment by antistreptococcus serum, no change, death. The fourth case was one of compound fracture of the thigh; involvement of the knee-joint, suppuration, amputation, serum injection, no improvement. The fifth case was one of general extensive purulent peritonitis from appendicitis; no benefit from the serum, death. The sixth case was one of perforative appendicitis; general suppurative peritonitis, operation, use of serum, the only effect being on the pulse, which fell to 60. The circulatory effects disappeared when the serum was discontinued. The patient succumbed on the fifth day after the operation.

In his remarks Dr. Weir said that most of the German writers had expressed an opinion adverse to the effects of the serum. But Aronson had pointed out that the serum lost its value if kept beyond a certain age. Marmorek and Baginski had reported good results from its use in scarlet fever—prevention and disappearance of glandular enlargements, etc. Remarks were also made upon the varying effect due to different kinds of pus-producing germs and of streptococci. Mention was made of Dr. Lilienthal's case and of Dr. Gerster's experience, which had been more favorable. Dr. Weir thought it was fair to draw the conclusion that Marmorek's serum had a good effect in erysipelas and probably in scarlet fever; that its value had yet to be proved in puerperal sepsis: that it was worthy of further trial in surgery.

Dr. Lilienthal was asked to open the discussion. He thought there ought to be a more accurate method of dosage than by cubic centimetres. As with diphtheria antitoxin, it would be desirable, if possible, to grade the dose by antitoxin units. The entire technique seemed to be in its infancy. The eight cases in which he had seen it used led him to think it had a great future.

The chairman, Dr. Van Arsdale, wished to put on record two cases of general septic peritonitis with recovery after operation and the use of streptococcus antitoxin. One was a case of appendicitis in a schoolgirl; laparotomy, abscess found, also general purulent peritonitis; insertion of drainage tubes, use of the serum, recovery. The other case, diagnosticated as general peritonitis, was found to be due to gangrene of the gall bladder; sero-purulent peritonitis present, drainage established, serum used, recovery. In these cases he had used from six to nine cubic centimetres of streptococcus antitoxin at a dose.

SECTION ON GENITO-URINARY SURGERY.

Stated Meeting, April 13, 1897.

Ramon Guitéras, M.D., Chairman.

Cancer of the Testicle, Cord, and Omentum.—Dr. Eugene Fuller presented a sausage-shaped mass, about two inches in diameter by five inches in length, consisting of the testicles, cord, and a piece of omentum, which constituted one carcinomatous tumor. The disease had extended up from the testicle, and had involved the omentum back of the internal ring, apparently by proximity. When he began the operation it was his impression that the tumor was a hæmatocele, the result of a kick received about a month previously, and that the tumor had undergone inflammatory changes. The pathologist had examined it and pronounced it sarcoma. The inguinal glands were enlarged and were removed. The man recovered and left the hospital. It was the only case known to him in which a cancer of the testicle had extended up and attached itself on to the omentum in this peculiar way.

Report on Catheterization of the Ureters in the Male (Seven Cases).—Dr. Willy Meyer read the paper (see page 613).

A Difficult Procedure.—Dr. Samuel Alexander thought the author had presented the subject as based

on his own experience in a fair and conservative way. One might, however, obtain a false idea of the ease with which the ureters could be catheterized, if he could judge from his own experience and observation of that of others. Dr. Alexander had tried to catheterize the ureters in four cases, and had succeeded in only one, using Casper's cystoscope. The successful case proved to be one of tuberculosis of the kidney, in which he performed nephrotomy and drained the kidney. Pus had been obtained by catheterization from both ureters, and in it were tubercle bacilli, yet after draining the one kidney the urine from the other cleared up. In the other cases he had seen the ureteral orifices, but had failed to enter.

Dr. F. K. Otis thought that a cystoscope constructed with the mirror at the outer instead of at the inner end would be easier to use than Casper's or Nitze's. Instrument makers here and in Paris had thus far failed to carry out his suggestions, although the theory, he thought, was correct and could be made practical. With such an instrument one could gain direct entrance into the ureteral orifice.

Dr. Frederic E. Sondern remarked as follows:

"Through the kindness of Dr. Willy Meyer, I have had for examination the specimens of urine obtained from the cases he has mentioned.

"It is for the consideration of such examination of urine obtained by ureter catheterism in the male, as compared with those made without the use of the separate analysis, in other words, an analysis of the bladder urine in similar cases, that I would intrude on your time for a few minutes.

"The difficulties presented by an examination of bladder urine in an endeavor to make a diagnosis of the surgical diseases of the kidney are manifold, and to infer the presence of a healthy kidney in addition to the diseased one is generally not possible without error, even in the most typical cases.

"Surgical diseases of the kidney being so frequently associated with primary or secondary affections of the bladder, the resulting bladder elements in the urine tend to hide the structures desired for diagnosis of the renal lesion.

"The large quantities of bladder pus, mucus, and groups of epithelial cells thus make it more difficult to find a few casts, tubular plugs of pus originating in the kidney, elements of pseudoplasm, pathogenic organisms, such as tubercle bacilli, gonococci, etc., and to differentiate groups of pelvic and other renal epithelial cells, to say nothing of the fermentation frequently begun in the bladder, which, if marked, as so frequently is the case, is apt to change the renal elements so that they cannot be recognized at all. The latter difficulty has been somewhat reduced by the use of the centrifugal apparatus, as I described in the *Medical Journal* of February 25, 1893, by means of which a specimen can be examined immediately after it is passed, and before the fermentation has been allowed to proceed.

"Let me cite a few points: Take, for example, a case in which a diagnosis of pyelitis has been made. The question is: To what extent is the parenchyma affected and have we a normal kidney on the other side? Urinary analysis, carefully done, without going into details, shows that we have to deal with a pyelitis. We find, say, some hyaline, epithelial-studded and possibly a few granular casts, and a practically normal daily excretion of urea. Have we a badly affected parenchyma on one side, with a normal one on the other doing the excretory work? Or have we simply a hyperæmia of the parenchyma secondary to the pyelitis, both kidneys doing normal work? Or have we a bilateral pyelitis with hyperæmia only of the parenchyma of each kidney? In other words, shall we consider a nephrotomy or a nephrectomy indicated in this man? In many instances it is well to know which before operation. From the point of view of the clinical microscopist, I have given these points much attention, and must conclude, as do others, that every specimen of this kind offers the same difficult problem.

"The separate analysis of urine from each kidney, in connection with the clinical data, makes such a complete and positive diagnosis absolutely unequalled by any procedure which has hitherto been at our service, and justifies a conclusion as to the functional activity of each organ which before has never been possible in the male.

"Such separate examination always decides whether the pathological process is unilateral or bilateral, and, with a record of the excretory power of each kidney in addition, we have the cardinal points in forming the indications or counterindications to surgical procedure. While we have been able to do all this in the female, Dr. Willy Meyer's paper fully demonstrates how successfully the same has been done by him in the male, which is a long step in the direction of improvement in the diagnosis, indications for treatment, as well as safety for the male cases of surgical kidney.

"As to the analysis of specimens obtained by ureter catheter, the fact that this procedure collects urine only as it is voided by the kidney, and therefore consumes not a little of the operator's time, and, in not a few instances, the pathological renal lesions calling for its employment are associated with more or less irritable conditions of the bladder, for the sake of both operator and patient it is essential to minimize the time of collection, and, therefore, to employ methods of analysis requiring the smallest amounts of urine which will at the same time be consistent with thorough work. I have been able to satisfy myself of the efficacy of the following technique, which I take the liberty of recommending under the circumstances cited. While I have found that six cubic centimetres form the smallest practicable amount required, it is, however, possible to use even less by carefully diluting the amount at hand, as would be indicated if for some reason a larger amount could not be obtained; and if ten cubic centimetres can be secured the work is even more easily done.

"For the purpose of collection I use two glass tubes with stoppers ground in, marked respectively 'Right' and 'Left.' These, after thorough cleansing, are sterilized in the usual manner and placed in a small box for safe transportation. On the back of the latter is a label calling for information as to the time required to collect the contained quantity from each kidney, and such other remarks as may be of value. Granted that we have six cubic centimetres in one of the sterile tubes, or, as before stated, if the amount is smaller, that an accurate dilution has been made, my method of procedure is as follows: This entire amount is poured into the receptacle of a Westphal's specific-gravity balance; and I may state that the apparatus is a very accurate one, far more so than the better class of urinometers. It is not possible to obtain one of the latter that will work with anywhere near such small quantities of fluid as we are considering here.

"After noting the gravity indicated by the balance with the use of a series of weights, the sediment of the whole quantity is obtained by means of a centrifugal device, for which purpose one of the many forms of apparatus now on the market may be used. I believe better results follow a speed not excessive and continued for a longer period than otherwise.

"The sediment thus obtained is sufficient not only for the routine microscopic examination, but after this has been made the same deposit can be used for staining for pathogenic organisms, or such other pur-

poses as the case in question may indicate (chemical tests to corroborate diagnosis of crystalline or amorphous deposits, etc.).

"The remaining specimen is then carefully poured through a small filter, and after the reaction has been determined at least five cubic centimetres remain. Of this quantity one cubic centimetre is used for Heller's cold nitric-acid test for albumin, or Tanret's, or the ferrocyanide-of-potassium test, as the analyzer may prefer; one cubic centimetre for Esbach's picric-acid test to corroborate one or other of the former. If albumin has been found, the remaining three cubic centimetres are then boiled and the former filtered off.

"One cubic centimetre is then used for the relative determination of urea, which I think is a most important point. Half a cubic centimetre properly diluted serves for the sugar test, for which at present I prefer the Whitney reagent, principally on account of the small amount of urine required and the fact that a quantitative result is obtained at the same time. Deducting shrinkage, one cubic centimetre now remains, which can be used for the approximate estimation of the chlorides present, or for one or other chemical test which the condition in question may indicate.

"After the specimen from each kidney has been thus manipulated and the results have been noted, it is an easy matter to draw logical conclusions as to the condition of each organ.

"Bacteriological researches by means of cultures made from the specimens, collected in the sterile tubes in the aseptic manner in which surgeons are in the habit of working, may be of much value in determining the etiological factors of the pathological conditions in question.

"To recapitulate, the points on which information is desired are the following:

"Do the specimens from each kidney differ from one another in the following, and to what extent?

"1. Quantity. Is there a unilateral polyuria, anuria, or diminished excretion in quantity?

"2. Color.

"3. Odor (as would be the case if there were a fermentation in the renal pelvis).

"4. Reaction.

"5. Specific gravity.

"6. Deposit.

"7. Quantity of urea and chlorides excreted in a given time, being the means of determining the comparative excretory power of each kidney.

"8. Presence or absence of albumin and sugar.

"9. Microscopic examination. (*a*) Evidences of the affection of the parenchyma, to be considered in connection with the amount of albumin and the relative excretion of urea and chlorides. (*b*) Evidences of the condition of the renal pelvis, pyelitis, simple catarrh, etc. (*c*) Evidences of a pyonephrosis. (*d*) Etiological factors, elements of pseudoplasm, pathogenic organisms, evidences of stone.

"Dr. Willy Meyer has pointed out the cardinal features of the specimens obtained from male patients, so I will not repeat them here. Let me, however, add the details of a typical examination of the character in question:

"Right kidney: 9 c.c. obtained in 14 minutes. Odor, slightly offensive. Specific gravity, 1.004. Urea, 1 per cent. Chlorides, ¼ per cent. Albumin, ¼ per mille (Esbach). Microscopically: Pus and tubular plugs of the same: mucus: hyaline, epithelial-studded, and granular casts: groups of epithelial cells from the renal pelvis; casts of sodium urate.

"Left kidney: 11 c.c. obtained in 14 minutes, normal. Specific gravity, 1.008. Urea, 1 per cent. Chlorides, ½ per cent. Albumin, none. Microscopically: No renal elements: no crystalline deposit.

"What conclusions are we allowed?

"1. The left kidney is normal.

"2. Right pyelonephritis, on account of the diminished excretion of urea and chlorides, presence of albumin, and the microscopic picture as stated.

"3. That if all the urine secreted by the kidney during the stated time was caught by the catheter, an estimate of the percentage of the excretory work done by each kidney would be: right kidney, 30 per cent.; left kidney, 70 per cent.

"As a portion of the urine is liable to descend alongside the catheter, there is some liability to error.

"Still, when we learn these details of each organ separately, how simple becomes the matter of diagnosis, how plain the indications for treatment, and how exact is the procedure as compared with former methods in male patients."

Dr. Eugene Fuller said he had made considerable use of Casper's instrument, but had not found ready entrance into the male ureter. He thought it could be improved upon, and the idea suggested by Dr. Otis seemed to him a good one. If a catheter could be introduced into both ureters at the same time it would be an advantage, for the traumatism caused by introducing it into one might cause sympathetic anuria before it was introduced into the other, and thus make it appear that the second kidney was secreting less urine. Among morphological elements, pus was of great value. One might think he had evidence of stone, and yet find none on operating. But such operations not infrequently resulted in relief.

Dr. Bangs would confess to failure in his attempts to catheterize the male ureter. His opportunities, however, had been limited, for he had made the attempt only in cases in which it seemed necessary for diagnostic purposes.

Dr. Ferd. Valentine said he envied Dr. Meyer his success, which no doubt depended upon skill, for Dr. Valentine had himself failed in his first attempts to catheterize the male ureter, although he had had the best instructors, including Casper himself. His first success was with Nitze's instrument, and among the advantages which this possessed were smallness compared with Casper's, the ease with which it could be turned to the right or left when in the bladder, and the fact that, on withdrawing the light tube, one could use it as a straight child's cystoscope.

Dr. Meyer said, in closing, that when the mouth of the ureter was farthest away in the cystoscopic picture, almost invariably the catheter would enter. He regretted that Dr. Otis was spending his ingenuity in improving or inventing instruments for ureteral catheterization, for the ground had been gone over thoroughly already, and the best points had been embodied in the instruments of Casper and Nitze. It would be wiser to employ one's time in mastering the use of these. The advantages expected from Dr. Otis' theoretical instrument would be more than offset by important disadvantages. For instance, one could not view the whole bladder through a straight instrument —only the picture immediately ahead; whereas with the other instruments an area was illuminated as large at least as a half-dollar. Dr. Meyer had limited his work to office patients and those whose consent precluded the possibility of a suit at law. He preferred Casper's instrument somewhat to Nitze's. He had never been successful with Brown's.

Malignant Disease of the Penis Sembling Fibro-Sclerosis.—Dr. Alexander repeated the principal points in the clinical history of the case which he had related in the discussion on Dr. Taylor's paper on fibro-sclerosis of the penis, read at the February meeting. Afterward the pathologists presented their reports on the tumor. It would be remembered that the man was troubled with upward curving of the penis

during erection; that there was a small lump on the dorsum of the penis, which on removal measured about two and one-half centimetres in breadth and length, involving the corpora cavernosa. It was examined by Dr. E. K. Dunham, and there was a question whether it was carcinoma.

Dr. E. K. Dunham demonstrated the microscopical appearances on the board, and expressed the opinion that it was endothelioma, and this opinion was concurred in by Dr. Johnson, Dr. Young, and Dr. Prudden. Dr. Pollitzer thought it was cancer, but of epithelial, not endothelial, origin.

Surgical Suggestions.

Immunity from Infection.—Dr. Stimson says that ahbitual immunity from infection creates an operative confidence that may lead to a neglect to give full weight to such warnings or contraindications as might be found in the probable severity of the operation, or in the deduction of the patient's vitality, especially in malignant disease.

Surgical Treatment of Focal Epilepsy.—Drs. Sachs and Gerster (*American Journal of the Medical Sciences*, October, 1896), in a paper on this subject, conclude as follows: 1. Surgical interference is advisable in those cases of partial epilepsy in which not more than one year, or at the utmost two years have elapsed since the traumatic injury or the beginning of the disease which has given rise to the convulsive seizures. 2. In cases of depression or other injury to the skull, surgical interference is warranted, even though a number of years have elapsed; but the prospect of recovery is brighter the shorter the time since the injury. 3. Simple trephining may prove sufficient in a number of cases, and particularly in those in which there is an injury to the skull or in which a cystic condition is the main cause of the epilepsy. 4. Excision of cortical tissue is advisable if the epilepsy has lasted but a short time and if the symptoms point to a strictly circumscribed focus of disease. 5. Since such cortical lesions are often of microscopical character, excision should be practised even if the tissue seems to be perfectly normal at the time of operation; but the greatest caution should be exercised in order to make sure that the proper area is removed. 6. Surgical interference for the cure of epilepsy associated with infantile cerebral palsies may be attempted, particularly if too long an interval has not elapsed since the beginning of the palsy. 7. In cases of epilepsy of long standing, in which there is in all probability a widespread degeneration of the association fibres, every surgical procedure is useless.

Uterine Drainage as a Factor in the Prevention and Relief of Pelvic Inflammation.—Dr. R. R. Kime concludes an article in the *Southern Medical Record* of February, 1897, as follows: 1. A uterine tampon is not a true drain and even obstructs drainage in many cases. 2. Capillary drainage is secured by carrying a strip of gauze up into the uterine cavity, not packing it, and then it drains for a few hours only. 3. Gauze cannot act even as a capillary drain when either end or centre is constricted, or when coated with mucus. 4. Gauze, when saturated with serum, unless it contains an antiseptic, forms a hotbed for germ development. 5. Never tampon the uterus in puerperal septic infection except to check hemorrhage. 6. The good effect of a gauze tampon in cases of endometritis and after abortion is not due to drainage, but to its effect as a tampon, *i.e.*, checking hemorrhage, stimulating uterine contractions, prolonging medication of the endometrium, and acting as a surgical dressing. 7. The uterine drainage tube is the most essential factor in the treatment of puerperal infection and the best method of securing drainage when demanded in other diseased conditions of the uterus. 8. It will save more lives, relieve and prevent more pelvic complications than any other one factor at our command.

Ovarian Tumors Complicating Pregnancy.—Dr. Hohl (*Archiv für Gynäkologie*, Band lii., Heft 2) concludes his paper on this subject as follows: 1. Ovariotomy should be performed during the early months of pregnancy if possible. Artificial abortion may be produced in cases in which the tumor is intraligamentous, or is firmly adherent, so that an operation would be difficult; puncture should not be considered. 2. During labor the tumor should be replaced, if possible, under anæsthesia; in case this does not succeed, puncture may be resorted to, with subsequent vaginal incision, if necessary. A Cæsarean section is indicated in the case of solid tumors, when the child is living. Ovariotomy may be performed immediately after, or it may be postponed until the puerperium. It is not justifiable to perform ovariotomy during labor. 3. If performed during the puerperium, the operation should not be done later than the second week.

The Antiseptic Value of Iodoform.—Dr. Lomry (*Archiv für klinische Chirurgie*, vol. liii., p. 787) has investigated this question and attempts to explain the different results obtained by bacteriological experiment and surgical experience. He confined his investigations to the pyogenic streptococci and staphylococci, because it is here that the difference exists. He found that iodoform aided the healing process in dogs as in human beings. In vibrio the growth of cultures was markedly diminished by the addition of iodoform to the nutrient medium. The negative results of previous experimenters are due to their having employed culture media in which iodoform is insoluble. In various kinds of serum in which iodoform is slightly soluble, the effect is very appreciable and explains the action in suppurating wounds. It was also shown that the virulence of the micro-organisms is diminished and their toxins are partly neutralized by iodoform, and instead of injuring leucocytes iodoform actually stimulates phagocytosis. But since it is not bactericidal, ordinary aseptic precautions should not be neglected, and clean iodoform should be used. Iodoform dressings should be renewed daily, so that leucocytes which have done their work may not remain as food for surviving microbes.

A New Method of Operating for Hydrocele.—Surgeon Lieut.-Col. E. Lawrie (*The Lancet*, June 13, 1896) presents the following method for the radical cure of hydrocele: The sac is punctured in the usual way, and after drawing off one-third or one-half of the fluid two drachms of a saturated solution of bichloride of mercury in glycerin are injected into the sac and allowed to remain for from one-half to one minute. The whole fluid is then drawn off. Little pain is experienced, and unless the patient is nervous and takes chloroform he is able to move about immediately after the operation. He may rest for a few days, but must not in any case lie in bed, and in the course of a week he will be entirely well. Provided the physician is careful that his hands, instruments, and injections are clean and free from micrococci when the puncture and injection are made, a uniform result is attained.

Cocaine in Surgery.—The "Codex Medicus" gives some useful suggestions as to the employment of cocaine in surgery: 1. The use of cocaine should not be abandoned because its irrational employment has produced deleterious results. 2. Always make a thorough physical examination of the patient before inject-

ing the drug. 3. It should not be used in cases showing organic diseases of the brain, heart, lungs, or kidneys, or in persons of neurotic diathesis. 4. Children bear it fully as well as adults. 5. The patient should always be placed in a recumbent position prior to its employment. 6. Constriction should be used whenever possible, to limit the action of the drug to a desired area. 7. Use a freshly prepared solution for each case. 8. Distilled water should always be employed, to which phenic, salicylic, or boric acid should be added. 9. A two-per-cent. solution has a better effect, and is safer than solutions of greater strength. 10. Never inject a larger quantity than one and one-eighth grains when no constriction is used. 11. About the head, face, and neck, one-third of a grain should never be exceeded. 12. When constriction is possible, the dose may be as large as two grains. 13. Every slight physiological effect is not necessarily to be taken as cause for alarm. 14. Cocaine does have effect upon inflamed tissues. 15. In case alarming symptoms occur, use amyl nitrite, strychnine, digitalis, ether, or ammonia.

The Conservative Tendency in Surgery.—Dr. Jabez Jackson says: "All along the lines in surgery a conservative trend is apparent. We are now sifting the gems from the sand we have shovelled in past years, and separating the true from the false doctrines of modern surgery. The most precious metals are, in mining, found oft mixed with many that are dross, and no true progress is ever made in life without mistakes along the way. The day of extreme radicalism is passing fast; but, had it never dawned, the sunlight of to-day's conservatism would never have dawned through ignorance's sable cloud."

Deep-Seated Thoracic Aneurisms.—Dr. Clarke (*The Clinical Journal*, December 9, 1896) outlines the symptoms of this affection in the following manner: 1. Pain, which is paroxysmal, sharp, or lancinating in character, often increased or brought on by any exertion: or the pain may be deep-seated, gnawing, burning, or aching in character, especially when the aneurism is eroding the vertebræ. It is generally more or less relieved by rest. The pain may radiate down the arms, especially the left arm, or up the neck, and attacks of pain like those of angina pectoris may be complained of, especially in aneurisms springing from the commencement of the aorta. 2. Dyspnœa, either in the form of paroxysmal attacks closely resembling asthma, or as constant shortness of breath on the least exertion. Dyspnœa may be due to pressure on the recurrent laryngeal nerves, or on the trachea or large bronchi, and is then often accompanied by stridor, unilateral or bilateral. 3. Cough. The cough sometimes comes in violent paroxysms, with the characteristics of the cough which is caused by the presence of bronchiectases, ending in retching or vomiting, and the expectoration of a quantity of watery mucus or of muco-purulent matter, which may be slightly fœtid. Or general bronchitis may be present. Or the cough may be due to pressure on the laryngeal nerves, and has then a peculiar brassy or ringing character. 4. Hæmoptysis may occur in the form of a coughing up of blood-tinged expectoration or of a more profuse hemorrhage. This symptom may be due to the exposure of the aneurism in the wall of the trachea, and may go on for some time before the final rupture. Sometimes hæmoptysis is due to erosion of the tissue of the lung. Any hæmoptysis in aneurism is a serious symptom, because we can never precisely know the exact conditions present. 5. Dysphagia. It must always be borne in mind that a bougie should not be passed into the œsophagus for dysphagia, until it has been ascertained from the analysis of the symptoms and physical signs that the cause of the dysphagia is not likely to be an aneurism. Otherwise the result of passing the bougie may be the rupture of an aneurismal sac, which when it presses upon the œsophagus has often a very thin wall.

Carcinoma Uteri.—Dr. Montgomery advises extirpation of the uterus through the vagina when the disease is confined to the uterus walls and the surrounding tissues are not involved. He advises abdominal hysterectomy when the disease has extended beyond the structure of the uterus, as it facilitates the removal of the entire mass, the observation of the position, and evasion of the ureters. He advises ligation of the internal iliac arteries after ligation of the ovarian arteries, if the broad ligament or the vaginal walls are involved.

Horsley's Antiseptic Wax.—This preparation consists of beeswax, seven parts; almond oil, one part; and salicylic acid, one part. Professor Keen introduced this preparation into Jefferson Hospital several years ago, and uses it extensively to arrest bleeding from the bone during operation. After removal of a growth from the jaw, as an exostosis or an epulis, the bleeding can be controlled by this application. The wax is of great service in bleeding from diploe or cancellous bone.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

HOSPITAL ABUSE—THE REFORM SOCIETY—REPORT OF VISITORS APPOINTED—ALLEGED INCREASE OF INSANITY—SPECIAL REPORT OF THE COMMISSIONERS—X-RAYS SOCIETY—INFLUENZA.

London, April 9, 1897

The new Hospital Reform Association is forging ahead under the able piloting of Mr. Garrett Horder. But it is a troubled sea on which he has embarked and already signs of storm are visible. A memorial to the Royal College of Physicians, asking it to undertake an investigation into the subject of hospital reform, has been adopted, but it requires great faith to anticipate anything from that venerable body, whose rulers have most of them complacently profited for years (indirectly of course) from the system which needs reforming. In the mean time the society has adopted a report prepared by Dr. Knowsly Sibley and Dr. E. A. Snape. These gentlemen were appointed by the society to inquire into the working of the special hospitals of London. They have personally visited forty-one such institutions, making eighty visits, nearly two each. Their report is now before me, and is largely made up from the reports of the hospitals for the year 1895. So far there is not much of interest in it, and the facts were at the service of any one who chose to collect and compare the reports.

It is otherwise, however, with the impressions gathered from interviews with the secretaries and other officials. Most of them were ready enough to give information and discuss the probabilities of abuse and the means of preventing it. Some few were reticent, and one or two refused all information. This is as might have been expected. The relative value of the several institutions may be partially gauged by the facts tabulated in this report, but it will be no revelation to any one who has experience in out-patient hospital work. A very important point brought forward is the extent to which these institutions rely on the patients' payments for a large proportion of their income, suggesting the possibility that these patients

could afford to employ general practitioners. In some of the most unexceptional institutions the patients contribute three times as much as the subscribers, showing how important an item these payments are in the aggregate. There are instances in which from ten to twenty-five times as much is obtained from the patients as from subscribers. On the face of it this is bad. The visitors recommend the appointment of paid inquiry officers, but managers will be reluctant thus to increase expenses. They further recommend a wage limit of thirty shillings a week for single and fifty shillings for married people. They propose to send a letter to every member of a staff of a hospital, to enlist their interest. Further they recommend the abolition of subscribers' letters. No great objection will be taken to this, for the production of these letters is seldom rigidly enforced. Finally they propose that consultants should reduce their fees for cases sent to the hospitals for an opinion by general practitioners. I think this would be a mistake and lead to unpleasant complications. No fee ought to be taken for anything done at the hospital, and the proposal is on the down grade. There are plenty of consultants who would be pleased to meet a general practitioner's views as to the fee his patient could really afford. Why, then, introduce him to the hospital?

Considerable anxiety is evinced by the public as to the alleged increase of lunacy and some important organs in the press have fostered the alarm, a process easy enough by the careless quotation of statistics. If the number of persons in asylums now, and the number a few years ago, be compared, of course there is a considerable difference. The population has increased as a whole, and all sections with it. That is the first point. Then the better accommodation that has been provided, and the ease with which the poorest can obtain the benefit of treatment in asylums, have induced among all classes, but especially the lower, a readiness to avail themselves of these benefits which could scarcely have been anticipated. Also there remains a reserve of cases outside official knowledge, from which there is a steady and probably increasing flow toward asylums. Among other causes may be named greater accuracy of registration; extended views as to what constitutes insanity requiring confinement; increased density of town populations and decrease of home industries, making it more and more difficult to care for cases in their homes; increased admissions of temporary cases, such as delirium tremens.

When all these and other points have been allowed for, are we to accept the alarmist's notion that there is such a frightful increase of insanity, and that it is due to the pace at which we live in this generation? Our lunacy commissioners think not, and have issued a special report on the subject which is as assuring as their previous utterances. They circularized the superintendents of asylums as to their opinions on the question, and asked for facts and figures on which these opinions were based.

Out of sixty-two replies received, ten admitted some increase and one writer attributed it to the prevalence of influenza in his district. In this view he is supported by Dr. Clouston's last report of the Edinburgh asylum. Of the other answers, thirty were to the effect that there was no increase, and twenty-two that no definite conclusion had been reached. The statistics in this report show that the increase of insanity is almost confined to the pauper class. The absolute increase in numbers of this class admitted to asylums is very considerable, and perhaps the ratio to the population may have recently increased, but former reports up to the last show that the ratio has been stationary for the last five years. The causes mentioned above seem sufficient to account for the apparent increase, and there is no justification for some of the sensational statements that have been circulated.

A skiagraphical society has been formed, the moving spirit being Dr. David Walsh, of the Western Skin Hospital. Scientific as well as medical members are to be admitted, which seems sensible enough, and with Dr. Walsh as honorable secretary the professional users of the *x*-rays are not likely to be neglected.

Influenza has abated and the deaths for the week are below the average for the seven years in which it has prevailed. The mortality from respiratory diseases as a whole continues greatly below the average.

IS CONSUMPTION CONTAGIOUS?

To the Editor of the Medical Record

Sir: In the decision of this question it would appear that the following facts should have an important influence:

In the Brooklyn Home for Consumptives there have been treated, during the fifteen years of its existence, twenty-two hundred and eighty-six patients. The number of employees outside of the staff is at present twenty-one. Of these, three nurses have been employed there for more than three years. In not one of the persons thus employed has consumption, in any form, developed. On the contrary, although some of them have more or less hereditary tendency to this disease, the health of many has decidedly improved since their employment there.

The sputa are all collected in china mugs, and are cremated. At irregular intervals the walls, which are all painted, are washed with disinfectants. The floors are of closely fitted pine, and rugs are used in place of carpets.

Still, many of the patients are ignorant and careless, and doubtless disobey the prudent regulations of the institution.

All of these facts tend to prove, it would seem, that if the disease is contagious it must be very mildly so, and that such contagion may be readily avoided.

W. S. Searle, M.D.

Brooklyn, N. Y.

THE INSIDIOUS INFLUENCE OF THE SOIL ON HEALTH.

To the Editor of the Medical Record.

Sir: Much attention has been given of late to domestic sanitation. The average modern house has better drainage than the millionaire's mansion of twenty years ago. In most cities plumbing must be executed under official supervision, and the public health has been greatly benefited in consequence.

Not enough thought, however, has been given to the insidious influence of the soil upon health. Dr. Bowditch, of Boston, and Dr. Buchannan, of England, by their simultaneous investigations showed the important relations which ground moisture bears to consumption, and I am inclined to think that the health of the community is more affected by the sanitary state of the soil than by all other influences. This is particularly true of New York, where there is so much made land, and where the soil in many places is made damp by old watercourses and polluted by the leakage from gas, water, and steam pipes. Wherever the earth is turned up to lay sewers or water mains, there is an unmistakable odor of illuminating gas, and the ground everywhere is more or less contaminated. It is well known that illuminating gas will pass through frozen ground and crevices in rock for a long distance, and so will cesspool air. Neither foundation walls nor cement flooring are a barrier to damp or foul air,

while their entrance is accelerated by the suction of stoves and open fireplaces. The well-known experiments of Pettenkofer and Professor Doremus may be referred to in this connection.

The mortality charts of the health board show a close relation between the prevalence of certain diseases and the condition of the soil. In low-lying or saturated sections, typhoid, diphtheria, malarial fever, and other diseases find a permanent home. If Manhattan Island could be thoroughly drained, consumption would undoubtedly diminish.

Our overheated houses are like gigantic cupping-glasses, and any impurities in the soil will inevitably be diffused throughout dwellings. In Bombay the plague has flourished most in houses with floors saturated with dripping faucets and drainage. House plants die if placed in a waterlogged soil, and human habitations, like their occupants, should not have wet feet.

In testing a suburban residence with the smoke test recently, I discovered that cesspool air was being forced back into the house through minute crevices in the soil from quite a distance. In a large apartment house the emanations from surface water in the cellar, heated by an adjacent boiler, rose through the casing around a waste pipe into a bedroom on the tenth floor, and caused malaria among the inmates. When the opening was plastered up, the attacks ceased.

Many like cases indicate that more attention should be given to the effects of such conditions on health. I should be glad to obtain from your readers further evidence to corroborate these observations.

CHARLES F. WINGATE, *Sanitary Engineer.*

119 PEARL STREET, April 20, 1897.

Therapeutic Hints.

Ichthyol as a Laxative.—Dr. Gunsburg reports in the *Bulletin Général de Thérapeutique*, October, 1896, that he has given ichthyol in three-grain pills once, twice, or thrice a day in treating women suffering from various inflammatory affections of the genitalia, accompanied by constipation and dyspepsia. He treated fifty cases with the uniform result that the constipation was overcome without colicky pain or diarrhœa: the appetite improved, and the pain in the abdomen decreased. Dr. Gunsburg suggests that the ichthyol be given in keratin-coated or enteric pills.

Ichthyol in Tuberculosis.—It is reported from the Belleville Hospital, Paris, that good results have followed the administration of this drug in the various forms of tuberculosis. The digestive functions were not disturbed; gastric fermentations were relieved. It is best given in the form of capsules; fifteen to fifty-five grains may be administered daily. The doses should be given before meals. Larger doses, when they could be taken, produced quicker results.

The Effect of Rapid Motion on Children.—Dr. John Madison Taylor, in an article on "Children of Feeble Resistance; Their Care and Management," published in the *Medical Times and Hospital Gazette*, December 19, 1896, says that it is very unwise to submit babies to rapid journeys and the looking out of windows at swiftly passing objects while flying along. He says that he has seen migraine develop apparently through the custom of giving small children exercise in a carriage with a pair of fast horses every day. Certain instances of profound disturbance have been caused by this means, and it is reasonable to infer that a continuance of such measures may produce lasting damage upon so delicate an organ as the eye, and the whole sensitive organism is thus imperilled. It is also unwise to encourage a child to sleep while being driven about. The motion is both regular and subject to sudden irregularities. The persistence of one kind of motion up and down is bad, not only producing unsound sleep, but keeping up a molecular agitation which has little to recommend it. If the infant be sufficiently old to sit up or be held up by the nurse, a strain is put upon the spinal column. Thus continuous mild concussions are administered to the brain and spinal cord; the eye is put upon a strain, thus acting directly upon the brain: an element of excitement is introduced, and physiological irritability is the probable result.

Treatment of Tetany.—The *British Medical Journal* points out that the two indications in the treatment of tetany are to favor the expulsion of toxic substances and to prevent their formation. Calomel meets both these indications, and Dr. Oddo recommends a dose of three-fourths of a grain, or a little more if the age of the child warrants it. Washing out the stomach is also a useful measure, but it must be used with discrimination, owing to the danger of exciting laryngeal spasm.

Laryngo-Pulmonary Phthisis.—Dr. Whaling concludes a particle in the *Journal of the American Medical Association*, February 13th, with the following summary: (1) We are still in need of a panacea in laryngeal phthisis. (2) Trichloride of iodine, guaiacol, and lactic acid are the best local remedies. (3) Good results have been reported from cutting away portions of the diseased tissues and applying lactic acid. (4) Guaiacol, or a solution of morphine, tannic and carbolic acids in glycerin and distilled water are most satisfactory to relieve pain. (5) Cocaine should be resorted to only in extreme cases. (6) Surgical treatment should not be recommended in advanced phthisis. (7) Tracheotomy should be peformed only for the promotion of euthanasia in cases of severe stenosis of the larynx.

Alopecia Areata in childhood is treated by a ten-per-cent. sulphur ointment, containing a little salicylic acid, the scalp is washed with a salicylic-acid soap brushed with a soft brush wet with a 1 to 1,000 bichloride solution. For the actual plague itself strong bichloride solutions are employed, 1 to 100 or 1 to 50, with the addition of ten per cent. of acetic acid.—FEULARD.

Phthisis.—Dr. Winternitz (*Deutsche med. Wochenschrift*) says that cold water is the best means of fortifying the system against phthisis, because of its general tonic effect. In cases already advanced cold water decreases the fever and night sweats, increases the body weight, and lightens and diminishes the cough and expectoration and other subjective complaints. The local condition is improved, and there is a lessening or disappearance of the bacilli. These statements Dr. Winternitz has proved by clinical work.

Repose in Bed for the Insane.—*La Presse Médicale* reports that in St. Petersburg this system of rest has been introduced on a large scale for noisy, excitable patients, and cases with psychic depression and general debility. Neither force nor narcotics are used, but the patients are simply accustomed to remain in bed, although they take their exercise as usual. It is not necessary to keep them in separate apartments, and the economy of space and trouble to attendants render the practice a great convenience.

The Treatment of Disabled Joints Resulting from So-Called Rheumatoid Disease.—Dr. Goldthwait (*Boston Medical and Surgical Journal*, January 28th),

in an article on the above subject, draws the following conclusions: Of the cases classed as rheumatoid arthritis two types are described, clinically, which for convenience are designated rheumatoid arthritis and osteo-arthritis. The differentiation between the two types is of the utmost importance in the treatment. Rheumatoid arthritis is much more acute than the other; it occurs in middle and advanced life, but early in life as well. During the acute stage the joints show a spindle-shaped swelling, which finally subsides, leaving the joint much atrophied and usually ankylosed. In these cases the joints should be manipulated after all acute symptoms have disappeared, and the character of the manipulation is of much importance. Cases are reported showing the results of treatment in this class. Osteo-arthritis is a much more chronic condition, occurring only in middle life or old age, and is characterized by a proliferation of the articular cartilage, with the formation of nodes about the joints. These cases should not be manipulated, as any injury or undue violence results in a more rapid development of the cartilage. It is this tendency which explains the impairment of function which so often results after comparatively simple injuries to a joint. Protection and immobilization in such cases are of importance.

Acromegaly.—Dr. Marinesco has reported three cases to the Académie de Médecine, in which he has treated acromegaly with tablets of pituitary-body extract. In this disease he finds the pituitary body constantly hypertrophied and altered. There was no diminution of the parts affected, but the headache and neuralgic pains in the limbs were either diminished or disappeared entirely, movements becoming slightly freer and the urine being increased in quanity.

Sciatica.—Inject deeply into muscles near the nerve one to four cubic centimetres of a solution of five grams of glycero-phosphate of sodium in twenty grams of distilled water. It does not produce pain, and recent cases end in recovery after a few days, while inveterate instances are improved.—Billard, *Gaz. des Hôp.*, January 21st.

Pertussis.—

℞ Tr. bellad.	10 gm.
Phenacetin	5 "
Spirit. frumenti	15 "
Ext. fol. eastaneæ fl.	60 "

S. For infants of one year, ten drops. For infants of ten years, one drachm every two to six hours.

—Lancaster.

Dyspepsia Accompanied by Acne.—To excite glandular secretion:

℞ Potass. sulphat., Sodii sulphat.	āā 0.05 cgm.
Pulv. ipecac., Pulv. strych. ignatii sem.	āā 0.01 "
Sod. bicarb.	0.30 "

For one powder. One such to be taken before each meal, the St. Ignatius bean being a stimulant to the muscular fibres of the stomach. Lebon.

Tincture of ignatia amara may be taken in fifteen-drop doses after each meal.—Mitour.

Ichthyol for Insect Stings.—Dr. W. Ottinger (*Wiener medizinische Blätter*, December 8, 1896) tells of his lack of success with ammonia, but says that he has found ichthyol an admirable remedy. He has tried it for the stings of flies, gnats, bees, and wasps, and has found that it causes the phenomena of inflammation to subside quickly and surely. He attributes its effect to vaso-constrictor action. He advises applying it pure in a thick layer, but it may be used in the form of an ointment.

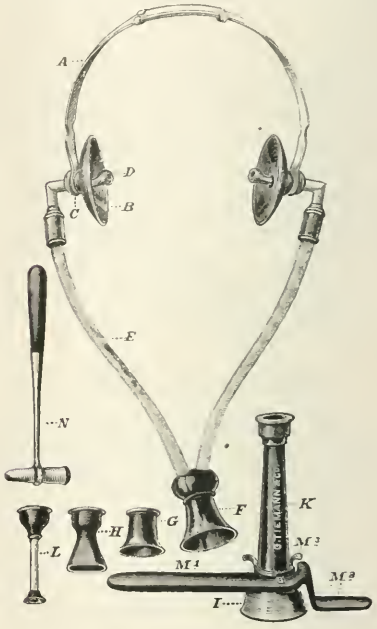
New Instruments.

AN IMPROVED STETHOSCOPE WITH AN ATTACHABLE PLESSIMETER.[1]

By S. A. KNOPF, M.D. (Paris and Bell., N. Y.),
NEW YORK,
FORMER ASSISTANT TO PROFESSOR DETTWEILER, FALKENSTEIN SANATORIUM

The last few years have produced, to an almost bewildering degree, an increase in the number of instruments designed to auscultate the chest and abdominal cavities. Numerous stethoscopes, auscultoscopes, phonendoscopes, ampliophones, microphones, etc., have been presented to the profession, each inventor claiming the superiority of his own instrument.

In presenting to you this evening an improved



stethoscope and an improved attachable plessimeter, I wish to preface the description of the instruments by saying that I have not sought to make a stethoscope which will have the acoustic powers of the phonendoscope, which sometimes so exaggerates the sound as to make it almost misleading, nor a plessimeter which will equal the finger of the experienced percussor possessing an acute and trained hearing. In thinking out the mechanism of both instruments I have been guided by the desire to combine and increase, if possible, the good which is found in the best existing instruments, and to do away, as far as may be, with the bad that is found in many. But, above all, I have sought to make the stethoscope, as well as the plessimeter, practical and useful, not only for the great specialist and clinical teacher, but also for the busy every-day practitioner.

The stethoscope is composed of a steel headband, earplates, eartips, tubes, and various chestpieces.

The headband (*A*) consists of two pieces, forming an adjustable spring, the steel so tempered as to allow of its being bent to fit the exact conformation of the cranial vault of the auscultator. This head-

[1] Read before the New York Academy of Medicine, section on general medicine March 16, 1897.

band does away with the downward pull on the ears produced by the ordinary Cammann stethoscope, in which the whole weight is supported by the external auditory canal.

The earplates (*B*) are concave, and are united at their external convex surface to the head band by a ball-and-socket joint (*C*), so as to fit any one, whatever the conformation of the external ear. These earplates, which, thanks to the adjustability of the headspring, can be brought very close to the external meatus of the auditory canal, serve to protect the auscultator, as much as possible, from hearing sounds coming from the exterior, which may creep in if the eartips alone have to fulfil that office, as is the case, at least to my knowledge, in all binaural instruments now in use. The earplates also receive the pressure of the spring, thus relieving the external auditory canal, and no pressure comes upon the eartips when in position.

These eartips (*D*), which have the typical curve, may or may not be used, since they are not fastened to the tube. When inserted they are movable in all directions, to fit the depth and conformation of the external auditory canal. Without impairing the accuracy of the sounds transmitted, they can be introduced just as far as the auscultator desires, in order to avoid the unpleasant sensation which a foreign body always produces if deeply inserted in this delicately lined passage. You will all agree with me if I say that this often amounts to real pain, especially when using a stethoscope in which the strong front spring is attached to heavy steel tubes which add their weight to the pressure of the spring. Clinical teachers, hospital physicians, and all who do a great deal of auscultating, become sometimes real sufferers from the prolonged use of the otherwise excellent instrument usually known as Cammann's binaural stethoscope.

By making the headband serve at the same time as a spring, the need of heavy metal tubes which serve in the ordinary binaural stethoscope for the attachment of the steel or rubber front spring is done away with. The transmission tubes (*E*) with chestpieces are attached to the earplates, which in their turn are suspended from the headband. The fact that the portion of the stethoscope connecting earplates and chestpieces is entirely of flexible tubing makes this instrument more pliable than those having metallic tubing for the attachment of the front spring. This also permits the transmission tubes to be shorter, and thus the sound is brought more directly to the ear. To intensify as much as possible the acoustic powers of the instrument, I chose for this flexible portion a wire tubing with airtight covering, which has also the advantage that it cannot take a sharp bend, as the soft-rubber tube may do when the chestpiece is moved from side to side, thus closing the passage to the sound.

Besides the usual chestpieces for lung (*F*) and heart (*G*) auscultation, I had an oval piece (*H*) made for intercostal auscultation; a soft-rubber one (*I*) to use for children and sensitive adults, with whom the pressure of the ordinary hard-rubber chestpiece proves sometimes painful; and a long intermediate piece (*K*), which will come handy whenever the auscultator wishes to be at a greater distance from the organs to be examined, as in gangrene of the lungs, for instance, fetid bronchitis, ozæna, etc. Its most important use, however, is in connection with instrumental percussion, of which I will speak directly. To meet the modern demand for an instrument of precision for tracing organs, I had this little steel delineator or localizer (*L*) constructed in such a manner that it is attachable to the stethoscope. I do not claim for this little delineator the acuteness and precision of the localizer of the Italian instrument or of the phonendoscopes recently patented in the United States, but I believe it will answer in the majority of cases (after all such cases are relatively rare) in which it is necessary or advantageous to outline an important organ by auscultation.

Coming now to the subject of instrumental percussion, that is to say, the use of the plessimeter alone or in conjunction with the stethoscope, I would like to state the reasons which may justify bringing this instrument again before the medical profession. Just as it is possible for the physician who carries, sometimes for hours, the tips of the strong-springed Cammann stethoscope in his ears, to get an otitis, it is easy for one who percusses a great deal during the day to get a periostitis of his left index or whatever finger he habitually uses as plessimeter. To any one who is called upon to percuss a good deal I would recommend the use of the plessimeter as a prophylactic measure.

The plessimeter (*M*) can be used with or without the stethoscope. Thanks to the long convenient handle (M^1) and the little bent part separating it from the plessimeter proper (M^2), it can be more easily manipulated than most of such instruments now in existence. But, as I stated above, neither this nor any other plessimeter will ever do as well as the experienced living finger, with which one can feel even the degree of elasticity of the tissue underneath. However, I claim that, in conjunction with the stethoscope, the inexperienced or impaired ear distinguishes more readily a lower or higher pitch, and differentiates more accurately between dulness and flatness. As you see, the attachment of the plessimeter to the stethoscope is very simple. The soft-rubber chestpiece with the long intermediate piece is attached to the stethoscope, the little spring of the plessimeter (M^3) encircles the neck of the chestpiece, and the whole is in position. The long intermediate piece (*K*) serves to make the act of percussion more convenient to the auscultator. I prefer to attach the plessimeter to the soft-rubber chestpiece (*I*), so as to be sure not to hurt the patient when striking with the hammer or fingers, especially since the plessimeter is in such close proximity to the chestpiece, although when used with the stethoscope a much lighter tap is sufficient to produce a clear percussion note. As a rule, of course, one should see that the plessimeter and the rim of the chestpiece touch uniformly the surface to be percussed.

To complete the outfit we must, of course, have a hammer. Flint's percussion hammer (*N*), having a steel handle and a soft-rubber head, seems to unite firmness and elasticity, and thus is well adapted for instrumental percussion.

As it is with all new instruments, so will it be with these; and especially with a new stethoscope, one has to get accustomed to its use.

In closing, I wish to thank Messrs. Tiemann & Co. for their great courtesy in so carefully constructing these instruments, until after much experimentation I believe I am in a position to present them to the profession, not perhaps as perfect, but, I trust, as useful, comfortable, and practical.

34 West Fifty-Eighth Street.

Dysentery of the Vermiform Appendix is a name suggested by Golouboff for certain attacks of appendicitis occurring as quasi epidemics. He has observed a number of instances (*Le Sailpel*) in the scholars of a lycée who sat together on the same row of seats; also four cases in another school during the month of March, no instance of appendicitis having occurred in the institution for several years. The author believes in an analogy between epidemic dysentery and epidemic appendicitis, the common microbes of the digestive tube becoming suddenly virulent in each.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 24, 1897:

	Cases.	Deaths.
Tuberculosis	243	118
Typhoid fever	8	4
Scarlet fever	177	13
Cerebro-spinal meningitis	6	7
Measles	235	6
Diphtheria	216	39
Laryngeal diphtheria (croup)	9	0
Small-pox	13	3
Chicken-pox	42	0

Roentgen Rays on Calculi.—The effect of the rays upon renal stone are studied by Dr. James Swain in the *Bristol Medical and Chirurgical Journal* for March. The article is illustrated and in many ways instructive, including a report of a case of renal calculus in which the diagnosis was confirmed by skiagraphy.

Danger in Temperance Drinks.—The *Daily Mail* has been led by the death of a prominent teetotaller from delirium tremens, caused by the excessive use of so-called non-alcoholic beverages, to make an investigation of this subject. One physician is quoted as saying that very many who drink supposed non-stimulants find in so doing an excellent way in which to swallow their principles and their alcohol at the same time, without endangering their reputations as total abstainers. This physician states that there are numbers of persons, in his knowledge, who would not wittingly touch a glass of spirits, and yet who are passing through the slow stages of alcoholic poisoning due to the temperance beverages. He cited the instance of a woman who glories in her principles of total abstinence, and yet she is being slowly but surely poisoned by the alcohol of a certain tonic wine. It is not the cocaine contained in it, but the alcohol which renders it so insidious and fatal. The amount of damage done by this class of drinks is regarded by this physician as appalling. A death in Jersey the other day was put down to the daily consumption of large quantities of seaweed tonic by a man who "never drank."

Marriage by Doctor's Consent.—In a presidential address delivered to the members of the Life Assurance Medical Officers' Association, Dr. Douglas Powell proposed to apply the doctrine of "doctor's consent and approval" to a very personal and delicate set of social affairs. "In the course of our professional work," said Dr. Powell, "we are often consulted, either by individuals themselves or by those interested in them, as to whether they are in a fit state to marry; and a family practitioner is often in some perplexity as to how to advise in this important matter." The word "perplexity," perhaps, hardly does full justice to the situation in most cases of this kind. As a matter of fact, between the parents on the one hand, and the irresponsible and absolutely unscientific young people on the other, the unfortunate doctor is not merely "perplexed," but is not seldom entirely at his "wits' end." If he advises to please the young people, the parents may scowl upon and repudiate him; if he advises to please the parents, the young people will hardly be content without his "head on a charger;" while if he takes the line of high science and future possibility, both parents and young people will alike regard him as an unpractical adviser and a pompous professor of scientific pedantry. What is to be done in a case of this kind? Dr. Douglas Powell says that life assurance, more especially that part of it which is medical, is the way out of the difficulty. Both parents and young people are willing that due provision should be made for emergencies when so serious a business as civilized marriage is in contemplation. In a doubtful case let the young man—and why not the young woman also?—be examined for life assurance. Then the family doctor, and even the occasional consultant, are both saved from a perplexing situation, and an absolutely disinterested and competent third party is called upon to solve the knotty question. If a man or a woman be not in a condition of health to emerge from the assurance specialist's consulting-room with a certificate of average healthiness—in other words, if the assurance doctor cannot pass the examinee as a "first-class life"—then it is at once made clear that he or she, at any rate at the moment of examination, is in no condition to enter upon the marriage state. It is not proposed that an unfavorable result of a first examination shall be a permanent bar to marriage. In such a case let the young man or the young woman submit to a probationary period of health improvement, not of course at the hands of the assurance medical officer; and if the probationary period result in the desired improvement, let the marriage take place, but if otherwise then let it be abandoned. There is only one course more logical than the foregoing, and that Dr. Douglas Powell does not fail to point out. Instead of waiting until two young people have been "engaged" for a more or less lengthy period, and until the time of the marriage draws near, let the physical examination of both of them by an assurance medical officer precede the preliminary "engagement." "Of course," says Dr. Powell—and we do not detect any evidences of a sympathetic tear on the pages of his pamphlet—"of course, in such questions considerations of sentiment will come in," as indeed they will; "but," he adds, "with sentiment we have here nothing to do." It is but too true; and because none, not even the most brilliant of modern physiologists, have succeeded in reconciling science with sentiment in these matters, therefore it is that we are at such a tremendous discount in all manner of daily affairs, and are regarded too often as scientific nuisances, whose great function it is to act the part of "kill joys," and to make life "not worth the living." But although we cannot get the dicta of science carried out in the absolute way in which they commend themselves to such scientific hierarchs as Dr. Douglas Powell, it does not therefore follow that science will continue to be altogether unheeded in this matter. Dr. Douglas Powell's "principles of right marriage," as they may be called, are at present to the multitude nothing more than mere "counsels of perfection." But there are always a few among civilized people who will strive to base their conduct even on "counsels of perfection." Then, as the application of these counsels in practice is seen to justify itself by results, other persons become convinced by facts, and so knowledge is extended, and a scientific principle converts itself into a commonplace of practice. That marriage among civilized people ought to be something more than a mere community of sentiment, that such a union ought not to be entered upon without adequate thought and preparation, not only for the future of the married persons themselves, but also for their probable offspring, surely goes without saying. Men and women are reasoning creatures; it is not for them to mate like the lower animals, without prevision and without preparation. All classes will do well to accept Dr. Douglas Powell's "Principles of Right Marriage" as altogether sound and wise in theory, and as being worthy of the fullest adoption in practice which the present state of civilization will allow.—*The Hospital.*

SOME OBSERVATIONS ON COLLES' FRACTURE BY THE AID OF THE *X*-RAY.

BY EUGENE R. CORSON, B.S., M.D.,

SAVANNAH, GA.

THERE will have to be a new treatise on fractures and dislocations, based on the *x*-ray. There are many surprises in store, many surgical bugaboos will go, and many revelations will simplify much which is still obscure.

I wish to present radiographs of four wrists injured by a fall on the palm of the hand, and all diagnosed and treated as Colles' fracture. I think they are very instructive and will help to clear up certain mooted points in regard to this very common and interesting fracture, about which so much has been written, the treatment of which varies so much, and which is not infrequently followed by poor results, even in the best hands.

I fear that in the reproduction of the photographs some of the finer details will be lost. It is the study of the negative viewed by transmitted light, with all other light cut off, which brings out the finer details. However, I think that even the half tones will pretty well tell their story.

Fig. 1 is the right wrist of a gentleman, aged about fifty, who broke his wrist five months ago. It was set and treated in the usual way, and was followed by considerable deformity and impaired motion. The hand is shifted to the radial side, the ulna overprominent on the palmar surface of the wrist, with an unsightly sinking in over the point of the internal lateral ligament. There is a general thickening of the tissues over the dorsal and palmar surfaces of the wrist. Flexion and extension are much impaired, and the movements of the fingers and grasp of the hand are restricted. Of course, there will be much improvement in this direction, but the unsightly failing of the hand to the radial side, with the sinking in on the ulnar side and the prominence of the ulna on the palmar surface, are there to stay.

The wrist was set and treated by a physician in one of the smaller towns, and the patient consulted a surgeon of national reputation who informed him that the bone had been set crooked, and that the only thing to do was to have the bone rebroken and reset. This the patient declined to do, but he naturally felt aggrieved with the man who had set his wrist. Now the radiograph shows in this connection two things: first, that the radius is in fairly good position, there being but a slight dorsal displacement of the lower fragment, and that the man who set it is exonerated; and second, that, had an attempt been made to rebreak the bone, it would have made matters worse. The mistake made was ascribing the deformity to the bones, when it was the ruptured ligaments which were the cause of the trouble. This seems to be the general idea among the profession, and the *x*-ray, I think, shows quite conclusively that, if we can hold the hand in a proper position and control the effects of the ruptured ligaments, the fractured bone or bones will take care of themselves.

A closer inspection will show the styloid process of the ulna broken off, though still held in position by the ligaments and surrounding tissues; that the fracture of the radius has been transverse and comminuted a good inch above the articular surface, with the styloid process of the radius broken off and tilted out, and, though there is evidence of a tearing up of the periosteum above the fracture on the ulnar side, this membrane has held the fragments in fair position, with only a slight dorsal displacement of the lower fragments. This is shown by examining the wrist and the difference in the planes of the articular surfaces of the radius and ulna, shown in the radiograph. Throwing them out of their common plane makes one appear longer than the other, though in this case it is the displaced ulna which produces most of the disparity. The callus which has been thrown out is evidently being quite rapidly absorbed. It has extended between the radius and the ulna, and evidently proves that the anterior and posterior radio-ulnar ligaments have been completely torn. There is evidence, I think, that the periosteum has been considerably torn up by *arrachement*, favoring thus Pilcher's view of the case. The carpal bones hold well their natural positions in relation to each other, but the entire carpus has shifted to the radial side. It also appears as if, in the jamming down of the carpus upon the comminuted fragments of the radius, more or less

FIG. 1.—Comminuted Colles' Fracture; Styloid Process of Radius broken off and tilted out; Callus being rapidly absorbed; Styloid Process of Ulna broken off; Displacement of Hand and Ulna.

fibrous adhesion had taken place between these fragments and the semilunar bone and a portion of the scaphoid. The extension of the callus between the radius and ulna explains the limited pronation and supination.

This radiograph shows us, then, that, though the fracture of the radius has been a very bad one, the periosteum and surrounding tissues have kept the fragments in pretty good position, and that the fracture *per se* is of secondary consideration in the production of the deformity. The displaced ulna and slipping of the hand toward the radial side are the chief deformities in the case, and they are due to the stretching or rupture of the anterior and posterior radio-ulnar ligaments, the internal lateral ligament, and the triangular fibro-cartilage, and more or less involvement of the anterior and posterior carpal ligaments. The blurring of the carpal bones, in such contrast to their distinct outlines in the radiograph of the normal wrist (Fig. 5), shows the fibrous thickenings in all these tissues following the accident.

Fig. 2.—Transverse Fracture of Radius one inch above Articular Surface, with perfect reposition of fragments; Styloid Process of Ulna broken off; Displacement of Hand and Ulna.

The wrist was set and put up according to the text-books, with straight splints on the flexor and extensor surfaces of the forearm, held midway between pronation and supination, with the hand allowed to drop by its own weight toward the ulnar side.

Fig. 2 is another instructive radiograph of the left hand, seeming the right in the illustration, with a history of two injuries at the wrist, both diagnosed as Colles' fracture. The patient is a lady, aged sixty. The first injury occurred two and one half years ago; the wrist was put up in plaster for twenty-one days, and little deformity followed. The second injury occurred one and one-half years ago, and under chloroform was examined and corrected by me. I made out a fracture of the radius, one inch above the articular surface. The swelling and pain from the injury were intense. I used a felt splint, with the forearm midway between pronation and supination, and kept on the dressings twenty-one days. When I removed the bandages, the ulna on the palmar surface was overprominent, though the hand seemed in fairly good position, but gradually the shifting of the hand to the radial side increased. This is an important and significant fact. I do not think the radius was broken in the first injury, and the ligaments were probably only strained.

A study of the radiograph shows the following: the styloid process of the ulna has been broken off and since quite absorbed, the anterior and posterior radio-ulnar ligaments probably torn loose, the internal lateral ligament torn, and the triangular fibro-cartilage displaced; the ulna has shifted toward the palmar surface as well as toward the radius, the bones overlapping one-fifth of an inch: the radius gives evidence of a transverse fracture a good inch above the joint, with two cracks running into the articular surface; the lower fragment has tilted somewhat toward the dorsal surface of the wrist, so that the articular surface is overprominent in the radiograph: again, the lower fragment has been tilted to the radial side, shifted there by the carpus and the muscular pull; the shifting of the whole hand toward the radial side is well marked. As the case now stands, flexion and extension are slightly impaired, while pronation and supination are reduced one-half.

Fig. 3 is the right hand of the same patient, injured by a fall on the palm of the hand twelve years ago, diagnosed as a Colles' fracture, and treated by hot water and a roller bandage. It was evidently nothing but a severe sprain, without any fracture. It is interesting to note, however, that the strain or rupture of the internal lateral ligament has caused the hand to fall slightly to the radial side, as shown by studying the relationship of the ulna and its styloid process to the cuneiform and pisiform bones (see normal wrist in Fig. 5).

Fig. 4 is perhaps the most instructive radiograph shown. It illustrates a case of fracture of the styloid process of the ulna, without any fracture of the radius, so far as can be made out—a rare condition according to Hamilton—but, judging from its frequency in Colles' fracture, must be more common than generally supposed in pre-Roentgen days. There are certain interesting conditions present. The internal lateral ligament has been torn, and probably, too, the anterior and posterior radio-ulnar ligaments, and the triangular fibro-cartilage displaced, for the articular surface of the ulna touches the cuneiform bone, being widely separated in the normal condition. The ulna has tilted toward the palmar surface of the wrist and toward the radius.

The injury occurred two years ago, and was treated by me. The patient, a woman of fifty-five, in falling, struck the ulnar side of the little finger and hand against a projecting ledge, and the fracture and ligamentous rupture were probably caused by *arrachement*, so much dwelt upon by Pilcher. The parts were much swollen and very painful, and almost entirely on the ulnar side. In this case there is also considerable falling of the hand to the radial side, as well as the overprominence of the ulna on the palmar surface of the wrist. This radial shifting of the hand is not so apparent in the radiograph, as the patient, in placing the palm firmly on the plate, was directed to keep the hand as straight as possible, and has somewhat corrected the deformity. The subluxation of the ulna, however, is shown by this bone appearing somewhat in advance of the radius.

Fig. 3.—Displacement of Hand and Ulna from severe Sprain; no Fracture of Bones.

There were so much swelling and inflammation at the time of the accident, and such severe pain, too, that the case was treated for eleven days by hot fomentations and no support but a roller bandage. The wrist was then placed in a short anterior and posterior splint, semi-prone, with the hand allowed to drop by its own weight toward the ulnar side.

This seems to me a very interesting and significant case. Though the fracture has been quite insignifi-

cant—simply the styloid process of the ulna—the ruptured ligaments have produced considerable deformity, quite equal in extent to the typical Colles' fracture, and with the accompanying thecitis so char-

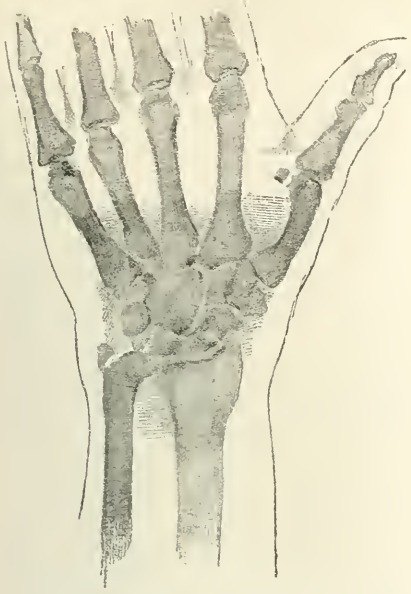

Fig 4.—Displacement of Hand and Ulna with Radius intact; fracture of Styloid Process of Ulna the only Injury to the Bones.

acteristic of this injury. Looking at the hand, one could easily take it for a Colles' fracture, and yet the radius was not broken.

A careful study of these four cases taken at random, being the most accessible at the time, seems to me to yield some very interesting facts, and to point to a line of treatment quite at variance with the present modes. The conclusions I have arrived at may be thus briefly stated:

1. That in the typical Colles' fracture, with the great strain on the internal lateral ligament and the anterior and posterior radio-ulnar ligaments, and a displaced triangular fibro-cartilage, one or all of these ligaments are stretched or torn, and that the styloid process of the ulna is frequently broken off, if not by direct violence, at least by *arrachement.* The surgeon who first called attention to this fact was Nélaton, but I believe his assertion has not been generally accepted. He considered this fracture the rule rather than the exception.

2. That the fracture of the radius near the joint, provided the fracture is transverse, which is usually the case, gives rise *per se* to but little trouble, as it is in the large majority of cases impacted and held fairly well in position by the periosteum. Even in comminuted fractures into the joint and in oblique fractures, and even if there is much displacement, they are easily reduced by gentle and continuous extension and a certain amount of flexion, abduction, or adduction, as the case may be. Hamilton has strongly insisted upon this point, and he is borne out by museum specimens. Radiograph No. 1 certainly bears us out here, as there was undoubtedly a comminuted fracture into the joints, and yet the fragments have been held in good position. Whatever callus is thrown out is quite rapidly absorbed from the great vascularity of the parts. In Fig. 1 the large callus evidently thrown out originally is, after five months, quite well absorbed. A year would probably be sufficient to dissipate it. I mean, of course, in strong subjects and not too old. Hamilton had never noted non-union.

3. That by the rupture of the internal lateral ligament and the anterior and posterior radio-ulnar ligaments, and a displacement of the triangular fibro-cartilage, the ulna slips toward the palmar surface of the wrist—probably under the influence of the strong anterior carpal ligaments—and under the same influence slips toward the radius, showing in the radiograph an overlapping of the two bones. I cannot see whereby this displacement could occur from muscular action, unless, indeed, that over-estimated muscle, the pronator quadratus, is to blame.

In the radiograph of the normal wrist (Fig. 5), the articular surfaces of the radius and ulna form a continuous curve, and a distinct line of separation is seen between these two bones. In the radiograph of Colles' fracture, or where the ligaments have been torn, this line is broken, and the two bones are seen to overlap slightly. In the natural state they are separated by a synovial membrane, and this the *x*-ray beautifully brings out, as well as all the synovial sacs of the carpus.

4. It seems also quite evident, as pointed out by Hamilton, that the slipping of the hand toward the radial side, producing the most prominent and unsightly deformity in Colles' fracture, is due to the stretching or rupture of the internal lateral ligament principally, aided by the rupture of the anterior and posterior radio-ulnar ligaments, and perhaps other ligaments in addition, in conjunction with the much stronger muscular pull on the radial side of the hand. There is a figure in Gray's "Anatomy," the full significance of which never occurred to me before, giving a transverse section through the wrist, showing the annular ligaments and the canals for the passage of the tendons. It is reproduced in Fig. 6. If we ac-

Fig. 5.—Normal Wrist.

curately bisect this figure, it is beautifully shown how the muscular pull predominates on the radial side. This must have considerable influence in intensifying this deformity.

5. That the treatment of Colles' fracture must be principally a treatment of the sprain and ruptured ligaments, and every effort must be made to keep the different bones in position which have lost their ligamentous supports. The fractured bone or bones will take care of themselves.

6. That the present methods in vogue are based in a measure on false premises. Keeping the forearm midway between pronation and supination started with the idea that in this position the two bones of the forearm were kept farther apart, and the pronator quadratus was less liable to pull the fragments together. In Gray's "Anatomy," Fig. 252, p. 402, the artist has shown a fracture of the lower end of the radius, with the upper fragment drawn in contact with the ulna, this latter bone being pulled far upward and inward. It shows how much easier it is to imagine than to ascertain correctly the real conditions present. Hamilton has shown the fallacy of this. The fracture of Colles is too near the joint to be influenced by the pronator quadratus, and a study of the movements of these two bones through the fluoroscope shows strikingly the fallacy of the idea. In the radiographs of the forearm perfectly prone, the radius and ulna are far apart above the radio-ulnar articulation. Again, allowing the hand by its own weight to drop toward the ulnar side has not the slightest influence in preventing the hand from falling to the radial side. On the contrary, it intensifies this deformity. As the hand and carpus move as one, the abduction of the hand toward the radial side would have more influence in overcoming this deformity.

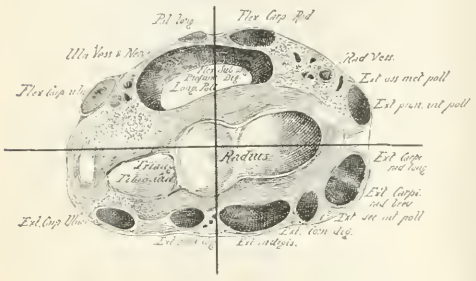

FIG. 6.—Transverse Section through the Wrist, showing the Annular Ligaments and the Canals for the Passage of the Tendons (Gray).

7. As in falling the hand is naturally abducted, the strain on the external lateral ligament is decidedly less than on the internal, and thus the former is less apt to give away. Hamilton, in his classic treatise, largely ignores it, and justly so, I think. Should it be ruptured, too, the falling of the hand to the radial side would be intensified, and allow also the muscular pull on the radial side to increase greatly the deformity. Hamilton reports a case where this probably occurred, and the hand was abducted almost to a right angle with the forearm.

8. These conclusions being admitted, the different results obtained in different and yet competent hands seem to be easily explained. When there is simply a fracture of the radius without tear of the ligaments, the result will be good with almost any treatment. But when there is, in addition, a severe straining or tearing of these important ligaments, the deformity will be more or less marked, according to the severity of the injury. As shown also by Hamilton, a severe strain or rupture of the ligaments without any fracture will be followed by marked deformity. Fig. 4 shows this in a striking way. The only break was in the little styloid process of the ulna, and yet the deformity was considerable, and a good year elapsed before the patient got much use of the hand. This case seems to me a most instructive one.

In 1878 Dr. Louis A. Pilcher published a paper on this fracture, which impressed me at the time as one calculated to better our knowledge of this injury and to aid us greatly in its treatment. He there set forth the importance of treating the sprain, and I have always attempted to follow his advice by reducing the inflammatory symptoms as soon as possible. He contended that the fracture was due to *arrachement* from the excessive dorsal flexion at the wrist. He contended also that by this *arrachement* the inferior fragment is tilted backward; the periosteum on the posterior surface, strengthened by fibres of the annular ligament, is torn from the radius, allowing the inferior fragment to ascend posteriorly, while the superior fragment penetrates the torn periosteum. While this may occur in very severe cases, in the ordinary Colles' fracture it must be rare. I have never met with it. Hamilton, while favoring this explanation in certain very severe cases, thinks it too exclusive, since Pilcher ignores the part played by the internal lateral, the anterior, and posterior radio-ulnar ligaments, and the triangular fibro-cartilage. No one, I think, devoted more careful study to this fracture than Hamilton, and much that he has written is confirmed by the *x*-ray. The value of Pilcher's contribution to me was his insistence upon treating the sprain. The *x*-ray so far bears him out, but it carries us, I think, much further.

9. The important question, then, is: How can we best carry out the treatment of this injury to the ligaments? There are three conditions which seem to me to be called for: (*a*) That the forearm and hand be perfectly prone and in a direct line with each other. In this position only can the ligamentous strain be equalized and the ruptured ligaments evenly supported. Again, I believe that the displacement of the ulna, or any backward displacement of the lower fragment of the radius, can be best corrected and watched in this position. Again, in this position hot fomentations or cold compresses can be more easily applied. I know a country physician, uninfluenced by the text-books, who treats his Colles' fractures prone on a shingle, and who gets as good results, if not better, than those who follow the old methods. (*b*) That the parts should be so bandaged that hot or cold compresses can be used to overcome the swelling and inflammation of the fibrous tissues, that the tendons can have free play, and that electricity, an agent of immense good in all sprains, can be used if necessary. (*c*) That while in from three to four weeks, or even earlier, complete bony union is assured, a much longer time is necessary for ligamentous union, and I should think that twice this time, at least, would be necessary for this purpose. This, I think, was exemplified by one of my cases, where the deformity gradually increased after I removed the dressings on the twenty-first day. I would suggest, then, the following simple bandage: Any displacement of the fractured bone being reduced, I should apply the hand and forearm perfectly prone on a straight splint, slightly padded to fit the flexor surfaces of the forearm, wrist, and palm, extending from one inch below the elbow to the metacarpophalangeal joints. This will permit perfectly free movements of the fingers, a very important part of the treatment.

To overcome the displacement of the ulna toward the palmar surface, I should insert a wedge, made of a roller bandage two and one-half inches wide, and rolled firmly to one inch in thickness, and placed under the lower extremity of the ulna and extending to the pisiform bone. This bridges the ulno-carpal articulation, and forms a *point d'appui* for the roller bandage. Another wedge of the same size, made in

the same way, is placed alongside the radius as a point of counterpressure; this bridges the radio-carpal articulation at this point. A smaller pad, similarly made, may be placed over the dorsum of the radius, also bridging the joint, although it will probably be rarely necessary, as the roller bandage gives sufficient retention.

Taking a narrow bandage, one and one-fourth to one and one-half inches wide, I start it on the ulnar side, over the ulnar pad, and carry it around under the splint to the radial side, and over the dorsum of the wrist to the point of starting, making two turns; then from the radial side diagonally over the dorsum of the hand to the metacarpo-phalangeal joint of the little finger, under the palm of the hand to the corresponding joint of the index finger, and finally across the dorsum of the hand diagonally to the starting-point of the bandage at the ulno-carpal articulation, thus making a figure of-eight; and this is repeated twice. The bandage is then continued up the forearm to the upper end of the splint. The straight flat splint should be broad enough to give one-half inch on each side of the forearm.

This will keep the hand in an exact line with the forearm. If the hand is so placed, it will be found that a straight line through the middle of the index finger will touch the outer edge of the styloid process of the radius. This is a good guide.

A hand so placed and bandaged will show the bones perfectly through the fluoroscope, and this will be an immense help in assuring ourselves that the bones are in proper position. Further, by this simple bandage, we can apply hot and cold compresses, as the case may be, as well as electricity. A rubber dam stall can be drawn over the entire dressing to retain moisture and get the effects of a poultice. I know no simpler arrangement to enable us to reduce swelling and inflammation.

If we can keep the hand from falling to the radial side, can keep the ulna from slipping toward the palmar surface, and the lower fragment of the radius from rising above the upper, we have overcome the chief difficulties of the problem before us. With electricity, massage, lubricants, with proper tendon exercises, and, later, careful efforts at pronation and supination, with ever a due regard to time, we shall have done for our patient all that in us lies. There are undoubtedly cases among the aged and infirm where deformity is bound to follow, in spite of any treatment, but the physician can always protect himself by a prognosis to that effect.

Other and perhaps better retaining and supporting bandages may be devised: the principle of cure must be the same, and the chances are the simpler the bandage the better it is.

I may state that my *x*-ray apparatus consists of a ten-inch induction coil, made by Willyoung & Co., with an adjustable condenser in the base, run by eight storage cells (five ampères, sixteen volts), furnished by the same company. I have been using a "Queen" focus tube, also furnished by this company. The entire apparatus has given me great satisfaction. I imagined in the beginning of my work that a rotary make-and-break was necessary for such a large coil, even when using the current from a storage battery, and with this impression I purchased a rotary make-and-break from Meyrowitz, as suggested in his catalogue. The model sent me does not work with that current. It is with the one-hundred-and-ten-volt current only that the make-and-break wheel becomes necessary, in which case I should advise the Willyoung model, or the model suggested by Dr. Morton, of New York. I have found the App's vibrator on my coil to work admirably.

I am indebted to Mr. W. H. Hoffman, of this city, a skilled photographer, for the development of my plates, which I have found to be a most important part of the process. He believes in a little overexposure, with a very slow developing.

11 Jones Street, East.

REPORT OF A CASE OF PSYCHO-SEXUAL HERMAPHRODITISM.[1]

By C. W. ALLEN, M.D.,

FORMERLY VISITING DERMATOLOGIST, AND GENITO-URINARY SURGEON TO THE CITY HOSPITAL, ETC.

Mr. President and Gentlemen: I regret that I am not enabled to show for your inspection the subject of the following sketch, which I have been asked by Dr. Sherman to present before you.

Viola Estella Angell, as the patient calls himself, applied for admission at the Florence Mission, a shelter for fallen women, with which Dr. Sherman is connected in a professional capacity, and to whom the patient was referred. The dress and general appearances were those of a female, and as such he asked admission.

The history given was that the subject was born in Nova Scotia, in 1874, the youngest of seventeen children; that the mother had been chased by a man and

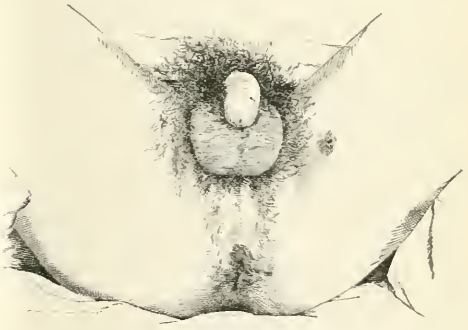

Fig. 1

frightened in the third month of her pregnancy, and that at the time of birth some deformity of the genital organs was made out by Dr. Mitchel and Dr. Murray, who officiated. The father is said to have had a "devilish temper."

Up to the age of fourteen years according to the subject, girl's clothing was worn, when, because of certain changes which had occurred in the appearance of the genitals and because the mother thought the child "would have less trouble in the world as a male," the dress was changed to that of a boy, and as such he was sent to the normal school at Truro, sixty miles from Halifax, where he remained for three years. Here, on account of his effeminate ways, manners, and general appearance, he was called "sissy," and, as he expressed it, "lead the life of a dog" from the taunts and jeers of his school-mates. He left school, and in passing through Halifax was followed by a crowd (which the subject states numbered thousands) calling out that he was a girl in disguise. A policeman interfered and took him to his friends, but did not place him under arrest.

He states that at the age of fourteen, while dressing in male attire, he began to have regular monthly losses of blood by the rectum, continuing for a period of four or five days each time. He states that this continued

[1] Read before the section on genito-urinary surgery, at the New York Academy of Medicine, Tuesday evening, March 9, 1897.

during the time that he was wearing man's clothes and ever since. The blood passes at times through the urethra as well as through the back passage, and occasionally has been attended with sufficient pain to cause medical aid to be sought, and he says that physicians have given treatment for painful menstruation and that their remedies have acted in a way to relieve the pain. He states that for a year or more before the hemorrhages began he was pale, sickly, had a cough, and was thought to be in a "decline." He was also subject to fits of unconsciousness or seizures of some kind, attended with headache, and for three months before the blood first appeared there were almost continuous abdominal cramps. The intervals between the hemorrhages have not been uniformly regular, at times three and at times five weeks intervening.

The statement is also made that urine has always been passed in both ways, *i.e.*, through the penile urethra and by way of the rectum.

The instincts are in every way those of a woman, and it is denied that any manly feelings exist; the penis has never been in a state of erection, nor has there been any discharge through its canal which would correspond to an ejaculation of semen, either in intercourse, in dreams, or in attempts at masturbation. There has been sexual intercourse with men a few times, and always rather against his inclination, but never any desire or attempt at intercourse with women.

He states that having found life at home and in man's attire unbearable, and having a repugnance for man's occupations and an attraction toward the pursuits of women, he left off male dress and ran away from home dressed as a girl.

In Boston he was engaged for a long time as a machine operator with a large number of girls in a factory, until, casually meeting in the streets one day a man from his native town, he was denounced as a man masquerading in female attire, and was placed under arrest. He states, however, that after he had told his story to the police, despite an examination made by the matron of the prison, he was released and went to Philadelphia, where he was employed as a female domestic and associated with women.

After a casual examination, it was decided that the applicant was not a suitable subject for the mission; but, being destitute and friendless, and seemingly desirous of having the question of sex definitely settled, he, was taken to Dr. Sherman's sanatorium, where Dr. Grandin and I saw him together in consultation, and a number of physicians who it was thought would be interested were invited to be present and take part in the subsequent examination. It is for the purpose of eliciting the opinions of these gentlemen and of others in the discussion upon the many interesting features which such instances of sexual psychopathy present, that I have consented to introduce the subject at this time.

Contrary sexuality or perverse sexual feeling, whether congenital in origin, depending upon hereditary neuropathic taint, or acquired as a result of environment, education, and external influences, has such important sociologic, forensic, psychologic, and pathologic bearings, that no apology seems necessary for presenting in this section the report of an instance of pronounced type, especially as it involves points of interest which I trust will receive elucidation in the discussion.

There are two reasons why these cases are not better understood. The first is that application is so rarely made by the subject for treatment, and when the case finally comes under observation it has passed into the stage in which often the lunatic asylum is the only prescription required. The second is that there has been and still exists a decided tendency on the part of physicians to pass by the whole subject of sexual perversion as one too likely to defile the investigator. I trust, gentlemen, that the eye of science may soon discriminate between pitch and that which looks like pitch, and that the hand of science will not hold back when it becomes necessary to touch. Strictly proper cases for the physician's ministrations have been left too much to the care of the magistrate and police, without according to these officials the knowledge they require from us to enable them to do justice at once to the individual and to society at large. Certain perverse impulses can undoubtedly be controlled by treatment better than by incarceration, but until the physician points out the factors upon which to base a differentiation we can scarcely expect the magistrate to decide justly in all instances, as between the criminal and the mentally irresponsible.

The examination of the subject in point gave the following results: Height, five feet ten inches; weight, one hundred and fifty pounds. Head of the Goethe type, the hair receding from the temples, rather coarse and wavy from artificial curling. Evidences of beard kept down by autoepilation; subject says he never shaves. Features—mouth, eyes, and general expression—both in repose and in animation, distinctly feminine. Voice soprano; subject says he has sung in concerts and theatres. The right breast is somewhat larger than the left, but has little about it to suggest gland formation. One hand and one foot approach the feminine type, while the other is distinctly masculine. The limbs, trunk, and pelvis correspond in measurement to the masculine type, and the physical characteristics are for the most part masculine. The pose in standing, walking, and sitting are easy and natural, but essentially feminine; and the manner of sewing and carrying out feminine pursuits suggests a natural bent rather than an acquired condition. The dress is that of a female in the lower walks of life, worn with some degree of carelessness, but showing a pronounced fondness for neat and clean bows, ruffles, and ribbons, finery, and flowers. This fondness for personal adornment with gay colors, while belonging more particularly to the feminine instinct, it must be remembered is occasionally strong in men, especially those of savage tribes.

The subject is slightly hysterical at times. The ego is pronounced. There is a somewhat exalted mental condition, with a tendency to expansive morbid ideas. There is perverted judgment in minor matters, but the psychic anomalies are not marked. The subject is of a rather low order of intellectuality and inclined to indolence, with fondness for poetry, music, acting, fancy drawing, letter writing—the letters showing extravagances of imagination and expression, especially upon topics of love.

Continuing the examination, a well-formed and normal-sized penis and testes were disclosed, with pubic hair of the male type. The perineum was strikingly long, giving the impression that the genitals were seated high up over the pubes. The rectal opening was large, lax, almost if not quite devoid of sphincter action, and surrounded with fleshy tabs, suggesting caruncule myrtiformes rather than hemorrhoidal formation or the remnants of ulcerative action. The condition is well shown in Fig. 1 from a photograph kindly taken and loaned by Dr. H. L. Callyer. A bloody discharge, most suggestive of a menstrual flow, was present at the first examination, and this continued in gradually diminishing amount until the time of thorough rectal exploration several days later, when some blood was still present. The subject explained that this was the terminal stage of one of the regular monthly periods—and, indeed, under inspection it seemed to cease entirely.

By rectal touch nothing definite could be made out.

No uterus or ovaries could be felt, nor did bimanual manipulation disclose any rudiments of female organs.

Through the rectal speculum, which could be distended largely without causing pain, the internal sphincter was found very tight, and resembled in appearance the cervix uteri, with very small external os. Near this, high up, was an ulcerated surface, and near it was what appeared to be an opening of a fistulous tract, through which a probe could be passed for several inches. There was no history of syphilis, but some cicatrices were found near the anus, upon the skin surface, suggesting previous ulcerative lesions.

No discharge of blood was seen to pass by way of the urethra. Under the close scrutiny of two observers, fluid was seen to flow from the rectal opening at the same time as through the urethra, though in lesser amount.

No opening into the bladder from the rectum could be discovered, and a sound passed by the urethra could be traced by rectal touch through the bladder wall at various points, without disclosing any such opening.

A point to which I would direct especial attention was the apparent lack of anything approaching normal sensitiveness in the firm, full-sized testes. The subject claims that they have always been devoid of feeling, and they can be pressed or even pounded without discomfort. I failed to elicit any complaint or indication of normal sensitivenes upon decided squeezing, even when the subject's attention was distracted. There was also apparent lack of cremasteric reflex.

Fearing that he was to be compelled to put on male attire before leaving the sanatorium, he absented himself in the night, leaving behind a note, in which he promised at the earliest opportunity again to resume men's clothing and get along in the world as best he can.

Such, gentlemen, is as much of the history as I am able to give of a creature persenting a type of perversion which is not unfamiliar to you, but which presents certain unusual features. Even in asylum practice it is rare that one finds the male possessed of the delusion that he is a female. The subject of this report appeared to be honestly convinced that nature had intended him for a female; but whether prevarication and deception were not largely employed to make others think the same way, is a question upon which personally I have little doubt. Although it may not have been so in the present instance, I can well imagine a pronounced state of mental hermaphroditism, without marked desires or inclinations for sexual congress of any variety, but rather a desire to engage in a legitimate and law-abiding manner in the pursuits of the sex whose instincts the subject feels.

If there is, as Uhlrichs thought, such a thing as *anima muliebris in corpore virili inclusa*, and coincidently an entire inability to make physiologic use of male generative organs which exist, the possessor should not, in my opinion, be looked upon as an outcast or as a criminal, by reason of such an unfortunate congenital combination.

Are we to believe that in this subject, with the present development of external genitals, there could have been up to the fourteenth year any question of sex? I would look upon this statement as a fabrication. If, however, for any reason, the dress, occupation, and environment were such as described, a lasting imprint may have been made upon the nervous system in the growing impressionable child. Were we in a position to state positively that a congenital deficiency of generative glands had an influence upon the psycho-sexual development, we might here look for an explanation of the psychic state and distorted type in the lack of functional activity of the testes, as claimed by the patient and apparently confirmed by the lack of normal sensitiveness in the organs, a sensitiveness which, as I believe, is always present in sexually normal man.

When we turn to leading authorities for aid, we receive but little in this direction. Krafft-Ebing says that so far as the anatomical and functional foundation for the psycho-sexual constitution is concerned, it is absolutely unknown. In the absence of generative organs of the female which can be made out, a theory of congenital persistence of rudiments, which up to the third month of fœtal life are common to the two sexes, might be invoked to form an anatomical basis for this psycho-sexual hermaphroditism.

Dr. Sherman has suggested that the urachus might have opened into the cloaca instead of into the allantois. If, however, we are to believe that the sexual 's wholly a function of the cerebral cortex we must look upon such instances of perverse sexuality, when occurring spontaneously about the time of puberty, as equivalent to congenital phenomena, since before this time during the earlier years there is supposed to be little or no development of the centre for sexual emotion. Westphal held firmly to the opinion that such instances as the one here under discussion are congenital.

I would conclude with the propositions:

1. If there is here a true delusion of sexual transformation, it is equivalent to a monomania and the subject should receive asylum treatment.

2. If it be an instance of one mentally and sexually degenerate, he should be removed from society and cared for; but not as a punishment.

3. That it is not just to class such a one with the vicious who practise pederasty from perverse inclination. (The psychic personality and mental state of effeminacy here seem to overbalance the perversion as it has to do with acts of homosexual nature. At least, according to the subject's statements, passive pederasty has been practised but rarely, and then against his inclinations. In many reported instances these acts have seemed to be as repulsive as they would be in a normal being.)

4. That if not mentally irresponsible, having been informed by those competent to judge that male attire is the only proper dress, the subject should be placed under arrest if found dressed as a woman. I would ask for discussion upon this point, *i.e.*, the physician's duties in the matter and the lengths permitted him to go in questions of knowledge acquired in his professional capacity.

The Anticipation of Post-Partum Hemorrhage.—Atthill (*British Medical Journal*, March 6, 1897, p. 576) expresses the opinion, based upon a long experience, that ergot, given alone or in combination with strychnine, may be taken by pregnant women in the usual doses for a considerable time, with absolute safety to both mother and child. When taken continuously for not less than three weeks prior to labor, it tends to delay the setting in of uterine action. Its exhibition for some weeks prior to the commencement of labor arrests the tendency to post-partum hemorrhage and facilitates the involution of the uterus, thus also lessening the chance for the occurrence of subsequent uterine troubles, many of which depend upon imperfect involution. Employed in this manner, ergot will not bring on premature labor or induce abortion unless uterine action has been previously set going. In cases of threatened abortion such administration of ergot frequently seems to act as a uterine tonic, and in some cases tends to avert the danger of miscarriage, provided the ovum be not blighted. If, however, the ovum be blighted, and especially if it be detached, ergot usually hastens its expulsion.

TEN YEARS' EXPERIENCE OF THE COLD-BATH TREATMENT OF TYPHOID AT THE BRISBANE HOSPITAL.

By F. E. HARE, M.D., late R.M.O.,

CHARTERS TOWERS, N. QUEENSLAND, AUSTRALIA.

BRAND'S system of cold bathing was commenced on January 1, 1887. From that date to December 31, 1896, every case admitted has been subjected to the operation of this rule, unless distinctly contraindicated.

The results of the first three years of this period have already been published,[1] and the cases therein referred to are consequently included in the complete statistics for the decade.

The results obtained before the introduction of the bath treatment, which have been already published, may here be conveniently reproduced:

TABLE I.

Years.	Cases.	Deaths.	Percentage Mortality.
1882 from May 15th.	147	25	17
1883	273	40	14.6
1884	575	89	15.5
1885	360	49	13.3
1886	464	68	14.6
Totals.	1,828	271	14.8

It is plain that during the expectant period in Brisbane the results obtained differed but little from those of the large hospitals of England and the United States at the present time.

The results of the ten years' bath period are as follows:

TABLE II.

Year.	Cases.	Deaths.	Percentage Mortality.
1887	239	27	11.3
1888	339	23	6.8
1889	595	42	7.0
1890	160	16	10.0
1891	137	7	5.1
1892	104	7	6.7
1893	50	2	4.0
1894	70	1	1.3
1895	69	8	11.6
1896	130	10	7.7
Totals.	1,902	143	7.5

There has occurred, therefore, a reduction in the mortality of the disease of practically 50 per cent.; or, in other words, about 7 of every 100 cases admitted have been saved by the bath treatment. This result harmonizes exactly with the latest conclusion of Osler on this subject. He says:[2] "The cold-bath treatment rigidly enforced appears to save from 6 to 8 in each century of typhoid patients admitted to the care of the hospital physician."

In order correctly to gauge the value of these figures, it is necessary again to refer briefly to the fallacies which tend to inhere in all typhoid statistics. These arise mainly from:

1. Paucity of data.
2. Variations in extension of the term typhoid.
3. Errors in diagnosis.
4. Differences in the age and sex constitutions of the series compared
5. Variations in the severity of the disease in different countries, climates, and districts; and in different epidemics in the same places.

[1] Practitioner, March, 1891.

[2] Johns Hopkins Hospital Reports, 1895

1. Paucity of data would appear to be the main stumbling-block of typhoid statisticians. The possible error due to this cause is found by Poisson's formula. Tested in this way, the expectant series of 1,828 cases shows a possible error of but 2.3 per cent. in its mortality rate. Similarly the bath series of 1,902 cases has a possible error of but 1.7 per cent.; *i.e.*, in any future series of cases equal in number, the limits of the mortality rate will be, *cæteris paribus*, between 9.2 per cent. and 5.8 per cent. Of course, the probable error is vastly less, but either is quite insufficient to account for the fall in death rate.

2. Variations in the extension of the term typhoid are a frequent and serious source of fallacy. In making up the statistics of the first three years, cases which were obviously febricular, together with cases which were apparently typhoid but which convalesced before the tenth day of the fever, were all excluded from the list. The result was that while 1,173 cases appeared as typhoid with 92 deaths, 201 cases of doubtful fever, or 14.6 per cent. of the whole, all of which ended in recovery, were excluded. During the last seven years, however, an even more stringent exclusion has been made. While 1,902 cases of typhoid have been treated during the decade, with 143 deaths, the exclusions of doubtful cases, all of which ended in recovery, have during the same period amounted to 616, or nearly 25 per cent. of the whole number admitted.

3. Errors in diagnosis do not in the case under consideration affect the statistics at all. The lists are prepared from the recorded diagnoses, which are entered only at the discharge or death of the patient.

4. Differences in the age and sex constitution of the series compared. The first is not of great importance in typhoid, except perhaps at the two extremes of life. During the last seventeen months of the expectant period, 1.1 per cent. were under ten years and 4.3 over forty. Of the 1,902 cases in the bath period, 0.7 were under ten and 6.7 over forty. As far as it goes, then, age constitution tells against the latter. Sex constitution in the two series is almost identical. Of the 1,828 cases in the expectant period, 668, or 36.5, were of females; of the 1,902 in the bath period, 714, or 37.5, were of females.

5. Variations in the severity of the disease in different countries and districts do not concern the present inquiry, since all the cases in either series came from the same districts and were subject to the same climatic conditions. There remain only therefore for consideration variations in severity of different epidemics. Without denying the existence of this epidemic influence, it may be permitted to contend that it has been greatly overestimated. It has been shown[1] that in the four complete fever seasons before the introduction of cold bathing, the natural seasonal variations in mortality did not amount (with one exception in which the numbers were inconsiderable) to 1 per cent. — a variation well within limits of error due to paucity of data. Again, on reference to Table II. it will be found that the annual mortality rate varies from 11.6 per cent. to 1.3 per cent. That this, however, is due to arithmetical and not to epidemic reasons, can be easily demonstrated.

The series being sufficiently long to exclude errors due to paucity of data, the variations have practically disappeared; there is instead, as pointed out by Osler, a remarkable uniformity in the results.

If from the whole decade we strike out the first six months during which the treatment was but inefficiently carried out, we have a series of 1,731 consecutive cases, extending over a period of nine and one-half years, with 122 deaths. If now, instead of into

[1] Practitioner, March, 1891.

years, this series is divided into three equal groups of 577 cases each, we obtain the following:

TABLE III.

Periods.	Cases.	Deaths.	Percentage Mortality.
July 1, 1887, to February 21, 1889	577	42	7.3
February 22, 1889, to October 14, 1890	577	49	8.9
October 15, 1890, to December 31, 1896	577	40	6.9

The most important result of the systematic employment of Brand's treatment is the alteration it has effected in the constitution of the mortality list. The statistics of the first three years of the decade led to the conclusion that the treatment was ineffectual to reduce the mortality from perforation and hemorrhage, and that the vast bulk of the reduction was due to the prevention of those complications and modes of death which, being more or less common to the febrile state however induced, are termed pyrexial. Further experience has simply verified this.

In the 1,902 cases in the ten years' bath period, 56 patients died of perforation, or 2.9 per cent.; 23 of hemorrhage, or 1.2 per cent.; while 64, or 3.4 per cent., succumbed to other causes. The following table shows the modification which has been imprinted upon the constitution of the typhoid mortality list by the introduction of the cold-bath treatment:

TABLE IV.

Causes of Death in Typhoid.	According to Murchison. Percentage.	Brisbane Hospital Before Introduction of Bath Treatment. Percentage.	Brisbane Hospital After Introduction of Bath Treatment Percentage.
Perforation	3	2.9	2.9
Hemorrhage	1.4	1.88[1]	1.2
Other causes	12.8	9.73	3.4
Total mortality	17.2	14.5	7.5

Thus almost the whole of the reduction in mortality, amounting to 7 in every 100 admitted, falls upon the third group of causes; or, in other words, perforation and hemorrhage, which together used to cause only about one-fourth of the total deaths, now under the bath treatment cause more than half, and this in spite of the fact that they are if anything actually less fatal.

This fact has an important bearing upon the comparative mortality of the sexes. Statistics on a large scale show that under ordinary treatment the female mortality is slightly higher than the male. In Brisbane, during the expectant period, 1,160 men and 668 women were admitted. Of the former 164 died, a mortality of 14.14 per cent.; of the latter 107, a mortality of 16.02 per cent. The difference is in spite of the admitted fact that men are about twice as liable as women to succumb to perforation and hemorrhage.

It follows, therefore, that the female wards offer a better field for the cold-bath treatment than the male. During the bath period, 1,188 males and 714 females were treated. Of the former, 103 died, a mortality of 8.7 per cent.; of the latter, 40, a mortality of 5.6 per cent. The reduction in the female death rate is thus nearly twice that of the male; and this is due almost solely to the greater incidence (nearly double) of perforation and fatal hemorrhage in the latter sex.

The series of 1,902 cases admitted into the Brisbane Hospital during the decade include every case which at its termination could fairly be considered to be typhoid, omitting only 23 cases still under treatment when the statistics were compiled. It includes, therefore, many subjects that were not bathed at all, because such treatment was contraindicated: many more that were not bathed because the pyrexia was insufficiently high to require it under Brand's rule; many that were hopeless on admission; some that died from old-standing or intercurrent diseases during the course of an attack of typhoid: and some that were only diagnosed at the necropsy. The death rate, therefore, is essentially a hospital typhoid death rate, and is quite distinct from that which might be expected were only cases suitable for the bath treatment selected.

[1] The percentage of fatal hemorrhage is rather too high. Similarly that of deaths from other causes is probably a little below the true average. This column was made up from only 586 cases.

Progress of Medical Science.

Tabes and Floating Kidney.—In a total of sixty-eight tabetic subjects treated in Eichhorst's clinic, six had movable kidneys. These were all in women, making a statistic of floating kidney in 14.5 per cent. of tabes, or twenty-five per cent. if the women alone are counted. This is too high a percentage to be put down to chance or coincidence, since in general diseases only one per cent. show this anomaly. It is more or less frequent in neurasthenia. In tabes loss of flesh or weakening of ligaments may be looked upon as a cause in subjects predisposed. Movable kidney at best is very rare in men.

Indications for the Induction of Abortion.—Dr. Jeffé (*Medicinische Neuigkeiten*), after a study of the literature of the last ten years, fixes the indications for the induction of abortion as follows: 1. Uncontrollable vomiting of pregnancy. 2. Incarceration of the gravid uterus. 3. Obstructions of the pelvic outlet by tumors or exudates. 4. Progressive and pernicious anæmia. 5. Grave chorea. Dr. Jeffé gives the following relative indications: 1. Great contraction of the pelvis with the conjugata vera below five centimetres. 2. Pulmonary emphysema, with signs of degeneration of the heart. 3. Nephritis, especially with eclampsia. 4. Chronic heart disease. 5. Other general diseases of the mother which would jeopardize her life at the time of delivery. The author thinks that conjugata vera of six centimetres and advanced pulmonary tuberculosis should not be regarded as indications for abortion, as it is not just to sacrifice a future life for one that is "certainly lost."

Sudden Death in the Puerperium.—Goltman (*Memphis Medical Monthly*, April, 1897, p. 145) reports two cases of sudden death during the puerperium, both as a result of pulmonary embolism, in one secondary to varicose veins, and in the other to cardiac thrombosis. He expresses the opinion that pulmonary embolism is the cause of death in most of the cases of this kind. Among predisposing influences are phlebitis, varicose veins, prolonged labor, hemorrhage, anæmia, sepsis, carcinoma, syphilis, etc. In the presence of peripheral thrombosis, etc., absolute rest must be enjoined, especially during the second and third weeks of the puerperium, as this is the period at which the clots disintegrate. Sudden death from air embolism in the puerperium is of doubtful occurrence from physiologic, pathologic, and rational standpoints. Shock may be both a direct and an indirect cause of death in the puerperium, and should be guarded against. Organic heart affections, renal disease, etc., are capable of causing death at any time, and are not to be overlooked during the puerperium.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43 45, & 47 East Tenth Street.

New York, May 8, 1897.

THE PROPOSED DISPENSARY LAW.

AMONG the bills now in the hands of the governor of New York and awaiting his signature is the one introduced by Mr. Sullivan and calculated to remedy the abuse of medical charity in the dispensaries of the various cities of the State. It is safe to say that no legislative measure presented during the past session carries with it more weight of approval on the part of the medical profession and more interest to the public at large than the one to which we desire at this moment to refer. Although, as originally drafted by a committee of earnest medical men, it contained some conditions that were somewhat arbitrary in character and a trifle unreasonable in application, the bill as finally passed, giving the State board of charities the control of all its provisions, now places the proposed law on the broadest possible basis of common good to all concerned. Thus far there has been a very practical outcome of the discussion which has occupied the serious thought and earnest endeavor of all parties concerned in remedying a gross and growing evil. Heretofore, with the differences of opinion which have existed between the managers of the dispensaries and the medical staffs of the same, there has been no court of appeal before which the vexed questions could be brought. Under the pending provisions all these are reasonably reconciled. In fact, there does not appear to be any tangible grounds for criticism either as to the real motives of the reform or as to the practical application of its principles. While there is no intention of interfering with legitimate dispensary work in the disposition to minister to the pressing needs of the sick poor, the line is very sharply drawn between such as use and such as abuse their privileges. The proper assumption is that all dispensaries shall be free to the poor, and very naturally it is concluded that all institutions that claim even nominal fees from applicants have no right to do business on a so-called charity basis. A system of registration and inspection is enjoined which is calculated to eliminate the undeserving patrons and punish them for misdemeanor. In the enforcement of these provisions the central board of control is vested with the power to annul the charters of such institutions as may directly or indirectly favor the present reprehensible practices of bidding for a large patronage and opening the doors to all comers. This will doubtless tend in a very direct way to prove the utter uselessness of many of the establishments which have been conducted on the purely business interests of managerial boards in obtaining extra donations and of the medical staff in securing increased clinical material. An opportunity will be offered also of demonstrating the comparatively small number of really deserving persons who have a right to apply for free medical treatment and the outrageously large number who cheat the poor, abuse charitable donations, and swindle the struggling doctor of his legitimate fee. It is absurd to suppose, even in the face of the utmost stringency in the enforcement of the proposed law, that any one in actual need of free medical treatment will suffer. With the well-known generosity of the medical profession this would be impossible, even if the majority of the bogus charities should go out of business at once.

As might have been anticipated, the opposition to the measure on the part of various dispensary managers was pronounced, but happily was useless in stemming the tide of popular opinion. The purely selfish interests were easily disclosed and the higher principles of pure and discriminative charity were triumphantly vindicated. All that is now needed to put a most commendable law in force is the signature of the governor. It is to be hoped that he will see his way clear in this matter and be the direct means to the end of favoring a measure which is sure to receive the cordial indorsement of the great majority of the working and thinking men of the State.

THE CONGRESS OF AMERICAN PHYSICIANS.

THE Congress of American Physicians held in Washington during the past week is an evidence of the good scientific work which can be done under proper organization and with becoming earnestness of purpose. It can hardly be denied that such gatherings of picked men worthily represent the true spirit of scientific progress in this country. Although modelled after similar associations abroad, it is in many respects an improvement on them, in the extent of territory covered by its membership as well as the guaranteed fitness of the membership by previously demonstrated qualifications.

Nothing could be more promotive of harmony of purpose or more indicative of substantial progress than the plan of a congress of special societies convened for the discussion of selected subjects of general professional interest. The topics for the past session were well chosen and well elaborated, thus infusing a solidity and a dignity into the proceedings which mark the association as the leading one on this side of the Atlantic. The novelty of the condition is in the fact that each participant is an expert in his own branch, and calculated to give his utterances, based on special experience, a becoming weight of authority and a lasting influence for good. No time is wasted in parliamentary discussions, in wire-pulling for official posi-

tions, or in the settlement of professional quarrels. Therefore, may the congress and its component parts long live and prosper.

THE PRESENT STATUS OF THE PUBLIC-BATH QUESTION.

About seven years ago a physician of this city inaugurated an agitation for free public baths, which seemed to bear much promise of success. Bringing the subject repeatedly before our medical societies and urging it in medical journals, he not only obtained the approval of his colleagues, but by arguments for and explanation of the rain bath, which he earnestly advocated as offering a solution of the public-bath question, several philanthropic societies were induced to adopt this economical and cleanly bath. The practical result of this agitation is the bathing of about two hundred and fifty thousand people annually, in clean warm water, with abundance of soap and towels at the nominal cost of five cents each.

Having thus established the practicability and value of this method of bathing, Dr. Baruch sought to interest the city officials in the subject of free public baths. The Medical Record has earnestly endeavored to further this great sanitary movement. Dr. Baruch interested the board of health, and the board of aldermen appropriated, in 1891, $25,000 for an experimental public bath. Unfortunately, the mayor pigeonholed the measure, and turned a deaf ear to the personal appeals of the projector. The latter approached the succeeding mayor also, in order to obtain his approval of a bill authorizing free public baths in the city, which the governor could not approve without such endorsement. This mayor also proved obdurate.

A flank movement was made upon the city politicians by Mr. Goodwin Brown, of Albany, who, with the aid of Dr. Baruch, succeeded in having an "omnibus bill" passed, which provided that "all cities of the first and second class shall establish and maintain such number of free public baths as the local board of health may deem necessary," etc.; "any city, village, or town may loan its credit, or may appropriate of its funds for the purpose of establishing such free public baths." This act became a law on the 18th of April, 1895, and seemed to contain all necessary mandate and authorization for the construction of free public baths. Now came upon us the great reform movement, which promised to purify city politics and bring untold blessings upon its inhabitants. The committee of seventy had promised the people public baths and lavatories. Unfortunately the law providing these had been passed without their assistance. What was the result? On June 25, 1895 (two months after the passage of the mandatory bath act), Mayor Strong created "The Mayor's Committee on Public Baths and Public Comfort Stations," to see if some means cannot be devised for erecting (?) and trying at once some of the recommendations of the committee of seventy. What has the mayor's committee accomplished during the past two years? Absolutely nothing, except the obstruction of this great movement. From a pretentious volume of one hundred and ninety-six pages, called a "Report," for which we are indebted to Mr. Tolman, its secretary, we learn among other things, to be referred to below, that the committee has obtained all possible information on European baths. We fail to discover the slightest value of this "investigation," since this city already possessed the best examples of true public baths. The plain mandatory law of April, 1895, which gives the board of health authority to direct the construction of public baths, and authorizes cities to appropriate funds for their establishment, would, it seems to us, have covered all demands of the case. But it evidently did not suit the "reform" politicians to give the board of health control of so important a measure. Nine months the mayor's committee "labored and brought forth a mouse," in the shape of the clumsy act, passed March 25, 1896, providing that "the commissioner of public works, with the consent of the board of estimate, is empowered to erect such and so many buildings for free public baths, and such and so many structures for the promotion of public comfort within the city, as in their opinion shall be necessary and proper," etc. Thus a sanitary measure belonging to the board of health was wrested from its proper guardians and relegated to the politicians. The mayor's committee obtained an appropriation of $200,000, we believe, to carry this act into effect. One year has elapsed, and what has this sapient committee accomplished besides its "Report"? On page 174 we have the following "lame and impotent conclusions" of its labors: "The law being mandatory with reference to the location of baths in the public parks only, and as there was no public park in which a public bath could be constructed that would meet the wants of the tenement-house population, it was seen that no further action could be taken without additional legislation," etc. Wise solons, these! We do not claim to be experts on public baths, as are these authors of the "Report," but we do claim to understand English, and we fail to find one single reference in the act of March 25, 1896, either to a mandatory or other permissive use of the public parks for public baths. The only reference to the public parks is contained in section 4: "The commissioner of public works is authorized and empowered to locate any or all of the structures for the promotion of public comfort in any public park of the city," etc. It will be seen that this applies only to lavatories, and not at all to baths, and, moreover, that it is not mandatory at all.

Thus the mayor's committee has succeeded by its own blunders in delaying the construction of public baths and in arousing needless, but just, antagonism against the unlawful use of Tompkins Square for public-bath purposes.

The act of April, 1891 (which by the way this sapient committee claims, on page 30, to be the result of its own work, despite the anachronism involved in the fact that the committee was not called into being until June 25, 1891, viz., two months later), made ample provisions for the erection of free public baths under the control of the board of health. Why the committee did not carry out the provisions of the

law can be explained only by the fact that it was the creature of "reform" (?) machine, and was controlled by it.

Thus has a great sanitary movement, begun by a medical man, urged through medical channels, and auspiciously brought to a happy conclusion, been wrecked by Mayor Strong's committee on baths. The latter should go down to posterity as "The Mayor's Committee on Bath Literature." The English bath houses, which the committee dilates upon, may be neat and ornamental and pleasant places for swimming; but they are not true types of a good public bath. The latter should offer ample warm water, soap, and towels, be cleanly and cleansing, accessible to the poor, built on a modest scale as to size and cost, and they should offer water as free as the parks offer air. Such is the bath the projector seems to have contemplated in all his addresses and writings and appeals. Instead of such small centrally located baths, the mayor's committee proposed to "ornament" Tompkins Square with a grand structure for one million bathers, provided with a public laundry, etc. Much as we regret the delay in this beneficent movement, due to the well-meaning but impotent mayor's committee, we shall regard the delay as a blessing if it arouses the city authorities to a sense of the impracticable character of the committee, and induces them to seek more practicable guides in the construction of these free baths.

COMMITMENT TO HOSPITALS FOR THE INSANE.

In a recent issue of the *Albany Medical Annals* attention is called to the peculiarity of our lunacy laws, whereby many patients in the incipient stage of insanity are precluded from treatment in State hospitals. The law, as it now stands, is very stringent in its provisions and does not permit voluntary admissions to asylums, but in many cases the symptoms of those who have the most to hope for from treatment are too slight to warrant the granting of a medical certificate. In this respect our methods in New York are behind those of Pennsylvania and Massachusetts, where voluntary admissions are allowed and where much good and no evil has been accomplished in consequence.

"The beneficial effects of voluntary admissions," says the *Annals*, "are seen in the results of the laws upon this subject in Pennsylvania and Massachusetts. In Pennsylvania a patient is permitted to commit himself voluntarily for a period of thirty days, and then to sign a renewal. This period was originally seven days, but was extended on the recommendation of the State board of charities. It is a constant practice of the private hospitals of the State to receive patients who commit themselves for medical treatment for nervous and mental conditions, and for the alcohol and drug habits, and the average results have been good. Numerous patients from New York, excluded from the hospitals of their own State, have sought and have received treatment in those of Pennsylvania. In Massachusetts a similar practice prevails, in accordance with a law which has been in operation since 1891, that 'the superintendent or keeper of any hospital, as aforesaid, may receive and detain therein as a boarder and patient any person who is desirous of submitting himself to treatment, but whose mental condition is not such as to render it legal to grant a certificate of insanity in his case; provided always that such boarder shall make written application for such treatment, and that he shall not be detained for more than three days after having given notice in writing of his intention or desire to leave such hospital.'"

It ought to be a simple enough matter to provide against abuse of the privilege of voluntary entrance into an asylum for the insane, and certainly the law should be so changed that those who stand most in need of the benefits of hospital treatment may be permitted to avail themselves of it.

THE CROWD PANIC AT THE BAZAR DE CHARITÉ.

The recent dreadful tragedy at the Grand Bazar de Charité in Paris, in which large numbers of persons lost their lives by fire, emphasizes the danger of instantaneous panic under readily provokable conditions. Although the gathering was not a large one, its concentration of selfish interest, culminating in the delirium of an overwhelming fear, amply demonstrated the well-recognized phenomena of crowd panic. With the lamentable example of the same condition on the Hodynsky Plain in Russia only a year ago, we are happily spared the comparison of an equally large death record. This is due to the respective difference in numbers rather than to the absence of the usual causes that start the explosion of uncontrollable human terror. The fire in a temporary building filled with inflammable material was in itself the powerful incitant to the wildest demonstrations of the most overpowering alarm. The great wonder is that so large a proportion of the spectators succeeded in escaping immediate death either by suffocation or burning. As in all similar cases, this result was due more to circumstance and environment than any influences within individual control. With the overwhelming aggregation of human force in one mad direction of safety, individual efforts at resistance are always futile. This is, in fact, the true psychology of crowd panics. The prevention of the thing is the only reasonable means for consideration. In all crowds the slightest cause for any alarm of danger or even anxiety for absolute safety should be thoroughly eliminated. It is lamentable to state that in the recent disaster there was hardly wanting a single contributing cause to the worst form of demoralization. The character of the building, the inflammable nature of its contents, the gauzy paraphernalia used in decorations, the lavish distribution of lights, and, above all, the lack of sufficient police regulation, were the necessary means to the lamentable end. The same conditions were present in the large and flimsy stands at the recent Grant parade, and the only blessing is that there was happily no spark to start the waiting train.

News of the Week.

The Omaha Medical Society. — The annual meeting of this society was held on Tuesday evening, April 13th. The following officers were elected: Dr. D. C. Bryant, *President;* Dr. W. H. Christie, *First Vice-President;* Dr. H. M. McClanahan, *Second Vice-President;* Dr. R. M. Stone, *Secretary;* Dr. W. R. Lavender, *Treasurer.*

Why Dispensaries are so Necessary.—In an article on "Medical Charity," in the New York *Journal*, April 27, 1897, appears the following paragraph: "'The fact of the matter is,' said Superintendent Lathrop of Roosevelt Hospital and Vanderbilt Clinic, among the largest in the city, 'that if we had fewer incompetent physicians we would have fewer dispensaries. The people are becoming educated to know that at a clinic or a dispensary they can obtain treatment from skilled physicians, whereas in going to private physicians they have to take chances.'" In the spirit of ordinary charity for all concerned, we trust that Mr. Lathrop is incorrectly quoted.

Dr. Thomas Manning has been appointed visiting physician to St. Joseph's Hospital, in this city.

Obituary Notes.—Dr. J. G. Maisonneuve died a few weeks ago in Missillac, France, at the age of eighty-seven years. He was at one time one of the leading surgeons in his country, and several instruments, notably a urethrotome, are called by his name. He retired from practice over twenty years ago.—Dr. Traill Green died in Easton, Pa., on April 29th, at the age of eighty-three years. He was born in Easton, was graduated from the medical department of the University of Pennsylvania in 1835, and immediately began the practice of his profession in his native place. In 1837 he was made professor of chemistry at Lafayette College. In 1841 he was called to the chair of natural sciences in Marshall College, Mercersburg. Washington and Jefferson College conferred the degree of LL.D., on him in 1866. Dr. Green built the astronomical observatory and presented it to Lafayette College. For nearly half a century he was a member of the American Association for the Advancement of Science. He organized the Pardee scientific department at Lafayette and until a few years ago was its dean. He was the first president of the American Academy of Medicine, and was a member of many other scientific bodies.—Dr. Louis A. Lebeau, of St. Louis, died in that city in April as the result of injuries received in falling from a bicycle.—Dr. Leoncido Ros, one of the resident physicians of the Woman's Hospital in this city, died on April 30th, from injuries received in consequence of the explosion of a jar of alcohol in which he and the hospital apothecary were sterilizing catgut. The explosion threw burning alcohol over both men, and Dr. Ros especially was very severely burned on the face, arms, and body. He was a native of Cuba, and was twenty-six years old.—Dr. Jefferson J. O'Connell, of Honesdale, Pa., died at his home in that city on April 12th, of perforating ulcer of the stomach. He was born in 1859, and studied medicine for a while in this city, but obtained his medical degree in Chicago in 1886.—Dr. Hugh McDonald Struble, of Middletown, N. Y., died very suddenly on April 30th. He was born in Newton, N. J., in 1852, and was graduated in medicine from the University of Pennsylvania in the class of 1875.—Dr. Graffius Miller Couch died at Altoona, Pa., on April 25th, at the age of forty-seven years.

Unveiling of the Gross Monument.—On Wednesday afternoon, May 4th, the unveiling of the statue of the late Prof. Samuel D. Gross took place in the Army Medical Museum. The exercises were to have been held in the grounds where the statue stands, but owing to rain the company was invited to the library of the surgeon-general's office. The ceremonies were in charge of the American Surgical Association and the Alumni Association of the Jefferson Medical College. After a prayer by the Rev. B. L. Whitman, Dr. Claudius H. Mastin, of Mobile, presented the statue to the United States government. The statue was then to have been unveiled by Miss Adele Horwitz, but this part was necessarily omitted. Surgeon-General George M. Sternberg, U. S. A., accepted the statue on the part of the United States government, and then the address was delivered by Dr. W. W. Keen, of Philadelphia. There was a very large attendance of the members of the congress, the large room of the library being more than filled, many being obliged to stand in the hall out of hearing of the speakers. The statue, of heroic size, stands on the grounds of the museum north of the building.

A Heavy License Tax on Physicians.—It is quite an expensive item to be a doctor in Richmond. The State of Virginia for the past ten years or more has been charging $25.75 for the license of a city doctor who has been in practice five or more years; and for the past two years or more those who practise in Richmond have been arbitrarily assessed by a committee of the city council, in addition, a city license tax varying from $20 to $75—the doctor of average prominence having to pay from $40 to $60 a year.—*Virginia Medical Semi-Monthly.*

Fees in this Country and England.—In a recent number of *The Lancet* is an item concerning medical fees in America, in which it is stated that the average income of a medical man here is higher than in England. Why fees here are higher than in England is a difficult matter for our contemporary to comprehend. "Less competition cannot be the cause, for in the States there is one medical man to every five hundred persons, whereas in England there is only one to every fifteen hundred. The working classes in America receive larger wages than in Great Britain, and no doubt this partly accounts for the higher medical fees, but a still more potent reason is the fact that in America the members of the medical profession stand well together and are resolved to resist as vigorously as possible any attempts to lower the rate of fees."

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

First Day—Tuesday, May 4th.

The Eye Manifestation of Gout.—The first part of the session was in charge of the American Ophthalmological Society, and the general topic for discussion was "The Gouty and Rheumatic Diatheses and their Relation to Diseases of the Eye."

DR. CHARLES STEDMAN BULL, of New York, discussed "Lesions in the Retinal Vessels, Retina, and Optic Nerve, Associated with Gout." He said that most authors mentioned only hemorrhagic retinitis as a common complication of gout. Gouty persons were well known to be prone to hemorrhages as a result of the great arterial pressure and the relaxed condition of the arterial walls. The changes produced in the arteries were now known to be partly due to certain little understood intoxications and also to senile degeneration. It should be noted that endarteritis and endophlebitis were found much more frequently in the retinæ of persons affected with atypical gout than in those who suffered from the ordinary and typical acute form of this disease. The inflammatory process occupies the centre of the fundus, affects both eyes, but rarely causes total blindness, as the periphery of the retina is rarely involved. According to some high authorities these vitreous hemorrhages were to be looked upon as almost pathognomonic of gout. Special attention was called to three features, viz.: (1) The changes in the arteries, capillaries, and veins of the retina; (2) the peculiar, localized retinitis found at the fundus only, with or without hemorrhages in the vitreous, and characterized by a peculiar yellowish exudation occurring in clearly defined patches; and (3) optic neuritis, generally with but sometimes without a retinitis. The subjective symptoms were deterioration in the vision and a certain degree of photophobia most marked with artificial light. The ophthalmoscope showed blurring of the outlines of the optic disc but without œdematous swelling. The retinal arteries were diminished in calibre. The white lines along both the arteries and veins were broad and distinct. Occasionally in places the veins would appear dilated, giving them an appearance resembling that of a fusiform aneurism. Yellowish-white patches of exudation, at first brilliant but subsequently becoming dull, were to be seen mainly grouped about the macula and disc, but without systematic arrangement. These had been proved to be situated in the deeper layers of the retina. In these patients the urine would usually be found to be of high specific gravity and loaded with urates and phosphates. Dr. Bull said that he had occasionally found a little albumin but never sugar or casts in the urine of these individuals.

In conclusion it might be said: (1) That the changes in the fundus were always bilateral though rarely symmetrical in the two eyes; (2) the degenerative changes in the walls of both the arteries and the veins were at first very minute, and were often overlooked; (3) the general angiosclerosis and patches in the retina caused marked impairment of central vision but little impairment of peripheral vision; (4) loss of central vision was always progressive up to a certain point; (5) hemorrhages into the retina were rare except in the comparatively early stages of the disease; (6) the most marked feature was the development of the angiosclerosis in the vessels of the retina; (7) that another important feature was the peculiar yellowish granular exudation in the retina, located by the ophthalmoscope around the posterior pole of the eye and generally leaving the macula intact until late in the disease; and (8) that the changes in the optic nerve seemed generally to be intra-ocular but had been occasionally traced for some distance back of the eyeball.

DR. S. OLIVER RICHEY, of Washington, D. C., considered the general subject in its special bearing on glaucoma. He said that among the earliest changes taking place in the blood-vessels was the contraction resulting from the irritation of the toxin in the blood itself. Later on thickening of the intima and arterial sclerosis and degeneration of the blood-vessels occurred. The increased intra-ocular tension in glaucoma, he said, is due to the distention of the blood-vessels—rarely to derangement of intra-ocular secretion and excretion. Associated with the increased intra-ocular tension was arteriosclerosis with functional disturbance of the heart and probably hypertrophy of that organ. As a result of persistent venous stasis thrombosis and substituting hyperplasia took place in all the tissues of the body. In chronic glaucoma the *materies peccans* of rheumatism could be excluded. Every form of glaucoma might be considered to be due primarily to gout or to acquired syphilis in the tertiary stage. Iridectomy, if performed after the first violence of the attack had subsided, would so reduce the intra-ocular pressure as to allow of the restoration of the intra-ocular circulation and the establishment of the normal tension.

Dr. Richey called special attention to an anatomical point which he said had not generally received much consideration. The venæ vorticosæ pass in the meshes of the sclerotic downward and backward. The shortest are 1.5 mm. in length, that is, half as long as the thickest part of the sclerotic. The longest are 5.5 mm. Given the high arterial tension found in gout, and the arteries would become engorged. The arteria centralis, being engorged, presses upon the vein and produces distention. The venæ vorticosæ pass directly through the sclerotic and the arterial blood has easy access to the interior of the eye. The moment there is any increase of intra-ocular pressure, no matter how small, there will be pressure exerted on the venæ vorticosæ. This produces some venous stasis and this in turn increases the intra-ocular pressure, thus giving rise to a vicious circle.

DR. S. D. RISLEY, of Philadelphia, continued the discussion with a paper entitled "Cataract and Its Association with the Gouty and Rheumatic Diatheses." He said that the classification of hard cataract as "senile" had served to fix the attention chiefly upon age as a factor. It should be borne in mind that while the lens loses its elasticity and becomes hard as age advances, it has only exceptionally lost its transparency to a degree that would seriously impair the vision. When the lens undergoes physiological hardening and at the same time becomes opaque, pathological occurrences should be looked for as the cause of these changes. The speaker contended that the gouty and rheumatic diatheses were the most frequent causes of chronic and subacute forms of inflammation affecting the uveal tract. The entire choroidal tract would be found more or less seriously involved in every case. It was not surprising that the unstable equilibrium of the cells would be disturbed by a change in the constituents of the fluid in and around the lens. He had noted remarkable and instructive

changes in refraction occurring in diabetics, apparently as a result of osmotic changes in the density of the fluids induced by variations in the saccharinity of the blood. If this were true of diabetes it was not improbable that similar changes in the nutrition of the lens might result from the changes in the blood brought about by gout or rheumatism.

Dr. Robert Sattler, of Cincinnati, then read a paper on "Gouty and Rheumatic Affections of the Uveal Tract." He said that the gouty and rheumatic origin of these and other ocular disorders could no longer be questioned. Jonathan Hutchinson assigned the major part to gout, but, according to his own experience, iritis and other choroidal complications were very commonly met with in this country in connection with rheumatism. As a rule ocular manifestations appeared in the earlier stages of gout. In early gout one met with the typical "hot eye" and with muscæ volitantes, but rarely with gouty iritis. If found it was usually only a feature of a complicated process involving other parts of the uveal tract. An insidious variety of choroiditis was sometimes observed, known as serous iritis. Experience showed that the degenerative processes of gout made operative interference dangerous, or at least prevented favorable results as regards restoration of sight.

Dr. R. A. Reeves, of Toronto, followed with a paper on "Rheumatic and Gouty Affections Involving the Cornea, Conjunctiva, and Sclera." He said that one form of keratitis met with in these cases was characterized by intense ciliary congestion, photophobia, lacrymation, and pain, with cloudiness of the cornea. It generally receded in a few days. A partial desquamation of the epithelium occurred only exceptionally. In another form there was a porcelain-like opacity of the cornea, looking as if the sclera had encroached upon it. The condition was commonly met with in persons over forty years of age and of gouty habit. A band-like opacity of the cornea should always give rise to a suspicion of gout. There is a variety of episcleritis presenting severe inflammatory œdema and often attended with severe photophobia, lacrymation, and pain. The attacks last from one to eight days and the total duration of the disease must often be measured by years. Episcleritis proper was to be found in adults, either of a gouty or a rheumatic constitution. The treatment was by the administration of salicylate of sodium and by the topical use of pilocarpine. Scleritis proper attacks the anterior part of the globe, is characteristic and diffuse, and, as a rule, is very painful. A dusky zone usually marks the diseased area.

Dr. J. M. Da Costa, of Philadelphia, opened the general discussion. He said that from the point of view of the general physician in relation to the eye diseases observed in gout and rheumatism, and what was called "rheumatic gout," it was well to bear in mind what these diseases really were. The typical phenomena of acute rheumatism were so well known as not to need repetition, but there was always great doubt in regard to chronic rheumatism and the rheumatic diathesis. He truly believed that four-fifths of all the cases called chronic rheumatism were not rheumatism at all; hence, one should be cautious about admitting the association of chronic rheumatism with eye affections. The case was, however, somewhat clearer with gout, because we knew a little more about the pathology of this latter disease. Certainly something connected with a faulty excretion of uric acid was the underlying pathology of gout. He did not believe there was any such disease as "rheumatic gout," although he believed in the existence of a condition which might be conveniently called "rheumatoid arthritis;" but even this in his opinion was an independent affection. So far as we knew anything regarding this curious affection of the joints, we knew that it was rather a neurotrophic affection than one connected with either rheumatism or gout. As a general practitioner he would say that in connection with acute rheumatism he had most commonly met with conjunctivitis, sometimes associated with iritis. This often occurred at the height of the rheumatic attack, just as one found acute inflammation of the endocardium and pericardium. With gout the case was different. Gouty inflammation of the eye occurred not only in connection with acute outbreaks of gout but at other times. He had found in gouty inflammations that the disease often began in one eye and then later involved the other eye. From the same standpoint—that of the general practitioner—he could hardly recall any case of association of any affection of the eye with rheumatoid arthritis. Again there was a class of persons presenting lithæmic symptoms, or what had been called "suppressed gout." In these patients he had also observed that it was apt to begin in one eye and go to the other. Headache was often associated with this, and he had even known ocular defects to be corrected in the effort to relieve the headaches when the case ultimately proved to be one of lithæmia.

The remainder of this session of the congress was in charge of the American Otological Society.

Otology in Its Relations to General Medicine.—Dr. Clarence J. Blake, of Boston, delivered an address with this title. After giving a historical sketch of the development of the specialty of otology, the speaker referred to the care of the ear by the general practitioner, especially during the course of the acute exanthemata. The great vascularity of the canal, drumhead, and middle ear in children made these portions susceptible to inflammation. The most frequent diseases of childhood, however, affecting the ear, were those involving the middle ear, chiefly by extension through the Eustachian tube. In the earache of childhood attention should be given to the nose and pharynx, as well as to the general health of the child. Dr. Blake insisted upon the importance of frequent objective examination of the ear during the course of the exanthemata, and incidentally called attention to the fact that bacteriological examination had shown the presence of the Klebs-Loeffler bacilli in the discharge from the ear long after they had ceased to be present in the throat. More attention should also be given to the existence of deafness among school children. Touching upon the surgery of the ear, Dr. Blake quoted Professor Politzer's description of the temporal bone: "The temporal bone has four sides. The outer side is bounded by life, for through the external meatus come many of the impressions from the outer world. The other sides are bounded by death." The speaker said that it was now recognized that an effusion or a hemorrhage in the labyrinth might affect the balancing power, giving rise to auditory or labyrinthine vertigo. But in many cases it would be found that a mass or epidermal growth, by pressure on the stapes from without, would give rise to various symptoms, prominent among which was vertigo. Another matter often overlooked was what might be called "the fatigue of deafness," a condition resulting from the great effort required in deaf persons in order to keep in communication with the outside world. Where there was formerly but one act, there were now three: (1) to hear; (2) to see; and (3) to understand.

ASSOCIATION OF AMERICAN PHYSICIANS.

Tenth Annual Meeting.

President's Address.—Dr. J. M. Da Costa, of Philadelphia, president of the association, delivered an address in which he briefly reviewed the progress

of the healing art in the past few years. He spoke of leucomains and ptomains as elements in the causation of disease, and said the work of physicians and that of surgeons were coming each year closer together. Drugs were used less and more frequently alone than in combination. Extracts and active principles were now more frequently employed and have taken away many of the terrors with which the practice of medicine was formerly invested. It is no longer a hardship to be ill. Capsules, tablet triturates, pills of æsthetic color, the dear little pink pills which so often contain potent drugs, as arsenic or strychnine, are now greeted with pleasure by the children. There is an endeavor now to overcome disease and not to permit a patient to fall a victim to its ravages. The expectant method of treatment is a confession of impotence, and is rarely followed now by the thoughtful man. The line of action is a more aggressive one, with new remedies. Digitalis and mercury, for instance, are given differently from what they were. We may return to bleeding, with immediate attempts at reconstruction of the blood with alkaline fluids. The bromides, the nitrites, the nitrates, nitroglycerin, and such drugs are more prominently used now. Many of these remedies, as, for example, the nitrites, come from the physiological laboratory. The antitoxin treatment gives hope of success in some directions, but has led to no great results yet except in diphtheria. Treatment by attenuated virus is more successful, as in rabies. Attempts are on the whole rather more hopeful. The *x*-rays have been a triumph in the popular mind: they certainly have accomplished much, but their danger, as in dermatitis, has not yet been appreciated. The tendency to immediate generalization is greatly to be deprecated. The discoverer of a new germ wishes to announce a new treatment at once, and so he who discovers a new germ daily blossoms out at the end of the year with three hundred and sixty-five new cures, and wishes to record himself as one who would revolutionize science. Immediate generalization is a tendency which should be discouraged. Fixity of opinion is on future clinical medicine. This must continue to be the final court of appeals. The more we investigate the more we know, as the more questions arise. There is no finality in medicine and a certain amount of empiricism must always remain. Clinical medicine would advance if statements were not so vague. Records are not, as a rule, well kept, and generally in the notes it is stated that the "usual treatment was followed" or the "usual dose was given." But what does this mean? It may mean different things, but it does not help the reader. The withholding of the size of the dose is a mistake. Other records are so confusedly kept that they are worthless. They lack the finish of the scholar and the color of the literary artist. The keeping of records should be improved, and, while profound literary style should not supplant the clear reason of scientific facts, the two should be united. One more tendency of the day is the excessive publication of lax knowledge. Half the fact is stated. This is a dangerous thing in any science. Medicine is an inductive science. There are to be no more "pathies."

The Serum Diagnosis of Typhoid Fever. Dr. George B. Shattuck, of Boston, read a paper with this title, in which he reported on one hundred and forty five cases at the Boston City Hospital. The diagnosis was made in the pathological laboratory, and, as many of the patients were far from intelligent, it was necessary to get a good history as to their state when the disease began. The tests were made with liquid blood. In the laboratory one hour was allowed for the reaction, and the time as well as the character of the reaction was noted. Of these one hundred and forty-five cases one hundred and twenty-five were typhoid, nineteen not, and one doubtful. The tests were made from daughter cultures from a spleen culture. Both room and thermostat cultures were used. In the former the organisms were fewer, larger, and more motile, while the reaction was a trifle slow. In the thermostat cultures there was often a sediment of dead organisms which interfered with the diagnosis. In one hundred and sixteen cases there was no reaction before the tenth day of the disease and at varying times up to the one hundred and twenty-second day. In some cases the subject entered the hospital late. In eleven cases the reaction was doubtful, and in four there was no reaction. In the four negative cases the true diagnosis was later found out. In eighteen cases with a clinical diagnosis other than typhoid there was no reaction in fifteen, and in three there was, which was subsequently verified. In the blood from thirteen negroes with clinical diagnosis other than typhoid, eight specimens showed no reaction, three were more or less satisfactory, and in two it was good. The diazo reaction was recorded in forty-two of the one hundred and twenty-five cases and not in forty-seven. In conclusion: 1. The serum reaction may be obtained toward the end of the first week, but is more pronounced later. 2. It may be present without relapse at the end of the fourth month. 3. It may be absent one day and present the next. 4. Of one hundred and twenty-five cases it was absent in one only. 5. In nineteen other diseases it was absent. 6. In one doubtful case there was a reaction. 7. In doubtful cases it was of great use. 8. This test will be a great aid to the clinical diagnosis.

Dr. A. C. Abbott, of Philadelphia, said that the conditions that surround the work in the municipal laboratory are not so satisfactory as in hospital work. Nevertheless, the results in the Philadelphia health department have been very good. Of 164 specimens of dried blood, 115 were examined, and of 68 with a clinical diagnosis of typhoid 66 gave the reaction, or 2.9 per cent. of failures, and 23 had reaction in less than a week. The longest time was twenty-three days. In some cases the primary reaction was negative, while the subsequent one was positive. Seven cases were doubtful at first and positive later. Two cases had very meagre histories.

Dr. J. H. Musser, of Philadelphia, said the reaction was confusing in the early stages, especially when typhoid was a terminal infection, and he related a case in which the reaction at first was negative and the case was treated as one not typhoid, and later the reaction was positive.

Dr. W. Osler, of Baltimore, said that in forty-four cases at the Johns Hopkins Hospital examined by Dr. Bloch the reactions proved satisfactory. Some of these were admitted late in the course of the disease and one during a slight recrudescence, and one was thought to be meningitis and one remittent fever. It was not usually found before the sixth day.

Dr. Hermann M. Biggs, of New York, spoke of the studies of the serum from blisters raised with cantharides in supposed typhoid cases. He thought the amount of blood examined should be taken into consideration.

Dr. James Tyson, of Philadelphia, spoke of the abortive types of the disease, and related the case of three young girls who went skating on the Skuylkill and drank water through a hole in the ice, and all had fever which gave a clinical picture of typhoid. One was well in one week, one in three weeks, and the other later, and in all the blood showed the reaction of Widal. One case which came in on the seventeenth day of illness was supposed to be typhoid, but no reaction could be obtained, and at the autopsy it was seen to be miliary tuberculosis.

Dr. Frank Billings, of Denver, thought that mis

takes were made from a faulty report of Wyatt Johnston's methods. It was stated that an old culture should be used, which was wrong. What he did say was that an old culture should be used as a basic culture, from which fresh cultures should be made. The technique should be understood as to the age of the culture and the proportion of serum to the test. Widal stated that seven years was the longest time that the reaction can be obtained. This was important to remember, for a reaction may be obtained when the disease has long been a thing of the past.

Dr. James T. Whittaker, of Cincinnati, mentioned a case which was first thought to be Bright's disease and later miliary tuberculosis, but which later proved to be typhoid.

Dr. Fred. Shattuck, Boston, also related a case which was of doubtful diagnosis, but which afterward proved to be what the Germans call "nephro-typhus."

Dr. E. G. Janeway, of New York, said he had seen the danger of trusting to the negative side of this test too early. He had been called in to see a case in which the tests had been negative. One test was on the twenty-eighth day of the fever with two negative reactions. There were collapse and intestinal perforation, and at the later stage the positive reaction was found. The negative did not by any means disprove the presence of typhoid fever. The danger was in regarding this test as pathognomonic, when it often misled. Negative results caused a treatment for other than typhoid fever, and often the reaction came too late or in convalescence. We should be very careful in negative cases.

Gall-Bladder Infection in Typhoid Fever.—Dr. A. Lawrence Mason, of Boston, presented the history of a case of inflammation of the gall bladder with perforation and intestinal rupture as a complication of typhoid fever. The literature of the subject shows that most of the forty-five cases on record are post-mortem discoveries. His case was that of a woman, thirty years old, with typhoid, anorexia, vomiting, and constipation. The reaction was positive. There were pain and swelling in the right abdominal region. The liver dulness was normal at first. Aspiration of the gall bladder was done and no stones were found. The pain was relieved and the patient recovered. The gall bladder was resected. The relief was instantaneous and defervescence ensued. He showed a photograph and a sample of the fluid withdrawn, which was much unlike bile. The typhoid bacillus was found in the fluid. Tests were made with it and rabbits inoculated. There are not many cases recorded. Rokitansky and Frerichs have mentioned some. Only in the past ten years has it been possible to use bacteriological methods in studying these cases. Gall stones are sometimes found, but not always. Reinfection from the gall bladder should always be borne in mind. The prognosis is unfavorable. If the gall bladder is much distended, the treatment should be to relieve pain and promote absorption, or else to operate and use surgical measures. He related another case. His conclusions were: 1. The gall bladder is often infected in typhoid fever. 2. Cholecystitis often results. 3. Gall stones complicate the trouble and should be removed. 4. The gall bladder may be a source of infection.

Hepatic Complications of Typhoid Fever.—Dr. William Osler, of Baltimore, read a paper on this subject, considering it under the following heads: 1. The focal neuroses. 2. Jaundice in the course of the disease. 3. Abscess. 4. Affection of the bile passages. He spoke of the rarity of jaundice in this disease, and said that of the first five hundred cases seen by him at the Johns Hopkins Hospital it had been present in only two cases in his practice. Blackstein at the Johns Hopkins Hospital showed that the bacillus lived fifteen and one-half weeks in the biliary passages, and the colon bacillus longer. In fourteen cases of gall-bladder disease that were fatal, the typhoid bacillus was found in seven casses and other organisms in two. In these seven fatal cases there were no hepatic symptoms. There was great possibility of infection of the gall bladder. The production of an acute cholecystitis without typhoid infection is possible, from the records of the present day. He saw a case in which there was a mass of gravel. After a hearty meal of beefsteak and potatoes the patient felt sick, and vomited the meal and the previous one too. There was a tumefaction in the right abdominal region. Halstead operated. There was no bile, but a sudden discharge of yellow liquid. The colon bacillus was found. Chiari's studies show very great care is necessary in discovering them. In an analysis of two thousand cases in Munich in only five was it found. The number of recent cases is greater than is usually regarded. In one case there was a laparotomy with recovery.

Case I.—Typhoid fever reaction on the twenty-seventh day; colon bacillus found. Final recovery. Three months later, pain in right iliac region, operation. Appendicitis first supposed; gall bladder found adherent and with perforation; yellow fluid; stones removed; gall bladder packed with iodoform gauze; colon bacillus present.

Case II.—In third week of typhoid fever; later came into hospital; was jaundiced. Numerous gall stones; gall bladder opened and drained; colon bacillus found; death.

Case III.—Supposed typhoid but reaction doubtful; thirtieth day of fever. Pain in right hypochondriac region; operation; recovery.

Case IV.—Typhoid; pain in side; dismissed. Later readmitted. Headache and weakness; Widal reaction; jaundice; cultures at first negative; late parotitis.

Dr. W. T. Councilman, of Boston, spoke of the frequency of finding typhoid bacilli in the gall bladder. They are nearly always found in typhoid fever. They enter the gall bladder from the blood. They are always in the liver during the disease. Very few organisms in the body escape the liver. Thence they can easily pass into the biliary vessels. He showed a very pretty specimen of typhoid necrosis.

Urea Estimation in Cases of Typhoid Fever Treated by the Brand Bath Method.—Dr. James Tyson, of Philadelphia, read a paper with this title. A patient with typhoid fever in the hospital had albuminuria and hyaline casts in three days after admission. He gave milk and other liquid diet. On the fourth day he began to collect the urine and estimate the urea during the Brand treatment. During the bath the secretion was markedly increased. The patient was tubbed five times in one day and the secretion of urine and urea was increased. Thus:

Day of Disease.	Urine.	Urea.
28th	2,100 c.c.	29.8 per cent.
29th	2,100 "	24.7 "
30th	2,280 "	32.0 "

The albumin fell to one-twelfth per cent. by bulk and finally disappeared, as did the casts. Cough grew less. There were no tubercle bacilli; an otitis media developed in both ears, but there was no defect in the hearing. The nephritis was mild. It is not the circulation of the blood in the kidney that is dangerous but its stagnation, and therefore the Brand method is not contraindicated in this passing nephritis. Of sixty-nine soldiers treated, five had nephritis and all recovered, and of sixty-nine others not treated by baths by the Brand method nine had nephritis and five died. The nitrogen came from the food ingested and from tissue waste.

Cancer of the Stomach in Early Life; and the

Value of Cells in Effusion in the Diagnosis of Cancer of the Serous Membranes. Dr. George Dock, of Ann Arbor, Mich., read a report of a case of cancer of the stomach (scirrhus) in a man of nineteen years. There were extensive infiltration of the stomach with early obstruction of the cardiac orifice; metastasis in the peritoneum and pleura with fatty ascites; later, effusion in the pleural cavities, first left, then right. In the various effusions were cells which, besides containing fatty granules and vacuoles, showed in a large proportion karyokinetic figures, both typical and atypical. After a reference to the literature, a comparison was made with the findings in other effusions in serous cavities, tending to give to such cells a certain diagnostic value.

Dr. Simon Flexner reported a case in which there was a large tumor extending into the intestine. The fluid contained many cells. The case was carefully worked up and found to be a tuberculosis of the peritoneum, while the history indicated cancer.

The Inflammations of the Colon.—Dr. Francis Delafield, of New York, read this paper. He spoke of the various forms of colitis found in New York and their treatment. He exhibited a large number of beautiful drawings and photographs. His treatment was principally flaxseed injections, opium, and castor oil.

Reflex Neuroses of the Abdomen.—Dr. Norman Bridge, of Los Angeles, Cal., read a paper setting forth, from a clinical standpoint, a large number of these reflex neuroses or symptoms, some of which are frequently overlooked and some confusing in diagnosis.

The Relation of Neurasthenic Conditions to the General Nutrition.—Dr. R. T. Edes, of Jamaica Plain, Mass., presented a communication with this title. Gain in body weight and improvement in neurasthenic symptoms usually go together, but there are enough exceptions to the rule to show that the nervous nutrition is something more than a mere sample of the general. The more nearly symptoms approach in character the "fixed idea" of the insane, the less amenable are they to the beneficial effect of mere somatic therapeutics. The blood color (Fleischl) of a considerable number of neurasthenic patients corresponded quite closely with that of the employees in the same institution. It was not possible to establish any correspondence between the degrees of anæmia and the intensity of nervous symptoms. Measurements of the excretion of uric acid afford no sufficient ground for supposing that neurasthenic symptoms depend in any way upon this substance. There may be such a thing as a chronic uric-acid headache, but the ordinary continued neurasthenic headache is not of this character. Indican determinations have not been numerous enough to be decisive, but do not seem to indicate that the poison consists in this substance or in those which may be transformed into it. If neurasthenia is a toxic condition, the poison has not yet been satisfactorily identified.

Two Cases of Erythromelalgia.—Dr. D. W. Prentiss, of Washington, presented the cases.

Case I.—Female, neurasthenic, aged fifty-eight years. Left hand only affected. Has continued in intermittent attacks since August, 1895, presenting in a characteristic form the train of symptoms described by Dr. Weir Mitchell as peculiar to this disease.

Case II.—Widow, aged thirty-seven years. Neurasthenic and hysterical. Pain in the heels extending to the soles of the feet and when more than usually severe up the calf of the legs. No history of previous disease, except the neurotic tendency, in either case, to throw light on the cause.

Diagnosis, pathology, and treatment were discussed with special reference to relation to other diseases classed as vasomotor. The treatment especially was considered worthy of note, since heretofore it had proved almost unavailing. The reporter also invited discussion especially with reference to surgical interference, that having been contemplated in the first case by cutting or stretching nerve in forearm.

AMERICAN GYNECOLOGICAL SOCIETY.

Address of Welome.—Dr. A. H. A. King, of Washington, delivered the address of welcome. Aside from the more serious scientific work of these meetings they were of special value in their social features, giving brief respite to the members from melancholy obstetric and gynæcological work. The Washington members extended a hearty welcome to their visitors.

Multiple Myomata in Abdominal Cavity.—Dr. Bache McE. Emmet, of New York, read a paper bearing chiefly on the genesis of multiple myomata, especially those in the abdominal cavity, and related a case. It was about the uterus that most myomata and the largest ones were found. Those in other parts of the body were uncommon, and seldom larger than a walnut. Their mode of formation was in all instances practically the same; that is, barring the question why they grew, they were believed invariably to take their origin from their own kind. In other words it was held by histologists that they could not spring from any tissue but unstriped muscular tissue. They were rare under the age of thirty-five, were most common in women because of the uterus, but in other organs were more common in men. After quoting Virchow, Ziegler, and various writers on points relating to origin, etc., the author said it seemed to him well established that leiomyomata arose by hypergenesis, and when found in regions where there were no smooth muscle fibres were due to detachment and migration. Although they were said to be permanent, undoubtedly many changes might take place in their size and structure, as was frequently seen in tumors of the uterus. It was not necessary to say anything about the diagnosis of such tumors in the abdominal cavity, as they were so rare. Of all collected he could find but two which were called fibrous tumors of the omentum, one by Dr. B. Woodward, one by Dr. E. Andrews.

On November 22, 1894, Dr. Bache Emmet removed from the abdominal cavity of a woman, aged twenty-five, a large solid mass extensively covered by omental and intestinal adhesions, attached over the fifth lumbar vertebra, ten by twelve inches, base one inch and a quarter in diameter, pronounced myofibroma (dense white tissue) by Dr. Freeborn, who also held that it was at one time attached to the uterus from which it had its origin. He also removed the left ovary, which was cystic, and tube. There was no evidence of any disease about the uterus. He considered that the mass was retroperitoneal, as it had raised the ureter up on its surface, and he then supposed it was a fibrosarcoma. He happened to sever the left ureter at that level and then made uretero-ureteral anastomosis. He watched the case closely afterward. The patient recovered. He heard of her through her physician, who had delivered her with forceps, April, 1896, seventeen months after the laparotomy. After delivery he felt a large mass, eight inches long, on the left side, and later he wrote that he thought it was unquestionably a return of the fibroid at the original site. Later he felt also a small tumor in the right side. Dr. Emmet operated again in November, 1896, for multiple abdominal tumors, which on opening the abdomen crowded the uterus out, but were independent of it. In succession he withdrew and removed seven fibroids, all lobulated and having a pedicle of omental tissue, containing large vessels. The seventh one had the appearance of a kidney, and was firmly adherent over

the spinal column. It was implanted directly over the uretero-ureteral anatomosis of two years before, and the attachment was so close that in its removal he excised a bit of the ureter. This was repaired with black silk and covered with peritoneum. The right ovary was found cystic and was tied off. The operation lasted three hours. The masses weighed seven pounds; microscopically they were nearly pure myomata. The patient recovered, but tumefaction developed, as after the first operation, at the site of removal of the tumor, and was continuing to increase in size, though more slowly than after the first operation. The case suggested many questions difficult to answer, among them being: If the tumor was originally attached to the uterus how came it to be retroperitoneal, and after its removal why should a recurrence take place at the same site?

The Development and Present Status of Hysterectomy for Fibro-Myomata and for Inflammation of the Uterine Appendages in America.—Dr. Charles P. Noble, of Philadelphia, read an abstract of a paper with this title. Hysterectomy, both for fibro-myomata of the uterus and for consecutive inflammatory lesions of the appendages, was of American origin. His conclusions were as follows: Surgery is indebted to America for ovariotomy and for hysterectomy for fibroids. Ovariotomy was originated by McDowell, 1809, and hysterectomy must be considered as an outgrowth from it, the first fibroid tumors having been operated upon with a diagnosis of ovarian tumor. The first hysterectomy for a fibroid, deliberately undertaken, was performed by Kimball, 1853. The type of hysterectomy in America has been supravaginal amputation. This method was adopted by Kimball and by Burnham in 1853. Many surgeons of all countries have worked in this field, notably Schroeder; but in the evolution of the operation the steps in the technique which have rendered it simple and safe have been originated by other American surgeons. These steps are, notably: 1. The retroperitoneal treatment of the stump—Emmett, 1884; Eastman, 1887; Dudley and Goffe, 1890. 2. Ligation of the trunks of the ovarian and uterine arteries in their course through the broad ligaments—Stimson, 1889; Baer, 1892. 3. Amputation through the cervix well below the internal os; and the omission of constricting ligatures in the tissues of the cervix—Baer, 1892. The substitution of a few catgut sutures to close the cervix and prevent secondary infection from the vagina through the cervical canal. 4. The origination of a systematic technique for the removal of intraligamentous fibroid tumors—Pryor, 1894; Kelly, 1896.

The mortality of fibroid tumors is greater than is usually stated. It much exceeds the mortality of operation for the cure of the disease. The mortality of supravaginal amputation for fibroid tumors at the present time is about five per cent.; that of total hysterectomy for fibroids is about nine per cent. The mortality of hysterectomy is greatly increased by the traditional policy of delay in advising operation for fibroids. Early operation should be advised upon the basis of genuine conservatism as contrasted with spurious conservatism. Early operation insures a low mortality. It permits the substitution of myomectomy for hysterectomy in women of child-bearing age in a larger percentage of cases than is possible with tumors of large size. It conserves the life and health of the patient, and when myomectomy can be performed restores the sexual organs to functional activity. Spurious conservatism entailed upon the patient years of invalidism and subjected her to greater risks than early operation. Myomectomy is the ideal operation for fibroids. The next advance in treatment will be the acceptance of early operation with the definite purpose of substituting myomectomy for hysterectomy in women of child-bearing age in cases having only a small number of fibroids.

Dr. R. Stansbury Sutton, of Pittsburg, opened the discussion. He spoke upon conservatism in operations for uterine fibroids. Before answering the question whether to operate, we ought to consider what was the mortality of fibroids not treated surgically. The late Mr. Keith made the statement that not more than ten per cent. of women who had fibroids, if left alone, would die because of their presence, and the inference was that the mortality from operation must be lower in order to justify it. Operations were dangerous, and women ought not to be operated upon simply because they were accidentally found to have a small fibroid but without symptoms. He could recall three young women whom he had advised under such circumstances not to undergo operation, but they went elsewhere, were operated upon, and died.

Dr. Arthur W. Johnstone, of Cincinnati, took the same conservative view as Dr. Sutton. Many women never suffered from fibroids present in the uterus; in many there was retrogression at the menopause; in some he had removed the appendages and brought on retrograde metamorphosis.

Dr. B. F. Baer, of Philadelphia, disagreed with the first two speakers. In skilled hands operative interference was more conservative in these cases than to let alone. Out of one hundred cases he would save more women with uterine fibroids than would live if let alone. Moreover, an operation saved those that lived a great deal of suffering.

Dr. A. P. Dudley, of New York, thought American surgery had been copied a great deal in Europe, with or without credit. In evidence he cited Jacobs' method modified since he visited this country two years ago. Dr. Dudley believed in making a clear diagnosis in each case and adapting the operation to the circumstances—always doing myomectomy when possible.

Dr. W. T. Lusk, of New York, said he saw many women with small fibroids which gave rise to practically no symptoms. They ought not to be operated upon until symptoms developed. He was strongly in favor of myomectomy when interference was indicated, if it were suitable to the case. He could not agree with those who removed the uterus only because the appendages were sacrificed, or left no portion of the cervix in hysterectomy; discomforts arose from altered nutrition in the rectum, vagina, and pelvis from cutting off the entire uterine circulation.

Dr. Baldy, of Philadelphia, thought conservatism was usually on the side of operative interference in fibroma of the uterus. Few women who consulted him did not have symptoms; trust could not be placed in retrograde metamorphosis; the patients might fall into unskilled hands if such men as Dr. Sutton refused to operate.

Dr. Beverley McMonagle, of San Francisco, believed in doing myomectomy, thus sparing uterus and appendages, whenever possible, and this possibility was usually greater the earlier operative interference was resorted to.

Dr. G. J. Engelmann, of St. Louis, expressed the opinion that the operative technique had come to be pretty perfect and that the important question was when to operate, and, bearing on this point, what was the cause of the growth of uterine tumors. Those who believed in interfering in all instances seemed to forget that observation in the autopsy room showed fibroids in a great many women who had had no symptoms referable to the tumor during life. Even large tumors need not cause symptoms and might well be allowed to remain until symptoms arose.

Dr. Gordon, of Portland, Me., referred to his paper read at the Philadelphia meeting, and expressed pleasure at the tendency toward operative interference which

he then advocated. No matter how small the tumor, if it caused the woman to consult him for relief, he operated. No patients had complained less subsequently to operative procedures than those from whom he had removed uterus and appendages.

Dr. Thomas Addis Emmet, of New York, mentioned some experience with fibroids which had become detached from the uterus and transplanted to other structures in the abdomen. In one instance the transplantation was from the uterus on to the abdominal wall, from there on to a growing ovarian tumor. He said he had been supposed to be opposed to removal of the uterus for fibroids. This was not true, although he seldom found hysterectomy necessary. A great many fibroids could be removed through the uterine cavity. He was disposed to think that fibroids would not develop in a healthy uterus, one in which the menstrual function went on normally and the woman bore children. Their commencement was, he thought, always in some interference with normal conditions in the lining membrane.

Secondary Operations.—Dr. H. J. Garrigues, of New York, read a paper on this subject. Patients had sometimes almost a superstitious belief in the efficacy of operative procedures and were greatly disappointed if not cured of every ill, whether related to the condition for which the operation was done or not. Gynæcologists themselves at times formed erroneous opinions of what should be the result of their work. In case of failure to give relief, the surgeon might hear nothing of it, for the patient lost confidence and went to another hospital. Often one operation was only a link in a chain of operations called for to secure complete relief. In many instances there was so great liability to relapse that the patient ought to be warned and instructed to return after a few months for re-examination. The additional treatment called for might be a mere trifle if there were not too great delay.

The speaker related the following case: Mrs. S——, aged fifty-one. May, 1895, he performed vaginal hysterectomy for fibroids and oöphoritis. He did not hear from her for a year, when she came to his office so weak that she had to be supported. There were frequent attacks of vomiting, diarrhœa, pain, vaginal discharge. Examination revealed a small granulating surface at the vault of the vagina and tender swelling in the fornix, corresponding to the stumps after the hysterectomy. Curettage, nitrate of silver, and electrolysis restored health. In other cases more serious, even capital secondary operations were required. A frequent cause of continued suffering was adhesions formed in consequence of the primary operation. Three illustrative cases were cited. In one the woman had undergone seven laparotomies before he saw her. She was then complaining of intense pain all over the abdomen. In performing the eighth laparotomy he removed the whole cicatrix, six inches long and four wide, which had resulted from five preceding operations to the right of the median line; he also freed extensive adhesions between the colon and anterior abdominal wall. This gave relief, although some time subsequently she complained of what seemed to be hysterical paralysis of the detrusor muscle of the bladder. The fifth and sixth cases reported were of patients on whom the author himself had preformed salpingo-oöphorectomy, and the symptoms continuing he added vaginal hysterectomy. Finally he referred to a case published in the Medical Record, November 10, 1894, and February 23, 1895.

Could anything be done to avoid secondary operations? Since extensive adhesions, as seen in some of the cases related, gave rise to great and protracted suffering, the surgeon ought to operate in a manner to avoid causing them, if possible. Raw surfaces could be covered with peritoneum, but the very sutures used for this purpose acted as an irritant, were covered with newly formed tissue, and adhesion took place to neighboring surfaces. It was also useful to cover such surfaces with iodoform or aristol, which to some extent prevented adhesions. But above all he thought the intestines ought to be handled with the utmost care. In our just apprehension of infection we were apt to forget that violent mechanical handling, by scraping off the fine endothelium which coated the intestines and prevented adhering, might become injurious in itself. Only the finest gauze pads or softest sponges should be used. The bowels should be moved early, as a rule forty-eight hours after the operation. Dr. Garrigues would not remove the uterus after double salpingo-oöphorectomy unless disease of the uterus demanded it, believing that patients were less likely to have subsequent symptoms if the organ were left in. In the exceptional cases in which the patient was not cured, hysterectomy could better be added later, when it was both easier and safer.

Dr. Bache Emmet believed that much work denominated secondary was due to wrong or incomplete diagnosis at the time of the original operation.

Dr. P. A. Harris, of Paterson, N. J., dwelt upon the necessity for care in operative detail at the primary operation, if one would avoid subsequent symptoms and secondary operation.

Dr. Lapthorne Smith, of Montreal, had hoped the author would touch upon indications for reopening the abdomen for symptoms during convalescence from laparotomy. He had recently had a case in which symptoms of intestinal obstruction developed; several of the hospital staff doubted the propriety of reopening the abdomen, yet on doing this he found obstruction due to fresh adhesions, broke these up, and the patient recovered.

AMERICAN DERMATOLOGICAL ASSOCIATION.

May 4th—First Day.

Address by the President.—Dr. James C. White, of Boston, delivered the annual address. The association was congratulated upon attaining its majority, it being the oldest national association of its kind in the world. The influence of the society's work upon the advances in cutaneous medicine was reviewed: it could now be justly claimed that American dermatological writings stand on a plane with those of European countries. The work of individual members had aided in the general result of securing an independent position for many dermatoses formerly confused. The advances in methods of cure did not, however, keep pace with the discovery of new affections and the separation of the older ones into more distinctively individual classes. The work of the association for the immediate future was mapped out in a suggestive way, and the necessity for meeting in cities offering an abundance of clinical facilities was discussed. The time of meeting in the future should be so arranged as not to break in upon college work, at so inopportune a period as that covered by the present session.

A Contribution to the Study of Bleeding Stigmata.—Dr. James Nevins Hyde, of Chicago, reported the case of an adult male subject who suffered from hemorrhages from the surface of the skin apparently spontaneous in origin. Some of these bleedings had lasted for six months at a time. Eventually there was a shortage of fifty-five per cent. of hæmoglobin and nearly sixty-five per cent. of erythrocytes. The author reviewed the literature collated under the titles bleeding or bloody stigmata, bloody sweat, hæmatidrosis, Hautblutungen, hysterical stigmata, and ec-

stasy; concluding as follows: "It is clear that at times spontaneous hemorrhage occurs from one or many points of the skin, simultaneously or successively, either as a result of morbid changes in the circulating fluid itself, or as a consequence of disease of other organs, in particular the nervous centres, the spleen, the liver, and the kidneys. One may look with tolerable confidence in the most of these cases, first, for an oozing of blood from many points at one time rather than from a single point at one time; second, for unquestioned evidence of a morbid state elsewhere than in the skin. Suspicion attaches to a second group of cases by reason of the fact that the effusion of blood from the surface of the integument seems to have shared with spontaneous gangrene in the devices of the impostor. In analyzing the phenomena exhibited in this class of subjects the possibility is to be set aside, first, of the staining of the physiological secretions by foreign matters or by micro-organisms existing upon the surface; second, of the substitution for human blood of that of one of the lower animals. When human blood is actually effused from the skin of a subject who has been instrumental in producing the result, not only are all the sites of the hemorrhage within easy accessibility of the hands of the patient, but there are mental and nervous changes which require recognition. The mental states of this class of subjects often defy analysis: among the nervous symptoms may be named disorders of the special senses, particularly of sight, hearing, olfaction, and gustation, and the occurrence of anæsthesia and of hyperæsthesia."

Four Cases of Hysterical Dermato-Neurosis.—Dr. A. Van Harlingen, of Philadelphia, reported these cases. The subjects were all young girls exhibiting evidences of anæmia or hysteria or both, who presented at intervals, often about the menstrual epoch, lesions often beginning as bullæ and becoming excoriated. One young woman, who developed excoriated lesions upon an œdematous base, ceased to show such manifestations after she married. The title "neurotic excoriation" was not considered sufficiently exact to be retained. In the second patient, a pale and slightly hysterical girl, there were repeated outbreaks of erythematous and bullous lesions. Case III. was neurotic. The face, breast, and extremities were the locations implicated by bullous and excoriated lesions. Case IV. likewise showed lesions upon the lower extremities. They were at first bullous, afterward becoming gangrenous. The condition was regarded as hysterical in its origin, but the designation "malingering" or "feigned" eruptions should be dropped, though the general appearance of the sores often suggested a self-inflicted origin.

In the discussion of these two papers conjointly, Dr. Duhring regretted the vagueness surrounding the subject of hysterical eruptions. Angularity of outline is not a proof that a given lesion has been self-inflicted. Many neurotic and hysterical lesions have this angular outline.

Dr. Gilchrist thought many so-called dermato-neuroses were in reality toxæmias.

Dr. Lustgarten spoke of cure by suggestion, as illustrated in a case he reported.

Dr. Bronson said there was usually some internal source of irritation to account for the eruption.

Two Cases of Linear Nævus, with Remarks on Its Nature and Pathology.—Dr. P. A. Morkow, of New York, read the paper. No provision, the author said, was made in the association's nomenclature for the affection in question, though many names had been given it by different writers. The chief characteristics are: absolute limitation of the eruption to one-half of the body; linear disposition in distinct streaks or bands; its papillary or verrucose characters; its congenital origin; often marked sensory disturbances; and the possibility of increase in extent, retrogression, or the occurrence of various degenerative changes in the lesions. An exceptional malignant transformation was alluded to. Two instances were reported and colored photographs shown in illustration. In one a male subject presented verrucose lesions extending in a narrow band-like line from the region of the elbow to the tip of the palmar surface of the fourth finger. The process began upon the palm twelve years ago at the age of seventeen years, and gradually extended. In the second instance a young woman of nervous temperament showed the first evidences of the process seven years ago in the form of a scratch-like streak upon the back of the neck. This gradually extended into the scalp and down the back, keeping to the left of the spine. As regards nomenclature, the speaker thought it well to retain the designation nævus, which in its modern signification is sufficiently comprehensive, but not such qualifying terms as unius lateris, since unilaterality is not peculiar to this form of nævus. The term linear should, however, be retained, as pointing to the type form. The argument that it is not of nerve origin, because the distribution is not that of known nerve supply, does not hold, since in zoster, which is due to a recognized affection of the nervous system, the configuration is not always such as to suggest nerve influence. In the absence of any positive proof of causal connection with alterations in the nerves, not the qualifying term "neuropathic" appears unwarranted. The title linear nævus sufficiently identifies the affection and possesses the advantages of simplicity and conciseness.

The Various Forms of Pityriasis and Their Relation to Erythema, Eczema, and Psoriasis.—Dr. George H. Fox, of New York, believed that many affections usually termed seborrhœal eczema, seborrhœa, pityriasis rosea, or designated by a great many other names, might all be classed under a single term. An acute erythemato-squamous affection occurring in patches or rings upon various regions of the body, and either dry and scaly or moist and greasy, according to the location and secretions of the part affected, is often variously named according to the clinical signs presented at the time the case is seen. To do away with this confusion, the speaker advocated some simple term to take the place of the many confusing names now in use. The term pityriasis, meaning a bran-like desquamating disease, was suggested. Numerous photographs were shown to demonstrate the great diversity of appearance presented by one and the same disease.

In the discussion the general sentiment was that pityriasis rosea constituted a distinct entity, which offered but little chance of being confounded with the dry desquamating varieties of so-called seborrhœal eczema. It was thought that confusion would only be increased by an attempt to group together the cases shown by Dr. Fox in a large collection of photographs. While many processes presented close clinical similarities, it would be unwise to attempt simplicity of nomenclature in the way suggested.

Report on Nomenclature and Classification of Skin Diseases.—Dr. James Nevins Hyde, of Chicago, presented this report, in which many names in the older schedule were changed, while some new ones were added.

AMERICAN NEUROLOGICAL ASSOCIATION.

Twenty-Third Annual Meeting, Held at Washington, D. C., May 4, 5, and 6, 1897.

First Day—Tuesday, May 4th.

President's Address.—Dr. M. Allen Starr, of New York, delivered his address. He referred to the trans-

mission of sensory impulses through the spinal cord, and thought that the conclusions derived from physiological experiments upon the lower animals were open to grave criticism, first, because of the fact that the majority of such experiments performed years ago were done without antiseptic precautions and were attended by secondary septic inflammations of the cord and its meninges which invalidated the conclusions drawn from them; and secondly, because of the great variation in the anatomical structure of the cords of the lower animals and of man. While investigations have abundantly confirmed the general results long known as ascending degeneration in the spinal cord, after lesions of the nerve roots and after lesions of a transverse nature, the recent methods of investigation, especially the staining methods of Weigert, Van Gieson, and Marchi, have furnished some interesting results. It is no longer possible to speak of the columns of the cord as being exclusively ascending or descending in the direction of their fibres. Recent investigations by Hoche have shown the existence of many association fibres of limited extent in the direct cerebellar columns and in the columns of Gowers, and therefore it seems evident that every column of the cord contains fibres which pass in both directions. It is thus proven that the number of the short tracts in the cord is far greater than the number of long tracts, and inasmuch as these short tracts can only be nerve roots, or else tracts of association, it is evident that there are but few very long fibres extending through the cord to the brain. Many of these long fibres, supposed to reach the brain, really terminate in the spinal cord itself. There is no tract passing directly from the cord to the brain cortex. Even if the lemniscus is continuous from the medulla to the cortex, it cannot be stated that the lemniscus forms a direct sensory tract from the cord to the brain, since it begins in the nuclei gracilis and cuneatus of the medulla. A sensory impression of sufficient severity, or if continuous, may practically throw into activity almost the entire subcortical nervous system. It therefore seems quite evident that the transmission of sensations through the cord must have for an anatomical basis a series of short neurons, each conveying the impulse from the level of its reception in the cord to a level somewhat higher, where again it is transferred to any other neuron, and so on till it reaches the cortex. Is it not therefore evident that in the transmission of sensation through the spinal cord, cerebral axis, or brain, we have to consider the tracts as different in their structure from those conveying motor impulses, and as consisting of a series of short neurons closely connected but with very numerous and widespread connections? Is it not probable that the result of this arrangement is to secure a diffusion of single sensations to various reflex, vasomotor, trophic, and automatic mechanisms, as well as to the organ of conscious perception? And is it not also evident that this view of sensory diffusion explains the apparent inconsistency at present prevailing between the clinical symptoms observed in Brown-Séquard paralysis and the pathological degenerations occurring in that disease? He concluded that in the conduction of sensory impulses to the brain cortex a large number of different neurons are concerned, which are located in the gray matter and in all the various columns of the spinal cord, and that there are no true sensory columns or long continuous sensory tracts between the spinal cord and the cerebral cortex.

Purulent Primary Spinal Leptomeningitis. Dr. Frank R. Fry, of St. Louis, reported a case of spinal leptomeningitis. A bacteriological examination showed the infection to be purely purulent. The source of the infection was a slight but rather chronic furunculosis on the back of the neck. The patient was twenty-seven years of age, and a house servant. The site of primary infection was the lumbar or lower dorsal region. The clinical history was that of an ascending paralysis with certain interesting features as to temperature, etc. There was no cerebral involvement. Sections of the cord were presented, chiefly interesting as showing diffuse degenerations in the cervical and upper dorsal regions.

Subarachnoid Serous Exudation Productive of Pressure Symptoms, after Head Injuries.—Dr. G. L. Walton read a paper with the above title, and said that in cases offering moderate febrile movement, prolongation of unconsciousness, and restlessness after trauma, it is of no vital moment whether we adopt the term contusion, bruising, or laceration; but when to these symptoms local paralysis is added the question of operation arises and exact ideas of the pathology become important. Operation over the area indicated sometimes shows only a tense dura, incision of which is followed by a gush of serum. Under the arachnoid membrane the greater part of the cortical cerebro-spinal fluid is collected. Serum may be exuded into the subarachnoid space as well as transuded, and sometimes the swollen and congested brain found under the fluid on operation shows that we have to do with an exudation resulting from increased blood pressure, rather than with a compensatory process. Little attention has been paid to this process. The œdema of Ballard accompanying hemorrhage is analogous; the serous meningitis of Quincke is analogous if not identical, in so far as he includes external meningitis, but he does not refer to this class of cases. The following cases were mentioned: A boy of six years was struck by a bicycle at noon one day, was restless and drowsy, and on the following day became unconscious, with unilateral paralysis including the face. Operation was considered but postponed. The paralysis had disappeared within four days. A child, three and a half years old, fell from a swing, striking the head; was drowsy, and the next day one arm was paralyzed. The paralysis began to lessen on the third day, and rapidly disappeared. A young woman fell, striking the head violently. Unconsciousness, restlessness, vomiting, and hemiplegia appeared. Operation revealed tense dura, incision of which was followed by a gush of serum. There was relief of pressure symptoms, but death ensued from the underlying condition. His conclusions were: 1. A severe blow may result in local bruising and congestion with subarachnoid serous exudation. 2. The fluid may be imprisoned and cause focal paralysis. 3. The process is not compensatory, and is allied to the serous meningitis of Quincke. 4. The lesion is self-limiting. 5. Diagnosis from hemorrhage is difficult. Atypical course, absence of steady increase of symptoms, and persistence of sensitiveness point to serous exudation. 6. Immediate operation is not necessarily indicated in focal paralysis, though perhaps always justifiable. 7. This condition is specially to be borne in mind before operating on children and young adults.

Dr. W. N. Bullard, of Boston, said that further investigation and study of these cases had confirmed his belief that this condition is the pathological cause of many of the symptoms arising in these cases, and that the presence and degree of this increased intradural pressure is one of the most important factors in determining whether or not operation should be performed. As to how far the symptoms due to this increased pressure within the dura, when localized in the form of paralysis and hemiplegia, are to be considered as indications for surgical interference has not yet been fully determined.

Dr. Morton Prince, of Boston, thought the theory of Dr. Walton was plausible but difficult of substantiation, and related the case of a child who had a fall

and showed symptoms of meningeal hemorrhage, such as unconsciousness and hemiplegia. Operation was deferred. The child was perfectly well on the following day.

Dr. B. Sachs, of New York, said the theory was not new. After head injuries three possibilities were to be considered, hemorrhage, local œdema, and purulent meningitis. The view of Dr. Walton was natural and plausible, and he agreed with his views as to differential diagnosis. He would not operate on the skull too soon, but would wait until positive of serious damage to the brain, not until after the lapse of forty-eight hours or several days.

Dr. J. J. Putnam, of Boston, had seen several cases in which such a diagnosis could be borne out, but there was shifting of symptoms, which was important. He had witnessed an autopsy on a woman who after influenza developed localized twitching of arm, leg, and face every twenty minutes; twenty-four hours later hemiplegia and rise of temperature. There were only œdema and a wet soft brain. There was no local accumulation under the pia. He thought the convulsions and hemiplegia were due to the general œdema. The pathology in these cases is not clear.

Dr. Hugh T. Patrick, of Chicago, added a case almost exactly like that of Dr. Prince. A child received a fall, which was not severe, in the latter part of the afternoon, after which he played about as usual. At the supper table he suddenly let fall a fork from his right hand, and soon thereafter had a one-sided fit. Following this he became stuporous, and when seen several hours later was almost comatose; but a distinct hemiplegia was made out. Operation was declined by the family, and two days later the child was absolutely well. A localized œdema is the only possible explanation of such an occurrence.

Dr. C. Herter, of New York, believed that local effusion could give rise to these symptoms, and spoke of a case of extreme general œdema of the arachnoid following syphilis. There was some doubt as to whether the fluid is a simple effusion or an exudate. Inflammatory process, however, could not occur so rapidly. It might possibly be due to cerebral anæmia. Pronounced general œdema of the brain in children may be unaccompanied by any cerebral symptoms.

Dr. Joseph Collins, of New York, related the case of a man, fifty years of age, who fell and struck his head in the left parietal region. This was followed by shock, stupor, and paralysis of the right upper extremity. At the autopsy there was some localized serous exudation, which was evidently of inflammatory origin.

Dr. Edward Angell, of Rochester, asked Dr. Walton if there was any temperature record, to which he replied that there was slight rise of temperature.

Dr. J. J. Putnam had seen venous hemorrhage into the pia which was accompanied by hemiplegia.

The President thought that the question of localized œdema should be one of fact and not of theory. He had seen three cases operated upon in which apparent inflammatory œdema was found. He had also observed a case in which there was a very large amount of œdema involving the entire hemisphere around a very small tumor.

Primary Idiopathic Hydrocephalus in Adults.—Dr. Morton Prince, of Boston, reported three cases with autopsies, besides two others which terminated in recovery. The first case followed trauma and simulated latent abscess with secondary meningitis of the base. Trephining was done with negative results. At the autopsy the ventricles were found dilated to three times their normal size, the convolutions flattened, and sulci almost obliterated. The same condition was found in the second case. The third case followed sunstroke and was of the external variety, the meshes of the pia and arachnoid being filled with fluid so as to resemble a layer of jelly. There are an acute and a chronic form. The acute simulates the purulent form of meningitis, but differs from it in its course and the variability of the symptoms. The chronic simulates and is usually mistaken for cerebral tumor. The affection is common, but not usually recognized.

Dr. P. C. Knapp, of Boston, said that the reader of the paper had omitted to speak of lumbar puncture in differential diagnosis between meningitis and effusion The negative findings are often important.

Dr. Collins felt certain that there were chronic conditions of this affection. He cited a case which presented all the characteristics of hereditary cerebellar ataxia, in which at the autopsy only ventricular distention was found.

The President asked Dr. Collins if microscopical examination had been made of the brain or cord, and was answered in the negative.

Dr. Sachs said that, as the examination was incomplete, Dr. Collins' conclusions should not be accepted as final.

Dr. Prince, in closing the discussion, said that unquestionably there was a chronic form. The principal differential point is in reference to the variation of symptoms from time to time in effusion.

Auditory Aphasia.—Dr. Howell T. Pershing, of Denver, read this paper, with the report of a case.

Dr. Philip Zenner, of Cincinnati, referred to a case with frequent attacks of word deafness and spasm of the right side of the tongue and face. At the autopsy a tumor was found in the lower part of the Rolandic fissure resting upon the first temporal convolution.

Dr. Charles K. Mills, of Philadelphia, agreed with the view of Dr. Pershing, and said that in such cases all forms of language might be affected.

Dr. Wooster, of Danvers, Mass., reported three autopsies in patients with sensory aphasia. There were softening and atrophy of the left first temporal convolution. He had seen sixteen cases. He also mentioned a case of subcortical aphasia. The patient could not speak and had no comprehension of spoken language. He had right hemiplegia. At the autopsy Dr. Wooster found softening of the external capsule and lenticular nucleus.

Dr. Collins said that the auditory centre was localized in too small an area. The speech area is purely a sensory one. There is only one variety of aphasia and that is sensory.

Dr. Pershing, in closing the discussion, said that he had attempted in his paper to combat the views expressed by Dr. Collins.

Poliomyelitis Anterior Subacuta Unilateralis.—Dr. F. W. Langdon, of Cincinnati, reported a case. The patient was an adult forty-four years of age, who made a complete recovery at the end of two months.

Anæsthesia in Spinal Diseases. — Dr. P. C. Knapp, of Boston, read this paper. He referred to the researches of Ross, Thorburn, Starr, and others. In syringomyelia the distribution of the anæsthesia is more apt to follow another type than in cerebral disease, in which the boundary of the anæsthesia is at right angles to the axis of the limb. Two cases were reported, and many others cited proving this distribution.

Dr. Mills thought Dr. Knapp's points were well taken. He had hoped that something would be said on hysterical anæsthesia.

Dr. B. Sachs referred to cases of spinal origin, but which did not seem to be of spinal type, but which he had good reason to believe to be a syphilitic affection of the cervical region of the cord. This type closely resembled syringomyelia. He did not like the term "cerebral anæsthesia," but preferred "regional anæsthesia."

The President said it was practically impossible

to lay down an accurate diagram of the anæsthesias from various regions of the cord. Individual variations must be considered and admitted. Irregularity in distribution is characteristic of spinal anæsthesia.

Syringomyelia.—Dr. Hugh T. Patrick reported the following case: A man of forty-four years began to be weak in the legs ten years before, which weakness gradually increased until he walked with difficulty. A year ago the hands also began to be affected. Examination showed spastic paraplegia with weakness of the grasp and slight atrophy of the small hand muscles. The sensory symptoms were the most interesting. There was a band of anæsthesia about the trunk and extending on to the inner surface of the arms, an area of analgesia covered this and extended beyond it about four inches on the trunk and two inches on the arms. This distribution of sensory blunting is exactly the same as that which has been described by Laehr and the author as occurring in tabes, except that in the latter disease the band of analgesia is much narrower than that of anæsthesia.

So-Called Poliencephalitis Superior and Inferior.—Dr. Patrick reported a second case, that of a woman of thirty, who was attacked with bulimia, following which complete external ophthalmoplegia and incomplete bulbar paralysis developed. She died of respiratory failure about two months after the beginning of the disease. The autopsy revealed nothing. Microscopic examination showed all the arterioles and capillaries of the bulbo-pontine region to be enormously distended. Other signs of inflammation were absent; there was no degeneration of fibres, and the cells of the various nuclei were all but normal. The author considered the case to be one of transition between the so-called acute poliencephalitis and poliomyelitis on the one hand, and so-called asthenic bulbar paralysis on the other. He thought the disease essentially toxic, and suggested as a therapeutic measure the so-called "washing of the blood;" that is, copious phlebotomy with simultaneous transfusion or the subcutaneous injection of salt solution.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

First Day—Tuesday, May 4th.

President's Address.—Dr. Charles H. Knight, president of the association, delivered his address. After a greeting to the members, attention was first called to the matter of antisepsis in clinical work. "When we become absorbed in clinical work, and are thrown into familiar contact with infectious disease, we are apt to become careless as to certain safeguards which involve both ourselves and others. A series of cases recently seen has impressed upon my mind the lamentable consequences of neglect of those precautions as to instruments and manipulations which we are all supposed to observe. In view of the possibilities thus acquired, and perhaps for a long time unrecognized, it has seemed worth while to call attention to the matter.

"Closely allied to this topic is that of antisepsis in general. In the growth of our specialty, surgical procedures in the upper air passages have assumed important proportions. Absolute asepsis in the wounds we are in the habit of inflicting may be impossible, and, in view of the satisfactory drainage usually secured, unnecessary. The modern aspect of this whole question was brought to mind at the last meeting of the British Association for the Advancement of Science. At this meeting, the story of the birth of antisepticism was told in an unassuming way by that distinguished surgeon who, more than any one else now living, has contributed to the advance of surgical science. In a single day Listerism banished hospital gangrene from hospital wards. Lister mentions that in the old days Syme, to whom he refers as 'the safest surgeon of his time,' was inclined to believe that amputation, rather than any attempt to save the limb, was the proper course to pursue in all compound fractures of the leg. Scrupulous ordinary cleanliness and the use of various deodorants were not able to banish putrefaction, but carbolic acid did, and the father of antisepsis still adheres to it as the safest and most efficient antiseptic.

"The work of our own association has always been characterized by a spirit of wise conservatism. We have not been carried away by the fads of the moment. The premature announcement of new cures for tuberculosis which experience has proved to be inert has taught us a healthy scepticism. As to antitoxin, there is reason to hope that, after making all due allowances, we have found in this substance one capable of at least restraining the ravages of diphtheria.

"Another question now much discussed is the value of the laryngoscope in relation to the singing voice. It has probably done little more than to corroborate theories and knowledge acquired in other ways. We know that a normal larynx is essential to a perfect voice. But on the other hand we know that one can learn to speak intelligibly without a larynx by means of the aid provided by the lips, teeth, tongue, palate, pharyngeal wall, nasal chambers, and the bones of the skull. A deviation from normal structure must inevitably modify the voice to a greater or less perceptible degree. While we are by no means agreed as to all the elements concerned in the production of the singing voice, it may be said that nearly all the informa tion given by the laryngoscope as to the movements and the position of the vocal bands during tone formation had already been furnished by dissection of the larynx. The laryngoscope cannot tell why, of two individuals with apparently identical vocal apparatus, one is a great vocalist while the other cannot sing a note. Nor does it tell us why a singer with a good voice of fine quality and perfect intonation and used in accordance with a good method fails to thrill us. In other words, no scientific theory and no instruments of precision will discover that musical instinct, that artistic temperament of every great singer. No more trying ordeal confronts the medical practitioner than the attempt to manage the case of a youthful aspirant for lyric honors to whom nature has denied those gifts essential to success. On the other hand he experiences no more intense satisfaction than in proving his ability to restore a lost voice or in giving such advice as will assist in its recovery. Here then is the chosen and successful field of our art. An individual comes to the physician with hoarse, husky, or whispering voice. No one can deny the importance and feasibility of determining with accuracy, in most cases, the site of the difficulty, whether it be a fault of innervation, a defect of muscular action, a neoplasm or overgrowth of tissue, or a simple inflammatory condition. In the detection and relief of disease and in thus protecting and preserving the singing voice, the laryngoscope will continue to be of inestimable value.

"No reference to the events of the year just elapsed would be complete which failed to mention the continued interest manifested in the new world opened to us by the Roentgen ray. We may take pride in the fact that one of our corresponding fellows, Dr. John MacIntyre, of Glasgow, has been especially active and successful in experimenting with this wonderful discovery. It remains to be seen whether it will be of any practical value to us in our special line of work. In locating foreign bodies, and in determining the dimensions of tumors and the extent of infiltration in malignant disease, it may prove to be of service.

"At the meeting of our association a year ago, a committee was appointed to draft a memorial to Congress protesting against the adoption of a bill to restrict vivisection. It becomes us to approach this subject with caution and at the same time with candor. Such apparent brutalities are said to have been committed in the name of science that we can hardly wonder at the earnestness of those who oppose vivisection. On the other hand, the extravagant and intemperate language of some fanatical antivivisectionists is most exasperating. One of our fellows whose memory we cherish was a particular object of attack by certain champions of the dumb animals. The subject is one of vital interest to all scientific physicians. Who shall say that vivisection has accomplished nothing, has bestowed no boon upon humanity, in view of the achievements of Harvey, of Magendie, of Claude Bernard, of Pasteur, and of our own investigators? The jubilee of anæsthesia might not have been celebrated last year had sympathy for the lower animals prevailed. Without preliminary tests, even Morton with all his courage would hardly have dared to apply his beneficent discovery upon human beings. Thus the race might have been long deprived of that blessed immunity from pain which it has enjoyed for the last fifty years. We claim that vivisection is justifiable and should be permitted as a means of impressing certain important phenomena upon the minds of students in our schools, not indiscriminately to a general medical class, but to the more advanced and special students in pathology and biology. No reasonable man can object to restrictions which look to the prevention of wanton cruelty, but those contemplated by the bill would practically prohibit animal experimentation in the District of Columbia. The adoption of this measure would be merely a step to the introduction of similar bills elsewhere, with the result of eventually closing all our schools of biological research. What shall we say of the sickly sentimentalism which evokes spasms of maudlin sympathy over the death of a worthless dog and sits with folded hands before the horrors of the unspeakable Turk, or denies to suffering humanity hope of exemption from disease, the study of which may be most readily conducted upon the lower animals? The childlike reasoning which jumps at the conclusion that every movement of an animal or of a human subject under anæsthesia is an index of pain is quite in keeping with most of the arguments against vivisection, and only merits attention because persistent repetition of even the most baseless of statements finally gives it a certain authority.

"It is to be hoped that the good sense of our lawmakers will enable them to relieve the question of the plausible sophistries and silly calumnies associated with it by ignorance and prejudice. Let it be our duty to show the world that we are not actuated by motives of frivolous curiosity. Let us demonstrate the fact that many of the advances in surgery and therapeutics hitherto made have had their origin and confirmation in experiments upon the lower animals, and that one of our great hopes for future progress in these departments rests upon further intelligent and unhampered exploration."

Guaiacol as a Local Anæsthetic in Minor Operations on the Nose and Throat.—Dr. James E. Newcomb, of New York City, opened the scientific proceedings by a paper under the foregoing title. He said that while cocaine fulfils to nearly an ideal degree the requisites of a local anæsthetic, its use is not always free from unpleasant consequences. Various substitutes have been suggested, notably eucaine and tropococaine, but even these are not always free from unpleasant after-effects, and they have not come into any extended use. Some two years ago, Lucas Championnière, of Paris, suggested the employment of guaiacol for this purpose. At first a five-per-cent. solution of the remedy in sterilized oil of bitter almonds was tried, but later pure olive oil was substituted. As guaiacol does not readily dissolve in this oil, it was found advisable to remove its resinoids, albuminoids, and coloring matters with dried sulphate of zinc, and its free fatty acids with absolute alcohol. With the oil thus purified, the guaiacol will mix freely. The result is a clear limpid fluid, looking like glycerin but having a more yellowish tinge.

The first application of the remedy in the special field of anæsthesia for intranasal operations was made by Laurens. In aural practice he advises cleansing the ear in the usual way and then the instillation of a few drops of the warmed guaiacol solution, which after remaining *in situ* for a few minutes is withdrawn by means of hydrophile gauze. Under these precautions, it is possible to perform paracentesis of the eardrum without pain. He suggests also that the remedy may be of service in incising furuncles of the meatus.

In the nose the operative field is to be bathed several times with the solution and then a saturated tampon applied in the usual manner. The latter must remain in position in the usual manner for at least fifteen or twenty minutes. Out of seven cauterizations of the inferior turbinate, anæsthesia was complete in four. In the remaining three there was a slight sense of burning. There was but slight retraction of the tissues. Hence guaiacol can never be so serviceable as cocaine in cases in which we wish to make a systematic examination of the nares, or when, in cases of supposed reflex neurosis, we wish to determine the existence of sensitive areas. The cold snare was used in six cases of nasal polyps without pain, and also in one case of polypoid degeneration of the middle turbinate the hot snare was used with a like happy result. In the pharynx it was found difficult to obtain anæsthesia owing to the fact that the application of the remedy caused active reflex movements. Granulations were cauterized five times without pain, tonsils three times, and twice tonsillar tissue was removed by forceps, all painlessly. The remedy proved a failure in one attempted removal of the tonsil with the hot snare. In the larynx the guaiacol solution did not act satisfactorily owing to the apparently slight absorption.

Laurens notes the formation of a whitish magma, a sort of emulsion, on contact of guaiacol with mucus. This can be easily removed with hydrophile cotton or gauze.

A little later Geronzi repeated the experiments of Laurens, using an alcoholic solution of guaiacol. His results may be summarized as follows: Perfect anæsthesia in four cases of nasal polyps, five cauterizations of the inferior turbinates, seven cauterizations of pharyngeal granulations. In the ears, removal of granulations from the drum membrane twice, five removals of polyps, four myringotomies, and three removals of the malleus. There was not always complete anæsthesia, but then this is not the case except very rarely with cocaine. Geronzi used an ethereal alcoholic solution in the larynx and found it well borne, but it did not produce sufficient anæsthesia, so that instrumental interference could not be attempted.

The writer of the present paper used the remedy thirty-six times on twenty-eight different patients, of ages ranging from sixteen to fifty-five years. The conditions treated comprised nasal polyps, diseased ethmoid sinuses, spurs of the nasal septum, cauterization of enlarged turbinates and of enlarged tonsils, curetting of the pharynx twice, and uvulotomy.

Of the results, so far as anæsthesia was concerned, it was perfect in fourteen, partial in sixteen, very slight in two, and wanting in four. The time allowed

for absorption varied from six to twenty minutes. The average was about ten. If the average time had been longer the results might have appeared in a better light. It is distinctly stated by both of the clinical writers quoted that the time to be allowed for absorption should be at least ten minutes, better fifteen. In spite of the fact that guaiacol is said not to retract the vessels, no greater bleeding in cutting operations was noticed than with cocaine. If, as is asserted, paracentesis of the drum membrane can be performed under guaiacol without pain, it ought to prove a remedy of great value. Cocaine has almost no effect on the drum, because the latter is cutaneous rather than mucous in structure.

The remedy is in no way superior to cocaine, but it affords a means of anæsthesia when cocaine may not be permissible.

Dr. H. L. Levain, of New Haven, inquired if Dr. Newcomb considered guaiacol to have the power of penetrating the tissues as deeply as did cocaine. Dr. Newcomb replied that in his opinion it had. It was merely a question of allowing more time for absorption than was necessary with cocaine.

Submucous Hemorrhage of the Vocal Cords.—Dr. S. W. Langmaid, of Boston, reported five cases. All were due to a definite cause and similar in appearance and situation. Few cases of this identical nature were on record. The hemorrhage in each of the five cases was at the junction of the anterior with the middle third of the cord. One was diffuse in appearance, but the remaining four showed a globule of blood under the mucosa as definite as the air bubble in a spirit level. Two of the patients were men, and three women. Four were singers, and one an actor. All hemorrhages were due to vocal strain, came on suddenly with vocal inability, hoarseness, and limitation of register in the higher tones. Four were on the right cord, and one on the left. In all a perfect cure resulted with a full restoration of vocal power. In all there were evidences of pre-existing laryngeal catarrh. The cause of the condition was referable to the over-force necessary to bring into proper phonatory position muscles already lamed by a catarrhal state. Congestion ensued with vascular rupture. Such cases were commonly referable to faulty vocal effort, but wrong vocal methods were not always the assignable cause, as the accident might happen to artists of the highest technical skill. The condition was in reality a laryngeal apoplexy. In one case the clot entirely cleared up in seventy-two hours. As to treatment, absolute vocal rest was imperative; then whispering might be allowed, and later the audible voice. It was a remarkable fact that in none of these cases was there any hæmoptysis. The peculiar globular appearance had never before (to the writer's knowledge) been reported. Dr. Dundas Grant had reported one case due to sneezing. In this instance a vascular tumor formed at the site of the clot. As a rule, both cords are involved. As adjuvants to the rest treatment topical astringents should be used, strychnine given internally, and later, intralaryngeal galvanization employed.

Dr. J. W. Gleitsmann, of New York, stated that he had previously reported one case due to a blow on the larynx. He recollected that a fellow of the association, the late Dr. E. C. Morgan, had reported one case occurring in the ventricular band.

Dr. C. E. Bean, of St. Paul, had seen two cases, in one of which the bleeding had recurred two or three times, and it was a long time before the clot finally cleared up.

Hysterical Dysphagia.—Dr. A. Coolidge, Jr., of Boston, read this paper. The condition had been described by Hofmann as early as 1733. It was sometimes confounded with œsophageal spasm or œsophagismus, which might be due to local disease of the gullet, to affections of the brain and pneumogastric nerve, reflex influences from other organs, various drugs, seasickness, or hydrophobia. In looking over the records of the Massachusetts General Hospital nose and throat service, hysterical dysphagia was found to have been present in about one out of every five hundred of all cases seen. It was more frequent in women than in men, but could also occur in young children. It sometimes occurred in pregnancy, and might result from emotional causes. In all such cases the œsophageal sound could be passed. The symptoms generally felt were pain, a sense of constriction, and the feeling as of a foreign body. The onset was sudden and might result from the temporary lodgement of a foreign body in the gullet, which later passed down into the stomach. It might be provoked also by pharyngeal or tonsillar disease. Patients frequently became emaciated. Regurgitation was rare. The sound might or might not pass readily. Auscultation as a means of diagnosis generally gave negative results. The laryngoscopic appearance might rule out certain supposed causes. The cases would often present temporary abatement of symptoms. The obstruction seemed to occur during the first part of deglutition. As to treatment, in addition to the removal of neighboring lesions if present, the bougie should be passed frequently. The electric sound should be avoided, as alarming effects had followed its use, presumably from the effect on the heart through the medium of the pneumogastric nerve.

Dr. Thomas Hubbard, of Toledo, referred to sacculated dilatations as a frequent cause of œsophageal obstruction.

Dr. John H. Lowman, of Cleveland, had seen one case in a child with gradual onset. The case was suddenly cured by suggestive treatment. He would utter a caution about the reckless use of œsophageal sounds. Three deaths had already occurred from the use of the ordinary stomach tube. We should always use cocaine previous to the use of the sound, as the passage of the latter was thereby greatly facilitated.

Dr. Gleitsmann had observed one case, in a girl of eighteen or twenty years, due to enlargement of the lingual tonsil and greatly improved by the latter's removal.

Dr. Swain had been led to attach great importance to the condition of the lingual tonsil in these cases. He though that lingual varix was, according to some, a frequently occurring causative factor, but such had not been his personal experience.

Dr. Samuel Johnston, of Baltimore, had seen one case, due to impacted wax in the external auditory meatus.

Dr. Emil Mayer, of New York, referred to a case previously reported by him, occurring in a child and proven to be due to a congenital stenosis of the gullet. In this case auscultation showed clearly that fluids would go down just so far, and would then seem to be arrested, but then would follow a sound as of trickling down into the stomach.

Dr. D. Bryson Delavan, of New York, thought that the etiology could always be found in some definite local lesion.

Dr. J. W. Farlow, of Boston, referred to one case he had seen, due to wax in the ear. In this case there was also a painful gland deeply seated behind the angle of the jaw. The patient was a gentleman who would have difficulty in swallowing and in reading aloud. During these acts a sudden spasm of the neck muscles would sometimes come on. Removal of the wax cleared up all symptoms.

Dr. Langmaid thought that there was a special class of cases due to anæmia, and occurring in young

women, especially domestic servants. There was no structural lesion and no apparent nervousness.

Dr. W. H. Daly, of Pittsburg, referred to one case recently under his care, in which he had talked somewhat sharply to the patient, a young woman, with a view of impressing her with the fact that her inability to swallow was purely imaginary and of getting her to throw off her nervousness. The girl died suddenly a few days later. No autopsy was allowed, and he was at a loss to account for this termination of the case.

In closing the discussion, Dr. Coolidge observed that with regard to the anæmic cases he thought the anæmia was the result rather than the cause of the inability to swallow nourishment.

Bacteria of the Normal Nose and Bactericidal Properties of Nasal Mucus.—Drs. W. H. Park, of New York, and Jonathan Wright, of Brooklyn, had prepared a paper which was read by Dr. Wright. The reader called attention to his own experiments on the bacteriology of the nose reported ten years ago. Von Besser had also found pathogenic germs in normal noses. Wurtz and Lermoyez had claimed that nasal mucus destroyed the bacilli of anthrax, while more recently St. Clair Thompson and Hewlett had claimed that the interior of the nose was comparatively germ free, though the vestibule showed many bacterial varieties. Dr. Park and the reader had examined the mucus from thirty-six normal noses. The vibrissæ or stiff hairs in the vestibule were cut away with sterilized scissors and the entrance to the nose was carefully washed with bichloride solution. Sterilized cotton swabs were then carefully passed deeply into the nose and inoculation experiments made with them. As a result of these observations it might be stated that in only six instances out of the thirty-six did the culture media fail to show bacterial growth. The nasal mucosa of two rabbits was examined and in both bacteria were found. Streptococci were not distinctly made out, but were undoubtedly present, especially as they were practically always present in the nasopharynx. In one case in the human species the mucus withdrawn was not bactericidal to the diphtheria bacillus, staphylococci, or streptococci, but there was a marked inhibitory effect on the growth of anthrax bacilli. A similar inhibitory effect on the growth of this particular micro-organism was produced by sterilized sheep serum. The scantiness of bacteria in the healthy nose might result from five different causes: 1st. Gravity; the clear serum draining down from the higher nasal regions not penetrated by the tidal air would tend to wash all the bacteria down and out of the nose. 2d. This action was assisted by the ciliæ of the nasal mucosa. 3d. Nasal mucus was not a good culture medium for most bacteria. 4th. The presence of the vibrissæ tended to keep the nose free from germs. 5th. There were but few pathogenic germs present in ordinary tidal air. One drop of a virulent bacterial culture had been allowed to drop into the noses of two rabbits. Both died of septicæmia inside of three days.

The Treatment of Chronic Affections of the Tonsils, with Demonstration of Instruments.—Dr. J. W. Gleitsmann, of New York, read a paper with this title. With the exception of hypertrophy, there is probably no other chronic affection of the tonsil more frequent than the chronic inflammation of its follicles. The smooth surface of the organ disappears, it presents an irregular contour, its follicles undergo a process of destruction, and the lacunæ often become filled with white masses, the products of inflammation, which being retained become a fruitful source of different ailments. These masses are often overlooked, as they give rise to little trouble. For these cases Dr. Gleitsmann gives preference to a little palate hook (exhibited) which enables exposure of the upper part of the tonsil to be easily made. It is in the latter locality that we most often find these whitish masses. For the proper exposure of the crypts which contain leptothrix deposits he has used for the past two years Moritz Schmidt's instrument, which is a blunt hook, but which answers the purpose very well. The side of the instrument has been sharpened but its blunt tip retained. This instrument is also useful for the separation of adherent faucial pillars. Frequently the presence of a flap or fold of the tonsil, sometimes occupying its whole surface, prevents an inspection of its posterior surface. On a superficial examination this fold may seem to constitute a part of the anterior pillar, but when the latter is drawn aside with a suitable hook an intervening space between the two is easily seen containing a small amount of lymphoid tissue. The larger part of the tonsil will always be found behind this fold. The writer believes that this fold is the result of a previous attack of acute inflammation combined with the chronic follicular disease. This condition has been fully described by Harrison Allen.[1]

Dr. Gleitsmann had recently seen a case of this nature occurring in a lady who suffered from severe indigestion and nervous debility. Behind the anterior pillars on both sides was a moderately deep groove containing a minute amount of normal follicles: then came a broad, dense, thick fold extending the whole height of the tonsil, and covering the latter to such an extent that it could only be seen when the fold was forcibly drawn forward. The tonsil was in a state of complete destruction, nodulated, and countless white deposits were interspersed in its tissue. The fold had to be first destroyed. The galvano-cautery was deemed inexpedient on account of the size and density of the fold. As Heryng's laryngeal double curettes were difficult to handle, Ruault's punch was employed. The result was satisfactory, though there is this criticism to be made against this instrument, viz., that it is too large and its vertical action renders it difficult to grasp the fold between its cutting blades.

Dr. Gleitsmann exhibited a tonsil clipper which he had devised. It was a modification of Ruault's punch, the blades being reversed and cutting in a horizontal instead of in a vertical plane. It was also much smaller in size. In some patients the use of cocaine is advisable when the fold is removed. If the latter is very large, it is better to operate at several sittings. The hemorrhage is not severe and can easily be controlled by cracked ice. As to after-treatment some light styptic or caustic solution can be employed, but this is by no means always necessary.

Several varieties of tonsil hooks and forceps were shown by Dr. Farlow, who also exhibited photographs of nose and throat lesions made by Dr. Arthur Henning, of Koenigsberg, and anatomical models of the nasal passages made by Otto Betz, of Heilbronn.

Dr. Delavan showed a set of electrodes for intranasal electrolysis.

(To be Continued.)

To Plug the Posterior Nares.—Twist up from three to six loops of stout thread twelve inches or more in length, leaving one thread hanging, the rest being waxed so as to form a rigid mass, which can be inserted into the nasal cavity as far as the posterior wall of the pharynx. The extremity is seized by means of a forceps through the mouth, and brought outside of the lips. The thread is then separated and a cotton tampon attached to fill the posterior nasal orifice. This is placed in position by drawing upon the threads which project from the nostril with the aid of a finger in the mouth. Leave hanging in the pharynx an end of the thread with which to extract the tampon.—Stephan.

[1] See Medical News, July 3, 1882.

Therapeutic Hints.

Castor Oil is made tasteless and odorless by thoroughly shaking in a flask with warm milk.—*Arch. of Pediat.*

Warts.—

℞ Ac. salic. . . . . gr. xv.
Ac. lactic. . . . . ♏ xv.
Collod. flex. . . . . ad ℥ ij.
S. Apply twice daily.

—*Practitioner.*

Nitroglycerin in Angina Pectoris.—The most efficacious form of administering nitroglycerin in angina pectoris:

℞ Nitroglycerin. . . . . gr. iij.
Tinct. capsici . . . . . ♏ ss.
Spir. rectificat.,
Aq. menth. pip. . . . . āā ℥ iij.
S. Two to ten drops.

In one minute the action of the drug is manifest, and in scarcely three minutes the pain is entirely done away with. As the patient grows accustomed to the dose, it must be increased, and if this be done carefully there is no great danger to be anticipated.—Schott, *Wiener klin. Rundschau.*

Painless Vesicatory.—

℞ Menthol,
Chloral hydrat. . . . . āā 1
Spermaceti 4
Ol. theobrom. 2
M. S. Spread upon linen and apply.

—*Pharmac. Centralbl.*, No. 46, 1896.

Extemporaneous Cold Cream.—

℞ Lanolin. 10
White vaseline 40
Rose water. 60

Melt the lanolin and vaseline together with gentle heat, and add in small quantities the rose water, while beating with a spatula.—Maveur.

Pertussis.—The following formula is much employed in the service of Albert Robin, having been devised by Dr. Voisin, interne of the service:

℞ Bromoform. 1.75
Tr. aconit. rad. . . . . 1.
Tr. nuc. vom 0.75
Tr. grindeliæ robustæ. 0.75
Tr. bryoniæ 0.50
Syr. opii ext 50
Syr. aurant. cort. am. 105
Spt. vini rect. (90 per cent.). 25

Dissolve the bromoform in the alcohol and a mixture of the tinctures; pour this into a mixture of the syrups and shake. This makes a perfectly clear solution, of which a soupspoon contains six drops of bromoform, from three to five of the tinctures, and one centigram of opium extract. The dose for a child is a teaspoonful at the time of the access, mixed with twice its bulk of water. In bronchitis the adult dose is a dessertspoonful. *Bul. Gén. de Thérap.*, February 8th.

Tincture of Actæa Racemosa, made from the Canadian or North American plant, has given good results in acute articular rheumatism, beginning with a dose of four drops every two hours and increasing until forty or fifty drops are taken daily. It is cheap, easily taken, and in many instances effective. Hewelke, *Th. Woch.*, February 7th.

Chlorosis and Anæmia.—Dr. Angelo Casati (*Gaz. degli Osped.*, January 10th) believes he has found in phosphorus a valuable adjunct to the treatment of chlorosis, in which appetite so often fails and retards the cure. Gelatin capsules containing one milligram in oily solution offer the best mode of administration. After a time patients can take sufficient food containing iron to obviate the necessity of badly borne iron preparations. Fresh meat, eggs, lentils, red wine, etc., can be given in large quantities. Begin with one capsule daily, and increase by one capsule every two days until a daily dose of five capsules is reached. Then run down the scale in the same way.

In Giving Calomel avoid acid, salty, and richly albuminous food. The latter favors resorption and increase the irritative working of calomel. The idea that the drug becomes transformed in the intestinal canal into corrosive sublimate is wholly erroneous.—Ottolenghi, *Gaz. degli Osped.*, January 3d.

Tuberculous Adenopathies.—Country life, cod-liver oil, followed by one-fourth of a gram of amylaceous pepsin, and at the end of each principal meal a liqueur-glass of the following:

℞ Glycerin. neutr. . . . . 50 gm.
Sod. phos.,
Calc. phos . . . . . āā 10 gm.
Ext. aq. quinquinæ . . . . . 15 gm.
Vini Malagæ. . . . . to make 1 litre.

—Sebileau.

To Abort Coryza.—Ten grains each of Dover's powder and phenacetin are put into four capsules; two of these are given at once, and the patient remains for about ten minutes in a hot bath. He then takes a hot lemonade or rum punch and gets between several thicknesses of heated blankets. In half an hour the second two capsules are given, unless perspiration is already abundant. Such perspiration should continue for an hour, after which the skin is slowly dried, and the patient retires for the night to a comfortable bed. —H. B. Whitney.

Cancer of the Stomach.—To increase the appetite:

℞ Bark of white condurango 15
Water. 250

Reduce by boiling to one hundred and fifty grams, filter, and add syrup. A soupspoonful is to be taken a quarter of an hour before meals. To favor digestion:

℞ Muriate of ammonia . . . . . 0.15 cgm.
Bicarbonate of sodium. . . . . 0.26 "
Dover's powder. . . . . 0.10 "

To be taken ten minutes before meals. To diminish fermentation: Sublimated, washed, or precipitated sulphur, fifteen to twenty centigrams.—A. Robin, *Journ. de Méd. de Paris*, February 7th.

Iodates, with the exception of iodate of silver, being soluble, may be used subcutaneously. Ruhemann gives a number of formulæ in the *Gaz. Hebdomad.*, February 7th. Iodate of oxide of mercury being but slightly soluble, the iodide of potassium is combined with it. One centigram can be injected as an antisyphilitic every second day. It is but slightly painful and does not produce salivation.

℞ Iodate of oxide of mercury 0.115
Iodide of potassium 0.08
Distilled water . . . . . 10.
S. Inject one cubic centimetre.

℞ Iodate of quinine 1
Distilled water. 10
S. Inject two to five cubic centimetres.

Vertigo of Hemiplegia.—When, after an icterus, a subject of hemiplegia experiences vertigo on attempting to walk, apply hot compresses to the head, as hot as can be borne, and keep up for an hour twice daily.—Erben.

Clinical Department.

RESUSCITATION OF THE NEWBORN.

By W. C. McGEE, M.D.,

HOUCKTOWN, OHIO.

MEMBER OF THE OHIO STATE PEDIATRIC SOCIETY.

It is the physician's high privilege to assist nature in the restoration of impaired health, thereby giving new hopes and frequently new life to countless thousands who would meet death prematurely were no assistance rendered nature in her efforts at reconstruction. We all agree that this assistance must be timely, and often requires a high degree of skill. A most unswerving and holy regard for the value of human life is a most essential quality in the make-up of a true physician. This deep regard for the value of human life will accompany a highly sensitive conscience, and will urge its possessor to every effort possible to save the lives over which it is his high station to keep sacred guard. Would that all of our number might be imbued with the holiness of our calling. It is sad to believe that any one could engage in a life-work of such mighty responsibility without the most sacred regard for the value of life. But occurrences of recent date within my knowledge confirm my belief in the fact that many men aspire to the high calling of physician who do not hold the proper estimation of such value. In one respect I fear there may be a great many of us lacking, and that is in the matter of resuscitation of the newborn. It is my firm conviction that we have never done our duty unless we have done our whole duty. If we do not attempt resuscitation or do not use proper means to that end, we are utterly conscienceless and not deserving of the title of physician. I am convinced that many in our profession need to have their consciences quickened in this matter, for I would impress the fact that none can tell the possibilities that may unfold in the life of the little innocent babe, if timely assistance is given and its life is saved. We should therefore under no circumstances neglect an earnest effort at resuscitation in a child that is born intact. I have recent knowledge of several cases in which no effort was made, and yet no excuse could be offered for the failure. Yet for every failure the whole profession must suffer. The mere fact that it is easy to deceive some if not all of the people does not excuse, and in the mills of justice such an excuse should merit and receive only the severest penalties for criminal neglect. We do not wish to be understood as proclaiming against the righteous judgment of honest men in all cases, but we wish to impress the young members of the profession with the prime importance of timely and earnest work on this line. For no one of us can deny having some uneasiness in connection with our first few cases of confinement. Practice is the only thing that will teach young men coolheadedness while attending confinements. To this end we believe that no student should ever be graduated from any college of medicine who has not been in actual attendance under competent instructors on at least a dozen cases of labor.

Now, as to the method of resuscitating, it makes little difference, providing the attempt is successful and the means used does not injure the child. Familiarity with several methods, so as to adapt some to the immediate case, is sure to be of use to the young doctor. In this connection I will give the course I pursue, with the hope that it may be of value to some one. I have not been able to find an account of it in textbooks or in the literature, and yet I am not presumptuous enough to claim absolute priority. And I can only add that if there is any grave objection to its use, it has never become apparent to me in a record of sixty-eight subjects resuscitated, with never a failure to bring on lung expansion and life.

If the child does not show the usual signs of animation within two minutes after its birth, I catch the feet in one hand, arranging the fingers so as to hold it securely, and place the other hand over the shoulders from behind, and two fingers on each side of the neck for its protection. Then I take the child with head down and feet up, and begin upward and downward movements, slowly at first, but soon getting up to fifteen or twenty movements per minute. I keep this up until there are distinct signs of animation, and then more slowly until breathing is fully established, which will be within ten or fifteen minutes, unless the case is hopeless. But generally less than a dozen movements reward the prompt effort. The moves should be rhythmical and simulate respiratory movements. I have employed this method in several extreme cases of asphyxia pallida, and have been rewarded each time with renewal of life. The reasons I have for its employment are its simplicity and because we can begin early without loss of time. We can use all the available space for movements, but if the cord is not long enough to permit of some degree of motion, wait five minutes and quickly cut and tie the cord, and then at once attempt resuscitation. If the mother requires prompt attention, I hand the child to the nurse with directions for movements, and require her to keep it going, and am very careful to see she does as directed. The advantages are that no time is lost and the child is given the greatest chance for its life. As stated before, this method has never failed to bring me success.

WORMS IN THE NOSTRILS.

By H. M. FOLKES, M.D.,

PANZOS, GUATEMALA.

Robert S——, a negro aged twenty-four years, of rather limited mental capacity, came to me, complaining of nose bleed and pain in the head. An examination revealed slight fever, right side of face much swollen, very large nostrils, and in the right one a mass of screw worms as large as a pecan. As they were within easy reach, I removed forty-one with a pair of small forceps, after which I irrigated the nose with a thymol solution. In the evening, after another irrigation, I removed with the forceps thirty-seven more. At this time I became convinced, by the size of the swelling and the pain complained of, that there was a collection of the worms in the antrum. The question in mind was whether to open the sinus or not. So I decided to use a spray of an alcoholic solution of chloroform, which was administered with a bulb atomizer, and then to wait until the next day for further developments. The swelling had markedly gone down by the following morning, the boy in the mean time having blown out twenty-two worms since the atomization. The next morning most of the expelled worms were dead, thus showing the effects of the chloroform, for those removed by the forceps were all alive. The same evening irrigation and atomization removed fifteen or more. By this time the swelling had almost disappeared, so I gave up all idea of operating. To make a long story short, five days of this treatment brought to light one hundred and thirty-one worms, all of the screw-worm variety, and none under ten millimetres in length.

An interesting thing in this case is the length of time this negro went without discovering his trouble, which he could easily have done by inserting his finger into his nostril. Up to the time of the first removal he did not comprehend the nature of his trou-

ble, but when he saw the first worm brought out he exclaimed: "I blew four or five of those things out of my nose this morning." The patient had a slight nasal catarrh, which probably accounts for the deposit of eggs at that location.

INFANTILE SCURVY—REPORT OF CASE.

S. E. LEARD, M.S., M.D.

LIVINGSTON, MONT.,

FORMERLY CLINICAL ASSISTANT IN DISEASES OF CHILDREN, OMAHA MEDICAL COLLEGE DISPENSARY; MEMBER OF THE MEDICAL SOCIETY OF THE MISSOURI VALLEY, ETC.

Up to 1895 there had been, in the United States, only one hundred and fourteen cases of infantile scurvy reported; and of those, only in thirty-six had detailed histories been given. Nearly all, if not all, the cases so far reported have come from the larger cities in the eastern part of the continent (the stronghold of rachitis). It may be of interest to hear a report from the mountainous regions of Montana, at an elevation of forty-five hundred feet above sea level.

The child, an eight-months-old girl, was born of healthy and well-to-do parents, and was their first child. The sanitary surroundings of the child were all that could be desired, with the exception that the house might have been kept too tightly closed and the child too closely confined during the last month of its illness, owing to the suspicion that it might be rheumatism that affected the child. It had been artificially fed almost from birth. Three or four months previous to my visit the child had been ailing. She commenced to lose in flesh and strength. Eight or ten weeks previously she manifested an inability to use her lower extremities with their accustomed freedom, and cried if they were handled.

When I saw the child I found that she had been slobbering an undue amount for a couple of months. The gums were slightly swollen and bluish, with no teeth. The eyelids were of a dark bluish or purplish color. There was sweating of the head of a cold, clammy character, at times also a cool, clammy feeling of the extremities. The bowels were constipated, having been kept open by the use of aperients, which were beginning to lose their effect. Anæmia was not pronounced. The child would lie perfectly still when undisturbed. It was also quite somnolent, dropping off to sleep in the mother's arms just after my examination. Emaciation was not extreme, yet the joints had an appearance of enlargement, due to the falling away of the flesh about them. The muscular weakness was most marked in the back, where the spinal column exhibited a posterior curvature in the dorso-lumbar region when the child was sitting up. It did not lift its head off the pillow when lying down (as it had done previous to its sickness).

The most marked symptoms were in the lower extremities. The legs were drawn up at right angles to the body, with the toes flexed on the foot. On touching or moving the legs or attempting to straighten the toes, the child would cry and give evidences of great pain.

On stripping the child and laying it on its back on a flat surface, and pressing the knees down in a horizontal position, the child tried to roll over on the side and the spinal column exhibited an anterior curvature in the lumbar region. At the junction of the middle and upper thirds of the thigh was found a fusiform swelling of the femur. This was larger in the right than in the left femur.

A change in diet was made to cow's milk in the following well-known formula: Cream, three ounces; milk, two ounces; water, ten ounces; milk sugar, one drachm; lime water, one ounce. I had the mother mix together cream, milk, and milk sugar, and add the proper proportion of hot water and lime water at each feeding, thus raising the milk to the proper temperature when required, without the trouble of immersing the feeding-bottle into hot water, with the possibility of cracking it; and, in addition, the water was thus sterilized. The child was also allowed the juice of one large orange a day, although I see no objection to giving it *ad libitum*, provided it is given between feeding, to avoid curdling of the milk; also the juice from three-quarters of a pound of fresh beefsteak each day. A simple laxative was given for the bowels. No other treatment was given. The mother claimed to have noticed an improvement on the second day after this treatment was instituted. On the fourth day the legs moved with more freedom and the pain had considerably abated. By the eighth day the pain had entirely disappeared, and the limbs moved with perfect freedom. One month from that date the child was learning to creep.

UNUSUAL VOLUNTARY CONTROL OF THE CREMASTER MUSCLE.

By J. K. BOUDE, M.D.,

WASHINGTON, D. C.

The following is a copy of a medical examination of an applicant for a pension on account of a left inguinal hernia, which was alleged to have been incurred while he was serving in the regular army in 1895. The examination was made by a surgeon in the regular army at the request of the bureau of pensions, and shows the possession of a voluntary control over the cremaster muscles beyond anything I have ever seen reported. The examination was made on the 4th of January, and shows that the applicant was twenty years of age, was five feet ten and three-fourths inches in height, and weighed one hundred and seventy-two pounds.

"There is on the left side a small oblique inguinal hernia, just through the external abdominal ring, but not descending into the scrotum. The testicle is small and undeveloped, and also lies in the groin, the cord not being long enough to permit its descent into the scrotum. On the right side the testicle, also small, may remain within the abdomen or lie in the groin just outside the external ring at the will of the man, the cord not being long enough to allow its descent into the scrotum. When this (the right) testicle descends below the external ring, a small knuckle of intestine follows it into the internal ring. The scrotum is undeveloped and has never contained the testicles. On the right side the ring is a little larger than usual, and its pillars are yielding; on the left it is apparently about normal.

"The man has the power of retaining the hernia and both testicles in the abdomen at will, and these conditions are congenital. That he has this power is proven by the fact that he made application to be again enlisted in the army at this post on December 2, 1896, and I made a preliminary examination of him on December 5, 1896, as did also another medical officer. At that examination the testicle on the left side lay just above the internal ring, and not only was there no hernia, but it did not seem possible that the testicle even could pass through the ring. To-day he has not only the testicle, but also his hernia down below the external ring, as stated above. At the examination for enlistment, December 5th, the condition on the right side was as it is now found, but, while it was difficult for me to return the testicle into the abdomen, he could do it easily himself by a slight movement of the abdominal muscles, without touching it with his hands. From this I know that he can keep both testicles and hernias in the abdomen when he

wishes to. He certainly did it when he wanted to re-enlist, and there was no evidence of a hernia past or present on the left side. Now that he is being examined for a pension, the hernia is very much in evidence. The conditions existing are evidently congenital."

HYOSCINE IN ANGINA PECTORIS.

By W. W. BOSTWICK, M.D.,

SECOND ASSISTANT PHYSICIAN, HOME FOR INCURABLES, FORDHAM, N. Y.

THE patient, a Swedish woman, twenty-nine years old, came under my care six months ago. She was suffering from chronic endocarditis, resulting in extensive valvular lesions and accompanied by angina pectoris. The attacks first observed corresponded to the description given of true angina, were of moderate severity, and yielded to the usual remedies. Of late the attacks have become much more severe, until at present large doses of nitrite of amyl (six minims) repeated at short intervals by inhalation, and large doses of morphine (three-fourths of a grain) and of nitroglycerin (one-thirtieth of a grain) hypodermically, even when supplemented by the use of chloroform, did not give any relief. Nothing, in fact, short of narcosis, relieved the distress. Obviously something had to be done.

Acting upon a recently advanced theory, that angina pectoris was a neurosis of the sympathetic, an injection of one-seventy-fifth of a grain of hyoscine hydrobromate was given. The effect was magical; in fifteen minutes she was relieved, and in half an hour was sleeping quietly.

This dose of hyoscine, although rather larger than a safe dose as a beginning in one unaccustomed to the use of the drug, was not followed by any poisonous symptoms. The pulse was accelerated, reaching 90; the respirations were quickened to 20 per minute; and the pupils were dilated to a moderate extent. The temperature was not raised, and there was no dryness of the throat or loss of voice. The patient complained of slight dizziness, and there was a perceptible flushing of the face.

A CASE OF PHYSICAL ENDURANCE.

By FRANCIS CRESSON, M.D.,

SANTA FE, N. M.

AMBROSIO MADRIL, a Mexican, aged thirty years; height, five feet seven and one-half inches; weight, one hundred and seventy pounds; was brought to St. Vincent's Hospital, December 20th, at 4 P.M.

On December 17th, at 11 A.M., he fell into a well, forty-eight feet deep. One of his companions lowered himself into the well with an extra rope and a board, to which the injured man was spliced and hauled to the surface by a horse. He sustained a fracture of the lower end of the femur and of the patella, and the knee-joint was completely destroyed, the femur projecting several inches through an enormous laceration just above the knee-joint. He also had a fracture of the radius and ulna near the wrist, and, in addition, several lacerations and contusions of the face and head. He was brought sixty miles overland in a wagon, none of the injuries having received any attention whatever —not even a bandage placed on either leg or arm. His condition was such when he reached the hospital that rest and stimulation were urgently indicated. On the following afternoon, with the assistance of Drs. Harroun and Diaz, of this city, I amputated his leg high up near the hip-joint. He reacted nicely after the operation, took considerable food, slept well without narcotics, and in every way seemed to improve except in the matter of his temperature, which was 102° F. before the operation, and which did not fall at any time afterward. Local and constitutional means were vigorously employed in an attempt to control the septic process, but everything failed, the patient dying at the expiration of forty-two hours after the operation, with a temperature of 105.6° F. The lacerated tissues of the leg were in an advanced gangrenous condition when he reached the hospital, and the amputation was made for this condition, as well as on account of his splendid physical powers, as exhibited by his ability to "hold up" after such an accident and the subsequent long trip over a rough country, without his having shown very marked signs of physical exhaustion.

AN EXPEDIENT FOR PRESERVING SURGICAL INSTRUMENTS FROM RUST.

By ROBERT BOYD, M.D.,

ISLAND OF GRAND CAYMAN, BRITISH WEST INDIES.

I SHOULD like to make known to the profession a valuable and simple expedient to prevent surgical and scientific instruments from rusting.

I am practising in the West Indies, and have found to my displeasure and to the detriment of my surgical instruments that rust will collect in spite of care and cleanliness.

There is a great deal of dampness and moisture in the atmosphere of the West Indies at all times, and especially so after heavy rains, which rains are frequent and often of short duration.

Immediately after rains the sun shines and is very warm; this quickly frees the amosphere of a large percentage of the moisture, but leaves enough to occasion rust, and especially is it prone to occur indoors, where moisture lingers at all times.

I have resorted to the following: The doors of my instrument case are made to fit tight, and on each and every shelf I keep a wide-necked glass receptacle (the ordinary whiskey glass will do), in which I place two or three drachms of sulphuric acid (C. P.), leaving the receptacles open. As sulphuric acid has a great affinity for water, it absorbs all the moisture in the atmosphere of the case, thereby keeping instruments free from rust and in good condition.

The fact that it absorbs all dampness and moisture is easily demonstrated by the fact that it increases in quantity steadily, until it becomes so dilute that it will absorb no more moisture and its good effect is lost. It is essential, therefore, to renew the acid every four or five weeks to insure its action. I use it constantly, and find that my instruments are in excellent condition and always ready for immediate use.

Chloride of calcium has been used in a similar manner, but it becomes saturated in a much shorter time, necessitating drying by artificial heat, naturally two disadvantages to its use: and, moreover, it does not act so well, to say nothing of its disagreeable odor.

A medical friend practising in Jamaica, a fellow-passenger on my southern trip this winter, stated he had great trouble in keeping his instruments free from rust; and that he was anxious in regard to a new static machine for *x*-ray work he was importing. He had tried chloride of lime but with poor results, and was glad to get my suggestion and intends to follow it.

I would recommend all physicians located in tropical climates and those practising at the seashore during the summer months to give my scheme a trial, as I believe they will be satisfied it is a good expedient and indorse my statements.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DUBLIN HALL SUCCESSFUL ON APPEAL — THE MUZZLING OF DOGS—OYSTER BEDS—ARMY SERVICE —LORD LISTER — GLYCERINIZED CALF LYMPH— COLLEGE OF PHYSICIANS—COLLEGE OF SURGEONS— ELECTIONS, ETC.

London, April 16, 1897.

THE Apothecaries' Hall of Dublin has defeated the General Medical Council. You will remember the circumstances under which the latter body determined to disestablish the hall, as I have had to refer to the proceedings at the several stages. In November last, the hall by the advice of the Privy Council, to which appeal had been made, asked the Medical Council to appoint examiners. This request was rejected and the hall had no course open but to ask the Privy Council to intervene in pursuance of the provisions of the medical acts.

Having heard counsel on both sides, the Privy Council has now delivered judgment in favor of the hall and directed the Medical Council to appoint such examiners.

This is a decisive defeat, and members of the Medical Council may regret having invited it. No one doubts that the Dublin corporation ought not to have been included in the list of qualifying bodies in the act of 1858. But, having been so included, it set to work to fulfil its duties, and, although not particularly successful, clung to the privilege as an important dignity. The Irish College of Physicians was jealous, and eventually the sister college joined forces against the hall, which had practically no defenders. When the Medical Council had the matter before it there was a strong effort to get rid of the hall, by a side-wind, as I reported to you at the time, and the case was pushed to the bitter end with so little regard to judicial impartiality that no surprise can be felt at the result of the appeal to the highest tribunal. A patient hearing was given to both sides by the lords of the Privy Council, who have decided in favor of the hall. Let us hope after this that the authorities of the hall will use the privilege they have secured for the good of the profession and the public, and decline to make a profit out of their dignity.

Medical questions are being thrust into the background by the excitement of the dog-muzzling order. The papers are full of indignant letters from owners of dogs on the cruelty of muzzling and the wickedness of the authorities, who are accused of selecting the most cruel pattern and enforcing its use. It seems to have been a mistake to adopt a regulation pattern, and any muzzle which would prevent biting might have been accepted. At the same time, it is idle to assert that all dogs are naturally disinclined to bite a human being, or that the fear of hydrophobia is baseless. Still less can I sympathize with those who represent that disease as a slight ailment and of great rarity. These ravings about the cruelties of muzzles would all be silenced by watching a case of hydrophobia. In this country, too, we ought to stamp out this terrible disease, but we muddle the matter by leaving it to local authorities, so that dogs may be muzzled in one district and not in the next, and a mad dog cannot be expected to observe the boundaries. We ought to enforce the muzzle for a year in every district at once, and carefully examine every dog imported. These islands are well adapted for such action, and there is little doubt that the country would be delivered from the scourge. But the law must apply in every district at once, and members of Parliament, who are being threatened very freely by their constituents, should reply by rushing through a simple act in this sense; any efficient muzzle should be recognized, and the grievance of dog owners would be largely discounted, as each could use the one he thought the least inconvenient to his pet.

Sir William Priestley, M.D., has signified his appearance in Parliament by a question as to what steps will be taken in view of last year's report on oyster culture, to protect the public from disease arising from contaminated oyster beds. I regret to say he obtained little satisfaction, for the government gave no assurance, though admitting the importance of the matter.

Further questions have been asked about the army medical service, and it is evident the government does not know how to make it efficient without putting down the offensive insolence of its "military advisers." Sooner or later this will have to be done, even though the commander-in-chief have to be informed that he must behave as a gentleman to those who are as well educated and as well born as himself, or, if he cannot do so, he had better make room for some one who can.

Lord Lister must be getting rather tired of compliments and congratulations. However, he will probably appreciate that which is to be offered by his former dressers and house surgeons of Glasgow, Edinburgh, and London. These gentlemen are combining to entertain his lordship at a dinner. Many of them must be scattered over the world, but it is hoped they will send their present addresses, as it is also intended to prepare a chronological list of these officers. It is therefore requested that names (with date of office) be forwarded to the honorable secretary, Dr. Thomson, 28 Queen Anne Street, London, in order that the list may be made as complete as possible.

The information obtained by Dr. Thorne and Dr. Copeman on their recent tour through continental vaccination establishments proved so satisfactory as to the use of glycerinized calf lymph, that I am informed the local government board will introduce the use of this lymph as soon as arrangements for its preparation can be completed.

Dr. Wilks has been re-elected president of the College of Physicians by 79 votes out of 87 present at the meeting.

The late Sir H. Halford bequeathed to the college the portrait of his grandfather, the distinguished court physician who was president from 1820 to 1844, and to whom the college owes its house and other benefits. The portrait is by Sir T. Lawrence.

The College of Surgeons has awarded the Jacksonian prize for this year to Mr. Robert C. Bailey; the subject of the essay is "Diseases of the Prostate." The dental prize in honor of the late Sir J. Tomes goes to Mr. Charles L. Tomes for original scientific work relating to dental surgery.

The honorary medal of this college has been conferred on Sir James Paget and Lord Lister. This is the first time the medal has been given to two persons simultaneously. It is indeed rarely conferred at all — only ten times since the year 1800 until this month.

A curious case has been before the law courts. The Rev. T. W. Belcher, who was formerly a censor of the Dublin College of Physicians, but left the profession for the church, sued Colonel Knollys for a libel contained in his life of Sir Hope Grant. The colonel gave currency in the book to a scandal which he seems to have heard, that the reverend doctor on one occasion preached an "immodest" sermon. The colonel was let off with an humble apology and the costs incurred.

OUR PARIS LETTER.

(From our Special Correspondent.)

MODERN FRENCH THERAPEUTICS—A NEW WAY TO APPLY OLD REMEDIES—NEW REMEDIES—FRENCH IDEAS OF PRACTICE—METHODS OF PROFESSORS ALBERT ROBIN AND HAYEM—TRIONAL AND TETRONAL—UREA IN ASCITES, ETC.—THIOFORM POSSESSES ALL THE ADVANTAGES OF IODOFORM AND IS INODOROUS.

PARIS, April 15, 1897

FRENCH methods of therapeutics do not, after all, differ so much from American. There is, however, this difference, that empiricism, although not entirely wanting in the former, is nevertheless present in a much less degree than in the latter. At one time the reproach was made that the French school was too theoretical, too scientific, and too apt to give less importance to therapeutics than to finer pathological, pathological-anatomical, and bacteriological work. This might, with some truth, have been said regarding the German school, but it is entirely without foundation, in so far as France is concerned, certainly the France of to-day. In no country have such rapid and important strides in therapeutics been made, and in no European country are investigations and experiments going on with greater zeal and constancy.

Among those who have labored most in the field of therapeutics in Paris, and to whose efforts we owe the highly valuable and efficient methods of treatment of disease now at the disposal of the profession, are Prof. Albert Robin, Professor Hayem, and Professor Dujardin-Beaumetz. And it is the former who is the most advanced and active in this department of science, and who has written very voluminously. It was Dr. Albert Robin who first discovered and introduced into practice the subcutaneous injections of the glycerophosphates of calcium and sodium, which may be given in the convalescent stage of almost any disease, in non-febrile conditions generally; also in anæmia and chlorosis. We shall refer to them again presently.

Professor Hayem is another distinguished man who has devoted most of his medical career to the study of applied therapeutics. His principal writings are "Memoirs on the Blood; its Pathological Alterations and How to Treat Them." It is to his initiative that we owe the injections of artificial serum and large quantities of salt and water in the treatment of Asiatic cholera.

One of his chief studies has been upon the different preparations of iron and the results obtained from their exhibition, based upon a long experience in hospital as well as in private practice. Professor Hayem prefers of all preparations of iron the protoxalate. This preparation of iron, in combination with oxalic acid, is administered in the same dose as other preparations of iron. It is claimed that owing to the oxalic acid the protoxalate of iron is more soothing and cooling to the blood than are other preparations of that base, and possesses in addition all their tonic properties. It has been objected by opponents of this preparation that oxalic acid is set free in the stomach. Oxalic acid being set free in the stomach would undergo exactly the same chemical changes as oxalic acid given by the mouth in ordinary medicinal doses, and so far from being an objection would be a decided advantage, for we all know the calming and refreshing action of oxalic acid when administered by itself in the form of lemonade or in the form of pastils to allay thirst; or, again, in combination with cerium, mercury, and potash.

Another favorite remedy of Professor Hayem's is lactic acid, which he prescribes freely in cases of green diarrhœa in children, in quantities of from two to four grams in a mixture of one-hundred grams.

A preparation of iron much in vogue among French practitioners is the lactate. The sulphate is quite obsolete, and even the carbonate is less prescribed than with American physicians. The proto-carbonate is exhibited to some extent but less than the lactate. The tartrate and arseniate are much used, the latter more especially in chlorosis, the dose of the arseniate being obviously much smaller.

Gallic ideas regarding the treatment of fevers have undergone a change during the last few years. For instance, considering fever as a symptom rather than as a disease, even in certain specific fevers, French practitioners "respect" it, as they say. That is, they regard it as a kind of pathological compensation, an effort of nature to throw off morbid process, and hence to be looked upon as benign, and if not actually encouraged at least left to itself. But it should not be treated actively. We might go through the whole of pathology and fill a large volume were we to note even the more important changes that have been made in modern therapeutics, and by that we mean recent therapeutics. The treatment of neurasthenia is typical in this regard. Static electricity and douches to the spine are the remedies now advocated. The combination of iron, quinine, and strychnine is a thing of the past. The bromides, however, are prescribed, usually the bromide of sodium. Take the salicylate of sodium as an example of the onward movement in French therapeutics. Salicylate of sodium, like other specific remedies, is now used in a variety of diseases; in fact, it has become a general remedy, except in cases in which the kidneys are affected. No longer the great specific for acute general articular rheumatism, it is frequently prescribed in chronic articular rheumatism affecting a single articulation, in muscular rheumatism, in neuritis, in neuralgia, gout, grippe, also in certain eruptive fevers. Its application to so large a category of diseases is based upon more recent experiments, principally those made by the late Prof. Germain Sée, in his wards at the Hôtel Dieu, and which have demonstrated beyond doubt that salicylate of sodium possesses three primordial qualities, viz.: antiseptic, analgesic, and antipyretic. It is therefore indicated in a still wider range of diseases than those in which it is already employed. The same generalization is likewise taking place with reference to the therapeutical applications of iodide of potassium.

Two hypnotics much used in French practice are hypnone and trional. Hypnone is a méthyl-benzoile, and is administered in form of gelatinous capsules or pearls, in doses of ten grains (maximum), the pearls containing each one grain. Hypnone is also prescribed in the form of syrup, as follows: *a* hypnone, twenty drops; syrup of orange flowers, twenty-five grams; from one to three teaspoonfuls. Trional is sulfonal in which an atom of méthyle is replaced by an atom of éthyle. The ordinary doses, fifteen to twenty grains, are best given in wafers or capsules, that quickly produce sleep. Trional is rapidly superseding sulfonal which is much preferred by the French school to hydrate of chloral and chloralose. Trional has these advantages over all three: it acts in much smaller doses and the effect is more rapid: often sleep is produced in from fifteen to twenty minutes. Moreover, it succeeds when sulfonal, hydrate of chloral, and chloralose fail, and the sleep induced by trional is generally deeper and more lasting.

Tetronal is another hypnotic of the same class and given in the same way and the same dose, the only chemical difference between them being that in tetronal two atoms of méthyle are replaced by éthyle. But the remedy that has stood the test of time and is the remedy par excellence in, perhaps, a wider pathologi-

cal range than any other is that introduced by Prof. Albert Robin, the distinguished academician and editor of the "Traité de Thérapeutique Appliquée". It was only after long experience in his hospital practice that Professor Robin presented the report upon his method to the Academy of Medicine and introduced it into general practice. His discovery was briefly this: that the waste in very many diseases, such as rheumatism, gout, diabetes, tuberculosis, albuminuria, neurasthenia, and others, including convalescence from grippe, was due, if not to an actual phosphaturia, at least to a phosphatic leakage. Instead, therefore, of acting upon the antiquated principle of trying to stop the leak, he conceived the idea of supplying the material (phosphorus) of which the organism, more especially the brain and nervous system, was being drained. The glycero-phosphates of calcium and sodium fulfil this indication; besides being of simple and easy composition, they are readily assimilated. The glycerophosphate of calcium is more generally used. They are given chiefly in five different forms: hypodermic injections, in wafers, in an elixir, in syrup, and in effervescing granules. From twenty to thirty centigrams twice and sometimes at the beginning three times a day are sufficient. One injection a day is, however, all that is usually required, if that method, which seems to be most in favor, be chosen. These injections may, at first, produce a little erythema, but that and the slight feeling of soreness caused generally pass off after a few days. The glycerophosphates may be given in all cases in which it is desirable to promote nutrition and increase strength.

For disinfecting the intestinal tract and in cases of typhoid fever, diarrhœa, and dysentery, salol is much prescribed in powder form, and in doses of from twenty five to fifty centigrams, or from five to ten grains. Dr Bressard, however, has just reported a case of intestinal calculus of considerable size due to the repeated ingestion of salol. This was undoubtedly an idiosyncrasy, and cannot be used as an argument against its ordinary administration. Urea is now finding application in French therapeutics in this formula: Urea, pure, ten grams, distilled water, two hundred grams. A tablespoonful every hour. It is used as a mild diuretic, although non-irritating, it is contraindicated in affections of the kidneys. Dropsy and ascites of non-renal origin, those more especially due to cirrhosis of the liver, are the conditions in which it does most good. If the diuresis is not augmented in five days after its administration is begun, which would represent about fifty grams, it should be stopped. In France, as elsewhere, physicians are given to trying new remedies, among which we note the following: Pental, or amylene, pure, administered in inhalations; aseptol, in wafers or solution; urethane, in mixture; and thioform, used instead of iodoform. The latter is non-toxic and inodorous, and is given in doses of six grains, two or three times a day, as an intestinal antiseptic.

Dujardin-Beaumetz's "Formulaire Pratique de Thérapeutique et de Pharmacologie" is a volume of convenient size, containing some thousands of prescriptions, besides being a condensed and exhaustive treatise on materia medica and therapeutics.

It was he who made a special study of the art of prescribing, the formulating being of as much importance, in his opinion, as the ingredients, and it is largely owing to his labors that antiseptics, both internal and external, have been made, as it were, the keynote in modern medical and surgical therapeutics. The tendency to abolish altogether the ingestion of medicines by the mouth is becoming every year more marked, and therapeutics may, ere long, be reduced to prophylactic and curative subcutaneous injections.

OUR VIENNA LETTER.

(From our Special Correspondent.)

THE FIRST WOMAN DOCTOR RECEIVES HER DEGREE FROM THE UNIVERSITY OF VIENNA—GREAT SCHOOLS AND MASTERS AND PRACTICAL ADVANCE IN MEDICINE—SOME HINTS AS TO REVELATIONS AT THE INTERNATIONAL MEDICAL CONGRESS AT MOSCOW—PSEUDO-LEUKÆMIA AND NUCLEO-ALBUMIN IN THE URINE.

VIENNA, April 20, 1897

THE question of the higher education of women in Austria has just received an impetus here that was as unexpected generally as it must be eminently agreeable to the advocates of woman's educational rights. On April 2d twenty-three candidates were "promoted" (as they say in Vienna) to the degree of doctor in medicine. Among the number was the Baroness Gabrielle Possanner von Ehrenthal, the first woman upon whom a doctor's degree from any faculty, or, for that matter, any other university degree, has ever been conferred by the Royal Imperial University of Vienna.

The rector magnificus of the university, Professor Reinisch, noted the "promotion" as of very special significance, and complimented very highly the praiseworthy energy and intelligence which had enabled the baroness to overcome the obstacles that lay in her path. He added some words that, coming from the official representative of one of the oldest and most conservative educational institutions in the world, will be read everywhere with interest by the many who are occupied with the questions of the day. "Men may think as they will," said he, "of the higher education of women, but this much every judicious and unprejudiced mind must admit—that the broadening of woman's intellectual circle of vision cannot but elevate the whole people to a higher intellectual level. To limit any longer the circle of woman's activity to the kitchen and the nursery is to sin grievously against progress."

This event does not as yet open the Austrian university freely to women, for this "promotion" is a particular favor, due, it seems, to a special rescript from the emperor; but it is surely the entering wedge that will soon inevitably force open the doors so long closed to women. The rector's words and the reception of the diploma were greeted by the students, who were present in large numbers, with loud acclamations and prolonged cheers, and these were repeated after the exercises were over when the newly promoted doctor was leaving the hall. This is not exactly what one has been led somehow to expect from faculty or students in Europe, and is not the less interesting for that.

So would seem to go another relic of conservatism, but they have them at Vienna to spare and can afford to let one go occasionally. While an American cannot but admire their practical thoroughness in "diagnostics" and their eminently careful pathological anatomy, he cannot but be surprised at the tenacity with which medical men cling to certain ideas that, to say the least, have been outgrown in the advance of scientific medicine. Of what use is it for a great master to advance beyond his times if his disciples are going to cling tenaciously to his opinions till the rest of the world has passed them? It is amusing to find the Vienna school still teaching that varicella is a very mild form of variola, due to a modified and attenuated virus, it is true, but one that is essentially the same. Another favorite dogma here is that secondary syphilis may develop without there ever having been a primary sore; not that this may not have been discoverable, but that it may even never have existed.

Some hints as to the interesting disclosures that the International Medical Congress at Moscow is expected to bring out are occasionally heard. Two of

the questions that French physiologists will introduce are to be (it is said) very strikingly illustrated from the clinical side by the Viennese school.

The discussion of the physiological significance of thyroids and parathyroids in the etiology of myxœdema will be supplemented by the tracing of many other congenital deformities and anomalies, besides the serious condition so well known, to the influence of these ductless glands in the neck. The different forms of diabetes, after their physiology to date has been thoroughly reviewed, will be distinguished clinically by certain modifications in existing tests for sugar and accompanying morbid products in the urine that will practically revolutionize the question as we now know it.

At the Wiener Medizinisches Doctoren Collegium, on April 5th, Dr. Adolf Jolles demonstrated the presence of nucleo-histon in considerable amount in the urine of a patient suffering from pseudo-leukæmia. The process is a somewhat complicated one, and will need modification before it can be applied clinically; but the demonstration seems chemically faultless. The presence of this important constituent of white blood cells in pseudo-leukæmic urine cannot but serve to throw light on a disease that has been thus far so much of a mystery in its etiology and evolution, while it may add to our knowledge of the functional importance of that physiological element that is just now attracting so much attention—the leucocyte.

EXPENSIVE SANITATION.

To the Editor of the Medical Record.

Sir: Some time since the board of health condemned a large number of tenement houses and caused them to be torn down. Presumably this was done under color of law and with the expectation that the city would have to foot the bill for damage. I see by this morning's paper that the amount required to settle the damages of this sort is estimated at $10,000,000, which the city will have to issue bonds for.

Referring to sections 1,315 and 1,316 of the charter of Greater New York, you will find the law governing the case in the event of the governor signing the new charter. It confirms the power of the board of health to institute condemnation proceedings, and makes the city liable for loss and damage to the property owner.

As I understand it, the board of health has not yet caused damage to the amount above mentioned; but a continuance of its present policy will, it is estimated, obligate the city to that extent. Surely sanitation under present auspices is an expensive luxury.

A. B. C.

New York, April 24, 1897.

Infectious Nature of Acute Rheumatism.—The infectious nature of rheumatism is shown, according to Jaccoud, by the case of an infant born while the mother was suffering from rheumatism. Twelve hours after birth the child was attacked by a fever and swelling of the joints. These signs disappeared under salicylate of sodium at the end of eight days. In a second case the mother was delivered on the fifth day of her polyarticular rheumatism. Three days later the infant became affected.—*Journ. de Méd. et de Chir. Prat.*, February 10th.

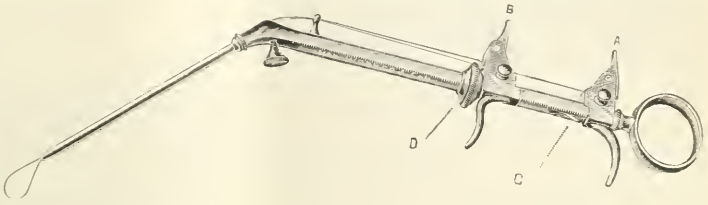
THE MECHANICAL PRINCIPLES OF THE ÉCRASEUR, AND DESCRIPTION OF A MODIFIED BOSWORTH SNARE.

By THOMAS HUBBARD, M.D.,

TOLEDO, OHIO.

The late Prof. William Goodell called the attention of his classes to an important mechanical principle involved in the use of the écraseur. He stated that he always fastened the ends of the wire independent of each other, so that one could be released and made fast to the main shaft in case the tension became too great. With one end fixed as the other is drawn home,



the cutting action of the wire is more of a saw-like character and much less tension and strain of wire and instrument are required to accomplish the same result. Having been several times forced to do this in nasal operations, I devised an instrument based upon the general lines of the Bosworth snare, in which one or both wires can be drawn home. The simplicity of the wire fastener commends itself, but I have found such diversity of practice as to the size of wire used that it is impracticable to adapt the eccentric-lever principle to all operators, and hence the belaying-pin fasteners on each side of the riders.

When the wires are in place, but not fastened, and the operator is seeking to get the loop over the body to be removed, it is a very useful procedure to take the free ends in the fingers and manipulate by pushing out and drawing in until the tumor is properly engaged—that is, until one feels that the wire loop is near the point of origin of the growth. Then the wires can be refastened by pressure on the levers and the loop tightened by drawing both together. Should the tissue resist to the point of severe strain of the wire, the screw nut is run down and holds the upper rider in place, while the rear one can be drawn home by the fingers unaided. Should there still be some wire out, the rear rider being caught by a small spring ratchet on the shaft, the other can be drawn or screwed down until the loop is all in.

As a general principle, as small wire as possible should be used, since it cuts more easily and with less pain. In a snare of this kind a very fine wire (No. 3 "German music wire") will do for all nasal and throat operations in as far as tensile strength is concerned. I always heat the loop over the lamp to render sterile, and by drawing the temper of the ends the wire is more pliable to fasten.

The question of angle of cannula and shaft is not so important, since an instrument constructed on this principle is never subjected to very severe strain; still all friction at the angle should be reduced as much as possible. All operators will appreciate the statement that the less the force used the more delicately can the tactile sense determine the progress of the operation and nature of the tissue involved. The use of a heavy instrument, with heavy wire and powerful lever force, confuses tactile impressions and is not without danger. The application of this principle, in some

such manner as I have devised, would be an improvement on all kinds of écraseurs.

Description of snare: The riders are independent of each other, one end of the wire being fastened to each. *A* and *B* are eccentric-lever wire fasteners, one wire passing through a groove in *B* to *A*. *C* is a spring catch holding the rear rider. *D* is an ordinary screw nut. The eccentric lever grips the wire, and the harder the pressure on it the tighter the grip. The extra pin fasteners on each side of each rider are used in case heavy wire is preferred. The instrument is made by Max Wocher & Son, Cincinnati, Ohio.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 1, 1897:

	Cases.	Deaths.
Tuberculosis	156	124
Typhoid fever	3	2
Scarlet fever	223	11
Cerebro-spinal meningitis	8	11
Measles	210	5
Diphtheria	255	20
Laryngeal diphtheria (croup)	11	0
Small-pox	6	4
Chicken-pox	32	0

Distinctions between Human and Animal Blood.—On mixing the blood in question with a little bile, there are formed crystals not exceeding 0.003 metre in size. Those of man are right rectangular prisms; those of the horse, cubes; of the ox, rhombohedrons; of the sheep, rhombohedric tablets; of the dog, rectangular prisms; of the rabbit, tetrahedrons; of the squirrel, hexagonal tables; of the mouse, octahedrons; of common poultry, cubes modified at their angles; etc.—*Scientific American.*

The Tanret and Esbach Tests for Albumin.—According to Boureau (*Gaz. Méd. du Centre*, No. 1), the reagent known by the name of Tanret, acetic solution of iodide of potassium and bichloride of mercury, is not trustworthy, because it precipitates at the same time the peptones and alkaloids. Thus the urine of an individual taking sulphate of quinine would show an abundant precipitate, causing a belief in the presence of albumin. In the same way, one taking antipyrin would have a reaction take place in testing with the Esbach solution. The author, therefore, believes these two tests should cease to be employed. He gives as a sure test for serin and globulin, the two pathologic albumins: Mix equal parts of urine and sulphate of sodium and add a few drops of acetic acid. If heat produces a precipitate, serin or globulin is surely present.

Starchy Foods.—Dr. Drinkwater, in some recent lectures on the chemistry of the kitchen, asserts that by modern processes of milling most of the nitrogen is eliminated from the flour. This fact is generally conceded, but he also maintains that the excess of nitrogen contained in the flour milled by the old methods is not in a form assimilable in the body, and that a large portion is not used, so that there is more waste in whole-wheat bread than in fine white bread. Starch itself is not a food. There is no doubt that hundreds of children are starved to death by this kind of alimentation. It is a carbohydrate pure and simple. Cornmeal is not a food. There is no difference chemically between starch used in the laundry and that found in the potato. Cornmeal and sago contain eighty-three per cent. of starch and rice and pearl barley seventy-six per cent. It order to render starchy foods digestible they must be well boiled. Dr. Drinkwater considers it no less than a crime to feed young children on starchy foods, as at this age the salivary glands do not act. He shows how the drawback to starchy food may be overcome in cooking, as, for example, in toasting bread, starch is transformed into dextrin. He would apply the same method to tapioca, putting it in the oven and baking it dry for ten minutes before using. He recommends the use of malt flour, since it contains something which has the power to turn starch into sugar.—*Sun*, April 11th.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

REMOVAL OF PART OF A SUBCORTICAL CEREBELLAR TUMOR. DEATH TWO AND ONE-HALF MONTHS LATER.[1]

BY JOSEPH COLLINS, M.D.,

NEUROLOGIST TO THE CITY HOSPITAL, ATTENDING PHYSICIAN TO ST. MARK'S HOSPITAL,

AND

GEORGE EMERSON BREWER, M.D.,

ATTENDING SURGEON, CITY HOSPITAL; ASSISTANT DEMONSTRATOR OF ANATOMY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE following case is recorded because we believe it demonstrates that a subcortical cerebellar tumor can be removed without sacrificing the patient.

Michael Delaney, twenty-six years old, single, by occupation a laborer. There is nothing in the patient's family history bearing directly or indirectly upon his illness. He denies syphilitic infection, and the only illness that he remembers is an attack of rheumatism and bronchitis about two years ago, after which the hair fell out. His present illness dates from October 20, 1896. He is very positive that the headache which was the prominent symptom developed suddenly on that day. The pain was principally in the back part of the head. It was of a boring, agonizing character and so severe that he had to forego work within a few days after its first occurrence. He did not, however, take to his bed. Soon after the beginning of the headache, dizziness occurred, and this symptom was always aggravated by exertion and by sudden movements. Within a few weeks after the beginning of the present illness he and others noticed that his gait was rather uncertain. According to his own picturesque phraseology, "he could not keep out of the gutter." He is not so positive about the date when vomiting first occurred. It may have been a month, or even longer, after the first occurrence of headache, but he is sure that when it did occur the headache was more continuous and severe, and that his sight began to fail. At this period the headache was no longer confined to the back of the head, but was sometimes of the frontal region; oftener it had no localization. From this time until he was admitted to the hospital, in the wards of Dr. C. C. Ransom, the vomiting occurred several times daily, and he became progressively emaciated and weak. Examination at this time showed normal condition of the lungs and heart, though the sounds of the latter were very weak. The pupils were equal, responded to light and in accommodation; the urine was normal. Muscular strength was fairly well preserved, there was no alteration of the special senses; no cranial-nerve palsy. The patient was put upon iodide of potassium, administered per rectum, and the dose rapidly increased. The patient vomited several times a day, retained very little food, and complained bitterly of severe pain in the front and the back of the head. He remained in bed and manifested no inclination to talk.

[1] Read before the surgical section of the New York Academy of Medicine, on April 12, 1897.

On January 16, 1897, the patient was examined, and the following notes were made:

"The patient is found lying in bed, the face and head half buried in the pillow, and the eyes closed. In response to the question in regard to his complaint, he says that his head is sore, that he has a great deal of dizziness, which is nearly as severe when he is lying as on sitting or standing, and that he cannot retain food. The patient gets up when he is requested, and walks across the ward. It is noticed that his gait, though by no means a staggering one, or one suggestive of cerebellar disease, is rather uncertain, and he has a tendency to go toward the left side, giving the impression of having forcibly to restrain himself from falling toward the left. He is able to stand with the feet together as with them apart, even with the eyes closed, but it requires a good deal of voluntary effort, shown by the rigid condition of the flexor muscles of the feet and legs. There is slight ataxia, or rather uncertainty of movement of the upper extremities. There is no paralysis or spasm of any of the cranial nerves. The pupils are moderately dilated; they respond slowly to light, more promptly in accommodation. The special senses are not altered. There is no tremor of the extremities, nor of the face and tongue. The right knee jerk is lively, and is not increased on reinforcement; the left knee jerk is diminished, and is slightly increased on reinforcement. There is no impairment of articulation and he swallows without difficulty. The palatal and pharyngeal reflexes are present, but they respond sluggishly. The patient does not hear so acutely in the right ear as in the left, but there is by no means deafness of the right ear. The pulse is weak, and beats sixty-eight times per minute.

"There is no difference in the strength of the two sides of the body. Repeated tests for the sense of touch and sense of position fails to reveal the slightest anomaly of disturbance of sensation.

"The only psychical alteration that can be made out is a hesitancy on the part of the patient to indulge in voluntary conversation. Memory and associative faculties are practically undisturbed.

"Repeated inquiry fails to elicit any history of spasm or tetanic contraction in any of the muscles of the body or of the extremities. There are no stiffness of the neck and no increased tension in the musculature supplied by the trigeminus."

The eyes were examined ophthalmoscopically, and a moderate degree of choked disc was plainly evident in both eyes, but more marked on the left side. The patient's condition remained practically unchanged for the next month, except that in addition to the headache, dizziness, and vomiting, the patient now complained of sleeplessness.

An examination made on February 10th shows no particular change from the status obtained before, except that the knee jerks are now very much diminished on both sides, but they are still elicitable, and the disturbance of gait is more manifest. Still, it is remarked that the gait is by no means a typical cerebellar gait, and it is specifically noted that it is the gait of asthenia. Patient apparently has to guard himself from walking toward the left. This

asthenia is likewise very apparent in standing; whereas three weeks previously he was able to stand without particular difficulty, now standing alone is almost impossible. With the exception of slight difficulty of hearing in the right ear, there is no involvement of the special senses. There is no cranial-nerve palsy or spasms, and it is particularly noted that the trigeminal nerves on both sides are intact. There is slight uncertainty of movement in the upper extremities, but it is not sufficient to be considered ataxia, and when the patient is lying there is no hesitation or uncertainty in putting the finger or toe upon any part of the body. The patient still complains bitterly of the headache and of the vertigo, and the former he now localizes in the middle of the occipital region. It is noted at this time that the patient can scarcely see across the ward, but that the pupils still respond somewhat to light.

On February 13th, it is noted that the patient's condition is practically unchanged, except that his knee jerks are absent, and that he is getting weaker, more

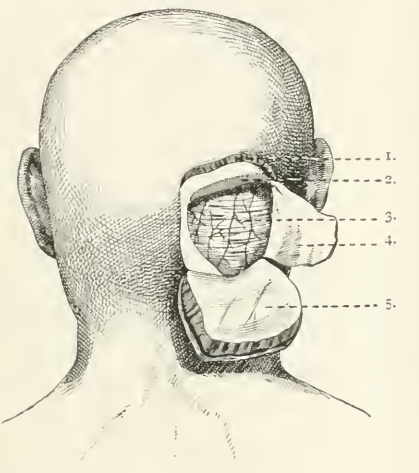

FIG. 1.—Showing line of incision and exposure of cerebellum, head in extreme flexion. 1, Cut edge of bone; 2, under surface of tentorium; 3, exposed inferior surface of cerebellum; 4, reflected flap of dura; 5, bone flap, with soft parts adherent.

restless, and more sleepless. His intellectual faculties are apparently unimpaired, and he avers that he does not care to live and suffer as he is now suffering. Since the beginning of the illness he has lost about fifty pounds in weight. The dangers of operation for his relief and the very slight prospects for recovery which can be held out to him if he submits to the operation are explained to him. He is not only willing to take the slight chance, but he is very anxious that the operation be undertaken at once, as it has not been possible to give him any relief by medication. Ophthalmoscopic examination at this time shows well-marked double neuroretinitis. All alimentation is stopped except bovinine, and the patient is prepared for operation.

On account of the absence of localizing symptoms, such as tumefaction of the conjunctiva, impairment of function of the fifth nerve or of any of the other cranial nerves below this, of tetanic contraction or localized spasm, of nuchal rigidity, or, in short, the absence of any symptoms other than the classical ones of cerebellar tumor, Dr. Collins was unwilling to say where the tumor was probably situated, but was willing to hazard the guess that it was subcortical in the substance of the right cerebellar hemisphere.

Operation.—After thorough disinfection of the patient's head, the position of the sinuses was indicated by needle scratches upon the scalp. Ether was given to complete surgical anæsthesia, and the patient placed face downward upon the table. An omega-shaped incision was then made with a convexity upward, beginning in the median line opposite the rudimentary spine of the first cervical vertebra, extending upward and to the left, then arching over toward the right mastoid process, then downward to a point about two inches to the right of the point of the original incision. The soft tissues were divided to the bone, and the bleeding point was secured. The bone was then carefully chiselled through in the line of the cutaneous incision. This part of the operation was unusually prolonged, owing to the care taken to avoid wounding the sinuses, three of which (the superior longitudinal and the two lateral) were crossed by the incision. The bone flap, with the soft parts adherent, was then raised, and the dura exposed over the lower portion of the occipital lobe, the right and a smaller portion of the left cerebellar hemispheres. At this stage of the operation, the assistant who had administered the anæsthetic reported that the patient was pulseless. The bone flap was quickly replaced, the head wrapped about with a sterilized towel, and the patient placed upon his back. Four ounces of hot whiskey and water were given by enema and about twenty-four ounces of hot sterilized salt solution introduced into the right median cephalic vein. As the reaction was prompt and satisfactory, the patient was again placed in the original position, and a triangular incision made in the dura covering the right half of the cerebellum. This gave an excellent exposure of the part, and allowed complete inspection and palpation of all of the exposed portion of the right hemisphere. Nothing abnormal was seen or felt. An incision was then made into the cerebellar tissue, half an inch in depth, parallel to the upper border of its inferior surface. The structures at the bottom of this incision were carefully palpated. This procedure, although carried on with the greatest care, resulted in a very considerable laceration of the tissues and free hemorrhage. The entirely negative result of this examination led to the making of another and deeper incision near the median lobe and at a right angle to the first. This region was likewise palpated with the forefinger, at first without result; but later, when the tip of the finger reached a point about one and one-half inches from the surface, a very distinct nodule was felt, about three-fourths of an inch in diameter, somewhat lobulated in outline, and decidedly harder than the surrounding tissue. As it was recognized now that the tumor occupied a position but little removed from the roof of the fourth ventricle, considerable care had to be exercised in its removal. This, however, was finally accomplished in three stages, by means of a Volkmann's spoon and the forefinger. As the patient's condition had become extremely critical, the lacerated and protruding mass of cerebellar tissue was quickly removed with the scissors and the parts were thoroughly irrigated with a sterilized normal salt solution. A gauze drain was then placed over the exposed cerebellum and carried outward through a fenestra cut in the bone flap. The bone was next replaced as accurately as possible, and the skin sutured with silkworm gut. A large gauze and cotton dressing was applied and the patient placed in bed. His pulse at this time was so rapid and weak that another twenty-four ounces of hot salt solution were introduced into the left median cephalic vein, a pint of hot coffee was injected into the rectum, and several hypodermics of whiskey were administered, one of which included a twentieth of a grain of strychnine nitrate. Reaction followed, slowly at

first, but improved during the next six hours. Food was administered by the rectum only for thirty six hours, then gradually was taken by the mouth.

His progress was uninterrupted by a single untoward symptom. The gauze drain was removed on the third day, and the wound was united and all stitches were removed on the tenth day. He has not vomited since he left the operating-table, nor has he complained of headache. His eyesight is now (two months after the operation) nearly normal and he has gained about thirty pounds in flesh.

There are a few points in the clinical history which this patient presented that are worthy of remark in relation to the attributable symptomatology of cerebellar tumor. The important symptoms which the patient presented were headache, vomiting, and dizziness. These were well marked and continuous. With the exception of the optic neuritis, which was a late manifestation, and the slight disturbance of gait, which, until the last two weeks of his illness, is better characterized as an asthenic rather than a staggering gait, there were practically no physical accompaniments. The fact that impressed itself more strongly than anything else upon those who were in attendance upon him was the total absence of any subjective or objective symptom that could be taken to point to compression or irritation of any neighboring structures such as the pons, the quadrigeminal bodies, the oblongata, or the cranial nerves at the base. It was the absence of symptoms that would result from such encroachment that led to the diagnosis of a subcortical neoplasm. There was very little in the patient's history or in the results of examinations to incline one to make a more localizing diagnosis than this.

The fact that disturbance of equilibration in both standing and moving was slight, taken in connection with the fact that such has been noted with tumor of the posterior segment of the worm, led to the suspicion that the lesion was closer to this than far removed in the hemisphere. The fact, also, that the patient in walking had an inclination to stagger toward the left, or rather to favor that side, was given due weight in suggesting that the right half of the cerebellum was the seat of the lesion.

It is worthy of note that optic neuritis was not an early nor a very profound symptom, as it is frequently in tumor of the cerebellum, and, although it had reached an advanced degree before the patient was operated upon, about four months had then elapsed since the first symptoms of the disease.

Although it has been shown a number of times that

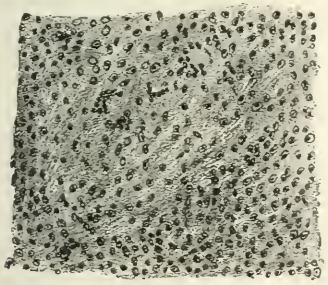

Fig. 2.

the seat of the pain of greatest intensity in the head has but little significance in suggesting the situation of an intracranial tumor, this case is in evidence that sometimes cerebellar tumor produces pain of the back part of the head predominantly, although late in the disease our patient did not admit he had a headache so much as a soreness of the head, and this was so universal that he could not localize it. Moreover the headache was not associated with stiffness of the neck, as it is in many cases. Other symptoms that have been noted with cerebellar tumor, with sufficient frequency to make them an integral part of the disease, such as tetanic contraction of the neck and back

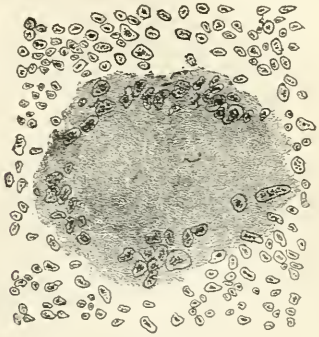

Fig 3.

muscles, general or unilateral convulsions with preservation of consciousness, ocular palsies, involvement of some of the lower cranial nerves, etc., were in this instance absent.

Microscopic report: Portions of the tissue which was removed from the cerebellum were hardened in alcohol, and embedded in celloidin, according to the methods usually employed. Sections were cut and stained with hæmatoxylin and eosin. Upon microscopic examination the sections showed numerous areas of necrosis throughout and largely replacing the normal cerebellar tissue. The areas consisted of disintegrated cells which had lost their nuclei, or they had failed to stain in the ordinary way and the cell bodies had been changed into homogeneous masses of detritus (Fig. 2). In various parts of the sections were large giant cells containing numerous nuclei and surrounded by epitheloid cells, and these in turn were enclosed by numerous lymphoid cells. Other sections were stained for tubercle bacilli, in the ordinary way, and on examination a few bacilli could be seen in the tissues surrounding the degenerated area, and also in and around the large giant cells (Fig. 3)[1].

Two interesting facts were observed during his convalescence, one being that he complained of a continuous salty taste in the mouth for three or four weeks; the other, that the secretion of the kidneys was markedly increased. During the first month following the operation on only one occasion did the patient pass less than one hundred ounces of urine in twenty-four hours, and the amount one day reached one hundred and ninety-six ounces. An effusion was discovered in the right pleural cavity two or three weeks after the operation and after the complete healing of the wound. Its presence was indicated only by a slight rise of temperature for three or four days. There was no pain, cough, or embarrassment of respiration. A specimen of the clear fluid was withdrawn and examined for micro-organisms, with negative result.

It is not our intention to discuss in any detailed manner the subject of the operability of cerebellar tumors. It has been the consensus of opinion of surgeons and neurologists, based upon the experience up to date, that the great majority of cerebellar tumors are not amenable to operative measures. This unanimity of opinion has not been reached without abundant trial of the efficacy of surgery. And, although a few instances of successful removal of neo-

[1] We are indebted to Dr. R. E. Peck, of New Haven, for these drawings, as well as for aid in section preparation.

plasms of the cerebellum have been recorded, they are very few indeed compared with the great number that have been subjected to operation. Moreover, they have in some of the instances been cases of cysts situated near the occipital surface of the cerebellum, in which evacuation of the contents has been followed by temporary relief, as in the case reported by Maunsell. This case cannot be reckoned, however, as one of removal, nor can the one reported by Herminidas, as the only surgical procedure after exposing the cerebellum was puncture of a cyst, in the first instance a hydatid, in the second a simple cyst. The other cases that have been reported as cases of successful removal of a tumor by no means positively indicate that the operation is a justifiable one, even though they have been recorded as successful. In most of these cases, the operation has been successful only in so far as it shows the possibility of exposing the cerebellum and extracting a portion of a tumor. But unfortunately, in the cases in which it has been done successfully, the operation has not contributed to the patient's life nor to his comfort. This is particularly true of a case recently reported in *The Lancet* by Murri, of Bologna, who describes in great detail a case operated upon by Bendani. The tumor was a fibro-sarcoma situated in the cortex. The patient was alive three weeks after the operation, and was reported as "rather better than worse." The same is true of the three cases of tuberculous growth reported by MacEwen, in which a palliative operation was performed to remove pressure. Although this was followed by a very marked amelioration of the painful symptoms for a period of several weeks, all three patients had hernia cerebelli and died within a few months. The only case which we have been able to find in which a subcortical tumor of the cerebellum has been removed, with any prospect of recovery, is the one reported by Stewart and Annandale. In this instance, the patient was reported two months after the operation as being free from the return of active symptoms, although the tumor was of the nature of a sarcoma.

Addendum.—May 1, 1897: Such was the report presented to the surgical section of the Academy of Medicine on the 12th of April, when the patient was shown, apparently quite well. Shortly after that date the patient sickened and publication of the report was delayed. Although it was recognized, because of the tuberculous nature of the cerebellar growth and the occurrence of a silent pleurisy, that the patient's life was in imminent jeopardy, no immediate disastrous developments were anticipated. We were led particularly to such a conclusion from consideration of the fact that the patient had gained no less than thirty pounds in weight in the nine weeks following the operation. Three days after the patient was exhibited at the Academy of Medicine it was remarked that his appetite was more ravenous than usual. The next day he complained of feeling ill and refused food, saying that if he partook he was sure that he would vomit.

The tongue was flabby, covered with a foul, whitish-yellow coating; the breath was very offensive; the bowels were constipated. He complained of pain in the hypogastrium, felt indisposed, and went to bed. Repeated small doses of calomel, succeeded by a saline purge, were followed by improvement in his general condition, and on the next day he felt quite well again.

A day or two later he had a second attack, similar to the first, but now he vomited three times within twenty-four hours. The symptoms were typically those of a "bilious" attack associated with slight elevation of temperature, 99°–101° F. The symptoms did not subside after calomel and salines had been given. A week after the first recurrence of the symptoms the patient's condition was such that the advisability of again laying bare the cerebellum was considered. At this time the gastro-intestinal symptoms continued. The patient complained of pain in the abdomen; the temperature, of a vacillating character, fluctuated between normal and 101° F., sometimes higher in the morning than in the evening and *vice versa;* while formerly (since the operation) the patient had been sociable and garrulous, he now became very reticent, non-attentive, and resentful of attempts to engage him in conversation, although when he talked and answered questions he was quite rational. The most striking feature of his mental state at this time were non-attentiveness and insistence on lying on his front. If he were placed on the back he resented and squirmed until he again got his face in the pillow. Aside from these there were absolutely no symptoms referable to the intracranial contents. The pupils were equal and responded promptly; the knee-jerks were present; there was no impairment of sensory or motor conductivity; vision alone was apparently less acute than normal. The eyes were not at this time examined ophthalmoscopically. The patient had no cough, expectoration, or sweats. He retained fluid food in generous quantities. On the following day there was general amelioration of all these indefinite symptoms and marked general improvement.

The improvement was only transitory, for a day or two later it was again thought advisable to consider the question of entering the cranial cavity. It was decided that first lumbar puncture should be tried, as the symptoms, if they suggested anything intracranial, pointed to increased intraventricular pressure. A meeting was arranged for the following day, April 27th. There was nothing urgent or alarming in the patient's condition on the 26th. Indeed there had been no haste to make a lumbar puncture, so indifferent had been the symptoms, pain in the abdomen, anorexia, coated flabby tongue, mental sluggishness. It came, therefore, as a surprise on entering the ward, to hear that the patient was dying; that about two hours previously he had without the slightest warning developed Cheyne-Stokes breathing. He was then apparently in the death agony. Restoratives were at once applied externally, intravenously, and rectally, and as soon as they began to revive the patient the needle was introduced between the third and fourth lumbar vertebræ and two and one-half ounces of clear fluid flowed out. As this was not followed by any beneficial effect, and as perversion of the rhythm of respiration was soon manifested again, it was decided to reopen the skull. The patient was given another injection of hot coffee through the rectum and alcoholic stimulant hypodermatically, and prepared rapidly for the operation. No anæsthetic was used.

An incision was made in the line of union of the soft parts and a few blows of the mallet on the chisel served to lay open the union of the bony parts. On removal of the segment of bone that had previously been the flap, the cerebellum presented an entirely normal appearance. There was not the slightest bulging or tumefaction or evidence of pressure in any form. The finger was carried into the substance of the cerebellum from which the tumor had been previously removed, and after it had passed for a short distance into the hemispherical tissue it impinged upon a large hard mass, fixed and of irregular outline. A gentle effort was made to get the finger beneath it: instantly the patient stopped breathing and was dead in a shorter time than it requires to state it. The tumor was not removed immediately post mortem, although the possibility of doing so was demonstrated.

An autopsical examination was made twenty-four hours post mortem. On removal of the calvarium the brain bulged: the veins of the diploe and the sinuses were congested: the dura was slightly congested and non-adherent; the pia was slightly cloudy over the

convexities and at the base, but its appearance did not suggest an inflammatory state. The interpial fluid was considerably increased. The cerebellum showed that the right hemisphere was about one-fourth smaller than the left, corresponding to the amount that had been cut away. In the substance of the right hemisphere and in close proximity to the ventral surface, approximating the superior vermis internally, lay the hard irregular mass that had been felt while the patient was on the operating-table. It was easily removed, and measured, after it was taken out, 4.5 cm. in length (which extended cross-wise in the hemisphere), 3.5 cm. in width, and 2.5 cm. in thickness. Of irregular shape, it was firm, non-yielding, almost fibroid to the touch. Externally of reddish-white color, on being laid open no doubt of its true nature could exist. Save for a reddish streak that ran across the middle of the mass, and for a similar streak toward one side, it was a pale yellowish, caseous-looking mass, of consistency diminishing as the finger approached the centre. In every respect it was a typical caseous tuberculoma.

On opening the cerebral hemisphere the ventricles and all their orifices and aqueduct communications were distended and enlarged, and correspondingly filled with fluid—a moderate degree of internal hydrocephalus.

On opening the thoracic cavity it was seen that the right lung was pressed upward so that it occupied less than one-half of its customary space, and that from the fifth to the ninth intercostal spaces was shut off by a sac whose walls, upward of half an inch in thickness, appeared as if constituted of compressed tallow or wax. These walls enclosed a cavity that contained more than a pint of clear limpid fluid. The right lung itself had no resemblance in size or shape or appearance to the normal lung. It appeared as a mass of finely hashed, closely pressed, and hardened dark red tissue; in short, it was one solid mass of small tubercles, from the apex to the base. No cavities existed in the lung; the finer bronchial tubes were effaced, the larger tubes compressed. The retro-pulmonary and post-mediastinal glands were enlarged. The left lung showed tuberculous infiltration at the apex; otherwise it seemed normal. The kidneys macroscopically showed evidence of chronic parenchymatous nephritis. The other visceral organs and their covering seemed normal to the naked eye. Microscopical examination has not yet been made of any of the tissues, save the tumor. The description of the part removed at the operation applies to this.

The interpretation which we put on the post-operative developments of the case are as follows: Only a part of the tumor, possibly an outgrowth or a detached isolated tuberculoma, was removed on operation. The operation sufficed to efface all symptoms of increased intracranial pressure, and with it the conditions that were causative of the patient's emaciation. The most patent consequences of this, aside from the disappearance of the intracranial symptoms, was the increase of the patient's weight, stupendous as it was. The only symptom that persisted was what may be termed, for sake of convenience, a fourth-ventricle symptom—polyuria, polydipsia. Soon after the operation a tuberculous pleurisy, almost symptomless, developed: it denoted general tuberculous infection. The serous exudate which accompanied it became circumscribed by a fibrinous exudate, which became a culture ground for the bacilli. Coincidently with or subsequently to the pleural infection, there was general pulmonary infection, which spent itself to the complete usurpation of the right lung and then extended to the left lung. Simultaneous with this general tuberculous invasion, or in part consequent upon it, a solitary tubercle in the right cerebellar hemisphere, part of which or a companion of which had been successfully removed, took on increase in size and in decay. The former, manifesting itself almost exclusively on the Sylvian aqueduct and the fourth ventricle, caused the internal hydrocephalus and its symptomatic entailments; the latter caused Cheyne-Stokes respiration and death.

THE STATE OF THE REFLEXES IN SUPRALUMBAR LESION OF THE CORD.

By JOSEPH FRAENKEL, M.D.,

NEW YORK.

Mr. President and Gentlemen: The unconditional acceptation of the results of experimental physiology in their application to human pathology has often been the source of clinical fallacies and errors. This is true for the pathology of the vegetative organs, and to a certain extent it is true for the pathology of the nervous system, which in spite of its similar anatomy has a materially different physiology in the human and animal being. When the spinal cord of an animal is severed, the immediate loss of the reflex capacity of the centres situated below the seat of severance is followed sooner or later by a marked increase of the reflexes. This is a well-established dogma of experimental physiology, and is the basis of the clinical rule that an interference with the function of conduction of the spinal cord leads to an exaggeration of the reflex activities of the centres situated below the lesion.

Accordingly, most text-books teach this, and all observers seem to agree to the correctness of it, notwithstanding occasional reports of cases that contradict such teachings. It is now nearly forty years since cases were first reported in which a supralumbar lesion of the spinal cord produced flaccid and not spastic paraplegia. Several cases of this type passed unremarked into the annals of medical literature. Even a case of Kahler and Pick, published in 1880, in which the attention of the faculty is called to the discrepancy existing between the teachings of physiology and the clinical findings of the case, had a similar undeserved fate. How universal this belief of an exaggeration of the reflexes in lesion of the motor conducting tracts of the cord is, is shown by the fact that not later than three months ago it was remarked in this society that the only way to account for the statement of one of the members—that the knee jerks were not always exaggerated in compression paraplegia, that on the contrary they were sometimes absent—was to assume that the observations were defective.

To Bastian is due the credit for having pointed out the necessity of reviewing the physiology and pathology of the reflexes, especially of the reflex manifest at the knee. Bastian's first publication was in 1890, and since that time numerous contributions to the subject have appeared. The most important of these are the articles of Bruns, Thorburn, Bowlby, Jackson, Babinski, Herter, Stieglitz, Gerhard, Habel, Bischof, Hoche, and Kocher. In addition to these, the state of the reflexes in high lesions of the spinal cord is to-day attracting a modicum of neurological discussion.

The paramount diagnostic and prognostic importance of the reflex activity of the nervous system for neuropathology induces me to report to you to-night several cases bearing on this question, and to ask your opinion concerning the advisability of an attempt to reconcile the clinical findings with consecrated physiological teachings. I shall report the cases as briefly as possible.

Case I.—This case was reported by Dr. Dana and

[1] Read before the New York Neurological Society, April 1, 1894.

myself in "Neurological Reports" from the Post-Graduate Clinic, being the July number of the *Post-Graduate Journal*. W. S——, sixty years old, a cigar maker, entered the Montefiore Home, on January 2, 1894, fourteen months after the beginning of his disease. His previous history is uninteresting. The attributable cause of his illness was exposure. During the first six months he complained of sharp darting pains in the lower extremities, and he was treated for rheumatism. Paralytic symptoms appeared rather abruptly, the initial paraparesis soon developing into a total motor and sensory paraplegia. This was accompanied by a disturbance of the sphincters. Extensive bedsores developed during the last four months of life. Pain was the predominant subjective symptom.

Examination of the patient was incomplete, on account of his profoundly asthenic condition. It was, however, determined positively that there was total motor and sensory paraplegia, with loss of the deep and superficial reflexes. The spinal column showed no abnormality, nor was there any tenderness over the spinous processes. There was no localized atrophy, but marked emaciation.

On the third day after admission the patient developed high fever and soon became unconscious. This unconsciousness terminated in death after a few days. The post-mortem examination revealed caries of the bodies of the eighth and ninth dorsal vertebræ. The dura at this level was greatly thickened, especially on the anterior surface. For about three inches it was firmly adherent to the vertebra. The cord was compressed and softened at this level, and on transection there was profound softening. On microscopical examination at the level of the carious vertebræ the cord showed very extensive changes, mainly of the nature of myelomalacia, the left half of the cord being more profoundly affected. Above the lesion there was secondary degeneration of the columns of Goll, and of an area in the lateral columns lying in front of the pyramidal tracts and separated from the periphery by a zone of normal axones. This area occupied therefore that allotted to the ascending lateral bundle. Below the lesion there was secondary degeneration of the pyramidal tracts. Examination of the area of meningitis made the tuberculous nature of the lesion highly probable.

Case II.—F. S——, twenty-one years old, Russian, by occupation a machine operator, entered the Montefiore Home on account of transverse myelitis. The patient's history was that she was well until nine months before coming to the hospital. The disease developed apparently without cause. The first symptom was severe shooting pain in the legs, but on account of its transitoriness she did not seek medical aid for its relief. It was not until disturbance of the function of the bladder aroused her to the serious nature of her malady that she consulted a physician. In a short time there developed heaviness of the legs and a feeling of numbness. Within six months from the appearance of the first symptom she was completely paraplegic and confined to the bed. Two weeks before death bedsores and absolute paralysis of the sphincters developed. On entrance she complained of severe pain in the right side of the chest.

Examination shows a well-built and fairly well-nourished but anæmic individual. The anæmia is more evident on the skin than on the mucous membrane. Temperature, 102° F.; pulse, 104; respiration, 24. The skin is smooth, soft, and pale, and shows no scars. Over the sacrum there is a very extensive bedsore. There is no atrophy. The lower extremities are very tender to superficial as well as to deep-seated pressure, but the tenderness is regularly distributed and not over the course of individual nerves. The spinal column is of normal configuration, though somewhat sensitive to percussion in the dorsal region. The lower extremities are flexed at the hip-joints and knee-joints. Attempts to extend the legs are met with elastic resistance, which, however, is not very difficult to overcome. The right thorax is bulging, the intercostal spaces are distended, and the respiratory excursions on this side are materially diminished. Percussion of the right side reveals a slightly tympanitic note over the first two intercostal spaces, and flatness below this. On the posterior and axillary surfaces the flat note is elicited at a higher level. The respiratory murmur is exaggerated above and absent below. There is compensatory emphysema of the left side. Exploratory tapping of the right thorax brings forth a ichoro-sanguinolent fluid. The cranial nerves and the upper extremities show no departure from normal. There is total motor and sensory paralysis of the lower extremities. The line of anæsthetic delimitation extends around the body about two inches below the mammillæ. All reflex activity to the lower extremities is lost, yet even when the soles of the feet are slightly tickled the legs are quickly drawn up. The quadriceps muscles were examined electrically on two occasions, and the only abnormality was a quantitative diminution of excitability. There were no polar changes.

On account of the offensiveness of the discharge from the bedsores, the patient was kept continuously in a bath. She died two weeks after admission, and after death there was found an ichoro-sanguinolent exudate in the right pleural cavity. At the level of the ninth dorsal vertebra there was a fistula, bordered by roughened bony walls, which led into the spinal canal. On the cord there was found a tumor the size of a small cherry, loosely attached to the meninges. This tumor was very vascular and soft, and had compressed and softened the tenth dorsal segments. On microscopical examination of the cord at the level of the lesion, it was seen that some healthy fibres kept up the continuity of the cord. The tumor was a sarcoma.

Case III.—J. W——, forty years old, Russian, a photographer, entered the Montefiore Home on September 17, 1894, on account of pulmonary tuberculosis. The patient had a good family record, was the father of healthy children, and stated that his wife had never miscarried. He had been moderate and regular in his habits; he denied infections and intoxications. His health was good until two years before, when he began to lose strength, which he attributed to constant work in dark and ill-ventilated rooms, and to the inhalation of brominized vapors which he used in his work. In spite of occasional pain in his side and progressive emaciation, he kept at his work until exhaustive night sweats and repeated pulmonary hemorrhages compelled him to forego it. During this time and up to two weeks before admission to the hospital, the disease showed the familiar symptoms of chronic pulmonary tuberculosis. At this time, however, he began to complain of pain around the thorax, and of darting pains in the extremities, which indicated the invasion of the spinal cord by the tuberculous process. On admission he complained of general weakness, cough, occasional hæmoptysis, girdle sensation, sharp shooting pains in the lower extremities, giving way of the knees, obstinate anorexia, and constipation.

On examination the temperature is 101° F.; pulse, 96; respiration, 24. Physical examination of the thorax reveals extensive tuberculous lesions of both lungs. The spinal column is of normal configuration, but it is tender from the lower dorsal region downward, and he resents jarring movements communicated through the head and through the feet. His skin is pale and dry, and shows no scars. The patient is

greatly emaciated, but there is no localized muscular atrophy. The feet show marked excavation of the plantar surfaces (Friedreich's foot). There is slight but distinct Romberg symptom; the gait is uncertain, and of a paretico-ataxic type. One is for a time in doubt whether the disturbance of locomotion is due simply to the extreme emaciation of the patient or to deficient co-ordination. The presence of the Friedreich's foot speaks rather in favor of the second hypothesis. The cephalic and upper extremities and the trunk as far as the level of the tenth rib show no departures from normal. The muscles of the abdominal walls are weak, and this probably accounts for the bulging of the lower abdomen. The position of the lower extremities, aside from the deformity of the feet, is a natural one. Testing for the superficial and deep sensibility of the lower extremity is painful, but this hyperæsthesia does not follow the course of the nerves. On the contrary, pressure on Valleix points is less painful. The extreme laxity of the reflectory tonus of the muscles of the lower extremities is somewhat surprising. When the legs are lifted they rest their full weight on the examiner's hand, indicating the absence of any reflectory tonus to take up a part of the weight. Motor weakness of the lower extremities and distinct ataxia are present. Scattered all through the lower extremities and trunk up to about two fingers below the mammillæ, but without evident topographical regularity, there are areas of anæsthesia, analgesia, and thermal anæsthesia; kinæsthetic and postural sensibility are disturbed in the toe-joints and the ankle-joints, less so in the hip-joints and knee-joints. All the superficial reflexes are present, but rather diminished. The plantar reflex is very much exaggerated. When the soles of the feet are tickled there is often only a vigorous dorso-flexion of the foot, and sometimes a drawing up of the whole leg. On tapping the patella tendon, a fairly good contraction of the tendon is felt by the tapping finger, and a contraction of the quadriceps is visible, but no locomotion ensues. When the left tendon is tapped there is often a contraction of the adductor muscles of the opposite side. There is double-sided ankle clonus of slight intensity, and the clonus soon exhausts itself. The bowels are constipated, but the patient experiences no difficulty in voiding urine. The urine is turbid, of alkaline reaction, without abnormal constituents. The alkalinity of the urine indicates probably a lessened sensibility of the mucous membrane of the bladder, which, together with the impaired expulsive power of the abdominal walls, allows residual urine and consequent alkaline fermentation.

Electrical examinations of the nerves and muscles of the lower extremities were made frequently, and at no time was there any evidence of degenerative reaction. Electrical excitabilty was diminished, particularly to the faradic current.

Examination on the 22d of September, five days after admission: The patient complains, in addition to what has been stated, of difficulty in urinating and of severe vesical tenesmus. Motor paralysis is more extensive and the sensory deviations are more profound. Disturbances of kinæsthetic and postural sensibility are now very marked. Superficial reflexes weak; no change in the plantar reflexes. The knee jerks are very much diminished. On tapping the quadriceps tendon, several bundles of the quadriceps muscle are seen to contract faintly. There is no cross-jerk in the adductors; there is no ankle clonus. Electrical reactions as before.

Examination on the 26th of September: Motor paralysis total. Sensibility somewhat improved. Deep sensibility gone. Knee jerks absent. Superficial reflexes very weak and easily exhausted. Plantar reflex as before. A bedsore is forming over the sacrum.

Examination, 28th of September: Bedsore getting larger. Paralysis of both sphincters. Motor paralysis of lower extremities complete. Superficial sensibility disturbed, but present. Deep sensibility gone; all reflex action has perished. Tickling of the soles is followed by drawing up of the whole lower extremity.

September 29th, *exitus letalis*.

On post-mortem examination, an advanced tuberculous condition is found in both lungs. On opening the spinal canal an area of purulent pachymeningitis, extending from the seventh to the tenth dorsal segments, is brought to view. On the cord there are numerous arachnoid plates. The cord is very much softened in the seventh and eighth dorsal segments. Microscopical examination of sections from these levels shows the presence of a number of healthy fibres. Aside from slight descending degeneration, the lumbar cord is normal.

Case IV.—L. S——, seventeen years old, a cutter, was admitted on July 1, 1896. His history was that he had been in perfect health until October 7, 1895, when he fell down a hatchway, striking the floor with the left side of the body. After the injury he was unable to move any of the extremities, but able to sit. He was taken to St. Vincent's Hospital, where he remained three days. While there he had retention of urine and painful priapism. The patient was transferred to Mt. Sinai Hospital, and after he had been there a time he regained a slight amount of power in the upper extremities, but a variety of other symptoms manifested themselves. He vomited incessantly for three days, and this ceased only when he was placed on a water bed. The bowels were very costive, and urination was difficult and painful. The bladder was frequently distended, and this condition was very painful. The priapism became permanent. Two months after the injury the patient began to swell up—as he termed it—and to complain of frequent, painful, involuntary contractions of the lower extremities, and from time to time of shooting pains in the legs. On admission to the Montefiore Home he had few complaints, except that he requested to be handled with care, as the slightest touch caused him a great deal of pain. A remarkable symptom was that when the bowels or bladder were expelling their contents, he had distressing vasomotor symptoms, such as sensations of heat throughout the body and sweating.

An examination of the patient shows him to be a well-built but slightly anæmic boy. No opinion can be formed as to the state of his nutrition, on account of the peculiar trophic disturbances in the skin and subcutaneous tissues. The patient looks somewhat gigantic. The extremities present a puffy, swollen appearance. The skin conveys an impression of resistance to the finger, very similar to that of scleroderma; only a slight indentation is left after severe pressure. There are numerous hypertrophic keloid scars. The hands and feet are found wrapped up in cotton, because the patient complains of the pressure of the bed clothes. There is a large bedsore over the sacrum. The sixth and seventh cervical spinous processes are prominent and tender, and there is slight scoliosis of the upper dorsal column. The temperature is 103° F.; pulse, 120; respiration, 24, and abdominal in type. Examination of the urine shows considerable albumin. Physical examination of the thorax reveals a moderate degree of pulmonary emphysema. Examination of the abdomen is unsatisfactory, on account of the tympanites. The head can be moved freely in every direction. The pupils are unequal, the right wider than the left, but the reaction to light is prompt on the right side. The left pupil is sluggish to light, but prompt in consensual and accommodative reaction. Pupillary pain reaction is

absent. Movements of the eyeballs are free, and the cranial nerves are normal. Respiratory excursions are superficial, and the patient has considerable dyspnœa. The abdominal muscles are very weak, and the abdominal cavity is extremely tympanitic. Examination of sensibility shows hyperæsthesia for all sensory qualities in the upper parts of the trunk, and total anæsthesia in the lower. The line of delimitation runs, in front, about two fingers above the mammillæ; behind, through the second dorsal vertebra.

Upper extremities: The left forearm is smaller than the right, and there is a hard osseous tumefaction of the left elbow-joint. There is a keloid on the flexor surface of the forearm. The whole extremity is swollen, but there is no indentation left after pressure. The swelling of the right extremity is most marked in the hands and fingers. On this side there are hyperextension of the wrists and atrophy of the thenar and hypothenar groups of muscles. There is well-marked motor paralysis of both upper extremities, involving principally the flexors and extensors of the wrists and the intrinsic muscles of the hand. Some motor power is still retained by the muscles of the shoulder and upper arm. So far as can be made out, there is no tremor or ataxia. The extreme hyperæsthesia to touch on the posterior surfaces of the upper extremity is very marked, though the pain sense is rather diminished when the reaction to painful stimuli is compared with the one to tactile stimuli. Temperature sense is perverted. Kinæsthetic and postural sense are very much disturbed. Electrical examination of the upper extremities shows no degenerative reactions, except in the thenar and hypothenar muscles of the right side and most of the intrinsic muscles of both hands. The reflexes of the upper extremities are lost.

The lower extremities show the same tapered appearance as the upper, and are the result of the same trophic changes. The feet show talipes equinus, and there is a bedsore on each heel. The muscles are seen to be in a state of complete flaccidity, although now and then a quiver of voluntary contractions is to be seen in them. There is no resistance to passive movements, except in the left knee, where passive flexion is reduced about one-third, and this is due to a keloid scar in the popliteal region. There is total motor and sensory paralysis. When the patellar tendon is tapped one can feel a contraction of the tendon; none is seen to occur in the muscle, and no locomotion results. The superficial reflexes have also perished. When the soles are tickled the legs are drawn up. The electrical irritability of the muscles is very much reduced, but there is no reaction of degeneration.

The sphincters are paralyzed, and there is extreme vasomotor irritability.

The patient remained *in statu quo* until death, which occurred from catarrhal pneumonia, the immediate cause of death being inability to expectorate.

Autopsical examination showed: The dura mater for a distance of eight to nine millimetres in the region corresponding between the sixth and seventh cervical segments is collapsed and narrow, so that both the anterior and posterior surfaces of the membrane are practically in contact. In dissecting this point in the dura mater at the crushed portion of the cord, the lower portion of the sixth cervical segment and the upper portion of the seventh cervical segment are absolutely destroyed. The cord at this region is reduced in volume to the thickness of a piece of tape, and absolutely none of the cord substances is apparent. Nothing is left of the cord except the anterior and posterior surfaces of the spinal pia mater, which lie in contact. While the cord is completely crushed at this level, however, the anterior spinal artery traverses the damaged region intact, so that the cord beneath the crushed places has been nourished and is perfectly normal, except for an ordinary descending degeneration. Above the crushed region there are the usual ascending degenerations in the column of Gowers, the direct cerebellar tract, and the column of Goll.

I have had occasion to observe four other cases, very similar to the cases reported herewith, during the last eighteen months, but I am not yet prepared to report them in detail. Suffice it to say that in one of these cases, probably one of tuberculous myelitis associated with solitary tubercle of the brain, which Dr. Sachs saw with me on several occasions, it was shown by repeated examination that the state of the reflexes depended on the condition of deep-seated sensibility. When there was clinical evidence that this variety of sensibility was interfered with, the knee jerks were always profoundly diminished.

The cases herewith reported are in evidence that occasionally lesions of the cord above the lumbar region produce flaccid paralysis. While it would seem to be wellnigh universally accepted that total severance of the cord above the lumbar region leads to abolition of the knee jerks, all the other points in connection with this subject—viz., 1, the occurrence of loss of the knee jerks with lesion of the cord which does not sever its continuity; 2, the relation between the clinical and anatomical evidence of the totality of the cord lesion; 3, the state of the superficial and visceral reflexes; and 4, the physio-pathology of the symptoms—are, one and all, still *sub judice*.

On looking over the literature of the subject, I find that about ninety-two cases have been reported, in varying degrees of completeness. Of this number there is not one case which will stand the test of criticism in which the knee jerks were preserved with complete interruption of continuity of the cord.

Before going further into the discussion of this subject, and before attempting to explain the phenomenon in question, it seems to me advisable, in the first place, to get all the information that we can from a review of the literature. Among the cases reported there is a variety of pathological conditions, and these are distributed in various parts of the cord. Tumors, fractures, dislocations, central hemorrhages, lesions of mechanical injuries, pachymeningitis caseosa, and tuberculosis have been found in almost every part of the cord above the lumbar region. It seems safe to assume that not much light can be thrown on the subject in question by a consideration of them. Whether the location, especially the horizontal, of the lesion stands in causal relationship to the abolition of the knee jerks in supralumbar lesions, I am not prepared to say. Some authors think that the localization may be in part responsible for the occurrence (Habel).

A consideration of the other clinical symptoms accompanying loss of the reflexes in supralumbar lesions and their temporal relation would seem to let some light in upon this question. In all cases there was absolute loss of motility. When the continuity of the cord is completely interrupted, this is easily understood; but when it is only partially destroyed, it is difficult to believe that a variety of pathological conditions which are not of a toxic order will cause unerringly affection of the motor axones, that it will select them alone for their malign influence. It seems reasonable to infer from abundant clinical experience that the motor fibres are always the first ones to suffer. This has its probable explanation in the fact that the more individualized the function of a fibre is, the greater is the necessity for its integrity, *i.e.*, for its perfect insulation.

Sensibility was absolutely lost in all cases in which the transection of the cord was complete. In every one of the eight cases of partial interruption of continuity, and in three of the cases reported to-night, sen-

sibility was only partly lost in six cases. I have not been able to gather from these cases any definite information concerning the extent and kind of sensibility that was perverted. In the third case reported by me, and in the last one casually referred to, the state of the reflexes seemed to have some dependency upon the kinæsthetic and postural sense. At one examination the reflexes were absent when the general sensibility improved and the kinæsthetic and postural sensibilities were lost. In view of the obscurity in which many of the physiological problems of the nervous system are enshrouded, speculation concerning these anomalous states of the reflexes would seem somewhat hazardous. Nevertheless, I cannot resist the temptation to attempt an explanation of the phenomenon. The fibres that serve the conduction of so-called deep sensibility seem to have, in contrast with those that conduct the general sensory stimuli—such as pain, touch, temperature—a more specialized function, and are probably the ones most prone to suffer, next to the motor fibres, when the cord is subject to increasing pressure.

In eleven cases reported by Bowlby, the state of the superficial reflexes is reported to have been variable, and this same statement is made by Thorburn in a report of nineteen cases. In one case the epigastric reflex, and in two cases the cremasteric reflex, could be elicited. With great uniformity the plantar reflex has been stated to be present and exaggerated, and almost invariably the statement is met with that on tickling the soles the whole extremity is drawn up. It seems to me that this is not the expression of a reflex act, in the usual interpretation of the term. It ought rather to be considered as a "pathological spinal reflex," after Jendrassik, a reflex without interference of the brain or higher centres. Concerning visceral reflexes, in nearly every case it is stated that the sphincters are derelict and paralyzed. Priapism has frequently been noted when the lesion has been in the cervical region.

Occasionally statements in the clinical histories could be interpreted as indicative of disease of the lumbar cord or the peripheral nerves—such as when wasting and flaccidity of the muscles of the lower extremities are spoken of; but consideration of other symptoms—such as the absence of reaction of degeneration in cases in which the electrical examinations were made—militates against such a view.

Trophic cutaneous disturbances have been noted in every instance, and of my cases the fourth one presented rather unusual cutaneous and subcutaneous trophic disturbances.

All the cases that I have considered have been of long standing, so that the element of shock and its influence on the reflexes can be eliminated from the discussion.

Turning to the pathological anatomy, we find that in fifty-one cases, and in one of my own, there is a report of a total transverse lesion of the cord. In eight cases and in three of mine there was partial destruction of the cord; and, in general, in every instance there have been found conditions bound to do serious injury to the cord.

Histologically in most of the cases there have been found the customary ascending and descending degenerations. The lumbar cord, every time that it has been examined, has been found normal. A few times reduction of the number of the anterior-horn cells and a paleness of the white matter has been mentioned. In one case of Bastian, and in a case of Dr. Dana and myself, ascending degeneration in the lateral tracts, corresponding to the tracts of Gowers, were found. In two cases of Hoche, in which the secondary degenerations were carefully studied by means of the Marchi method, ascending degeneration of Gowers' tract was very striking, and in this case the tracts of Gowers were followed for the first time to their termination in the cerebellum.

The peripheral muscles and nerves have been examined once (case of Bruns), and slight incidental changes only were found, and Bruns adduces the statement of Oppenheim to show the absence of grave lesion that could account for the absence of the reflexes, the knee jerks particularly.

Various theories have been advanced to explain this absence of the jerks in these cases. Of all these, the theory of Jackson and Bastian seems to have met with widest acceptance, and, indeed, it seems the most rational one. This theory posits the causal influence of the cerebellum, and a consideration of the physiological, pathological, and clinical facts bearing on the reflexes, and especially the knee jerk, seems to me to lend support to their hypothesis.

The exact nature of the knee phenomena is not yet definitely known. Whether the contraction of the quadriceps muscle following the stimulation of its tendon is the result of a true reflex act or is simply the result of mechanical stimulation, cannot yet be said positively, although the first hypothesis is the one usually accepted.

I remarked in the fourth case that often a distinct contraction could be felt in the tendon on tapping, although there was no appreciable contraction in the muscle, and I have often made a similar observation in cases of peripheral neuritis. Furthermore, it has been shown that the time from the stimulus causing the contraction to the appearance of the motion is four-one-hundredths of a second. From a consideration of these two facts it seems probable that both elements, the mechanical and the reflectory, go to make up the knee phenomenon. We all know that the knee jerk is dependent upon the integrity of the reflex arc, and we know positively that some superior influence exerted by a higher centre may control the reflex, or inhibit it, I might better say. The nature of this influence is difficult to interpret. According to Helmholtz, the nerve impulse travels at the rate of 33.9 metres per second; in four-one-hundredths of a second the sensory stimulus applied to the tendon ought to travel one hundred and thirty-six centimetres; considering the length that it must travel and the intraspinal breaks, this distance is almost exact, and there is certainly no time for the stimulus to travel much farther up. This superior influence spoken of must therefore be looked upon as a constant physiological nerve stream flowing in the intraspinal pathways. One of these pathways, the pyramidal tracts, we have recognized as being connected with the function of the reflex. Contrary, though, to the symmetry of the architecture of the nervous system, we have considered only a centrifugal pathway, and have endeavored to explain the difficulties that arise by positing an inhibitory impulse which runs in these pathways, and assuming at one time an irritation and at another a paralysis of this inhibition. It seems reasonable and more conformable with the structure and functions of the nervous system to have the superior influence run in an arc too, and in an arc with a centrifugal and centripetal leg as well as an intraspinal connection. Concerning the latter, it seems to me that we are not in a position to speculate. The centripetal branch of this arc is positively in some of the ascending columns of the cord to which has not as yet been allotted a definite function. Whether the fibres of Gowers' tract perform this function, I do not attempt to say, but the aforementioned clinical and pathological evidence is very suggestive and prompts me to call your attention to it, that a closer study of this tract may be made in future cases. This view would seem to get further corroboration from an analysis of the familiar procedure of eliciting the knee jerk. In such a case we apply the

sensory stimulus through the peripheral sensory part; this is transformed in the intraspinal gray matter into a motor effect, which we then see manifest. Occasionally we make use of Jendrassik's or some similar aid, by which we remove some inhibitory influences running in the centrifugal leg of the supposed arch. Every time we put the leg in a certain position, and by this probably stabilize the influence running in the centripetal branch of the arch, thus putting the muscle concerned into a state best fitted for the execution of an additional contraction. Whether this latter function is conveyed along Gowers' tracts, the future will decide.

One word on the practical side of the question. The loss of the knee jerk in supralumbar lesion of the cord is not always an omen *prognosis infaustissime*, and not necessarily indicative of total anatomical destruction of the cord, that is, beyond improvement or outside of any consideration of surgical interference.

In conclusion, I desire to express my sincere appreciation of the valuable assistance accorded me by Drs. Dana, Elliott, Van Gieson, and Sachs.

THE LOCALIZATION OF FOREIGN BODIES IN THE EYE BY MEANS OF THE *X*-RAY.[1]

By PERCY FRIDENBERG, M.D.,
NEW YORK.

But little more than a year has elapsed since the report of Roentgen's brilliant experiments first attracted attention to a new form of radiant energy, whose practical importance for medical science was soon demonstrated by the successful application of the *x*-ray to a variety of diagnostic purposes.

Increased familiarity with established methods, independent research, and improved appliances have in turn opened new fields for practical radiography in the wide domain of clinical medicine, so that to-day that method has established itself as a valuable diagnostic aid in surgery as well as in many other branches of our science.

In sharp contrast to these excellent results, ophthalmology has, almost without an exception, so far derived no benefits from the use of the Roentgen rays. It is just in this field, however, that positive results would be most welcome. In many cases of ocular traumatism, especially in penetrating wounds and gunshot injuries, ophthalmoscopic examination is rendered impossible by reactive changes in the superficial tissues, or, more frequently, by effusion of blood into the interior of the eye; while, even when clear media are found, a foreign body which lies buried in the coats of the eye, at the bottom of the vitreous, or free in its extreme periphery on or near the ciliary processes, may easily escape detection. At such a time the question as to whether the affected organ harbors a foreign body, one of great importance for treatment and prognosis, cannot be decided. For, although the history of the case, subjective symptoms, and theoretical considerations may at times lead to a positive conclusion as to the presence of a foreign body, its exact position in the eye will remain undetermined as before. The same indecision must follow the diagnostic use of the electromagnet (Hirschberg) and the compass-needle sideroscope of Asmus,[2] which, by causation of intra-ocular pain and by deflection of the astatic needle respectively indicate the presence of a body in the eye which is magnetically attracted or attractive. Even extraction with the magnet is difficult, except in those cases in which its manipulation can be controlled by the ophthalmoscope, while its application is excluded, *a priori*, in the large number of accidents due to penetration of the eye by copper, lead, or glass particles. A practical substitute for the magnet in these cases, as well as a more accurate method of localizing steel or iron bodies, has been sought, with but small success so far, in the use of the Roentgen ray. It is remarkable that theoretical views and considerations, based on the negative results of experiments which in no way conformed to the circumstances of actual practice, were able to discourage investigation in this direction. It was argued by some that the low degree of permeability of the eye by the *x*-ray, as shown by the experiments of Dariex,[3] would effectually prevent the production of a skiagram. For others the thickness of the cranial and orbital wall seemed so insurmountable an obstacle that they suggested a variety of procedures, more ingenious than practical, to avoid the necessity of having the rays traverse bony structures. Lewkowitch,[4] in London, for instance, placed the sensitive plate along the side of the nose and the Crookes tube at the temple. His radiographs show only the lids and the summit of the cornea, yet this author claims valuable results for his experiment, as he was able to get a shadow picture of a gilt spangle which he had introduced, not into the interior, but into the conjunctival sac of his own eye. Besides the limited field exposed to the rays, this method is unsatisfactory on account of its complexity. The author took two views after having the eye abducted and then adducted *ad maximum*. The three principal meridians were to be marked by a wire bent in three corresponding angles and brought into immediate contact with the surface of the globe. The position of the sensitive plate was determined by a special "north-pole indicator." All these factors were made the basis of an elaborate calculation, by which the position of a foreign body could be determined. It need hardly be said that such a body, situated so near the surface of the globe as to be included in the pictures produced in the above manner, could be detected more easily in other ways, while one in the vitreous would not appear on the plate at all. Van Duyse,[5] who had also come to the conclusion that only the anterior portion of the globe was capable of being skiagraphed, went a step further in his attempts to get a more extensive picture, and suggested producing an artificial protrusion of the globe by forcible injection of salt solution under Tenon's capsule; while Clark[1] surpassed all previous efforts by inserting a sensitized film into the nasal passage along the septum, until its point touched the lower surface of the cribriform plate of the ethmoid. Although this manipulation was performed on the cadaver, or rather on a skull, this author expresses his conviction that its application to the conditions during life would be quite feasible.

In the case reported by this author a chip of steel in the iris angle was extracted, after being located, after one unsuccessful effort, not in the manner he describes, but by direct skiagraphy and exposure for eight minutes. The details of the process are not reported, and the skiagraphs were not shown.

One other case of successful location and extraction

[2] Graefe's Archiv, vol. xi, p. 280. The author's instrument is a modification of Guerard's, made more sensitive and portable, improved by the addition of a telescope for reading off the amount of deviation of the needle on a scale. The first application of the compass needle to the diagnosis of magnetic bodies in the eye was made by Dr. Thomas Pooley, of this city, whose interesting and novel experiments were reported at length in vol. ix., p. 219, of Knapp's Archives. The deflection of the astatic needle was, with great ingenuity, assisted by rendering the foreign body magnetic by induction. The above-mentioned methods are simply an elaboration of Pooley's original idea.

[4] Transactions Am. Ophth. Soc., vol. vii., p. 711.

of a piece of copper cartridge shell was reported by Dr. C. H. Williams,[1] of Boston. The patient was laid on the table, with his injured eye close to the plateholder, while the Crookes tube was placed so that the rays passed partly across the bridge of the nose and partly through the thin nasal and orbital bones to the injured eye, and so on to the plate. After ten minutes' exposure the developed plate showed what appeared to be a foreign body a little back of the centre of the eyeball. A second radiograph with the tube in a different position showed no foreign body, but this was accounted for by the fact that the metal when found was a thin strip; therefore the rays in the first case may have struck it on the flat and given a picture, and in the second case have struck edgewise, with no effect.

About three months ago, Mr. B. H——, aged twenty-six, of Freehold, N. J., was brought to me suffering from the results of a gunshot injury, which had at once destroyed his sight. While out quail shooting with a party of ten or more, on the day before, he was unfortunate enough to receive a charge of small shot (No. 9) in the left shoulder, the face, and both eyes. On examination, after separating the tense and swollen lids, the point of entrance of a shot was found a little above the cornea in either eye, and, corresponding to this, a penetrating wound of the right and left upper lids. The cornea and lens had escaped injury, but the vitreous was filled with blood and vision reduced to perception of light only. The patient was admitted to the New York Eye and Ear Infirmary, where, under appropriate treatment, the inflammatory reaction subsided, without any signs of a purulent process in the eye. The vitreous, however, was still opaque, from the hemorrhagic exudation, and ophthalmoscopic examination was impossible. To decide the question as to whether the shot were in the interior of the globe, I determined to make an attempt with Roentgen photography.

It was evident that definite results could be reached only by obtaining a shadow picture of the entire orbit to a distance in depth at least equal to the antero-posterior diameter of the eye. To accomplish this it was necessary to have the rays from the Crookes tube pass directly through the bones of the skull, and to place the sensitive plate close in front of the eye. I succeeded in doing this in the following manner:

Two narrow Carbutt plates, about three and one-half inches long, were cut out and trimmed roughly, so that they would fit into the inner margin of the orbit. The eyes were covered with some absorbent cotton, and the plates bandaged on in such a manner that they were at right angles to the line of the orbit. These plates were covered with black paper, into which pins had been stuck, one on the right, two on the left side, points down, to distinguish the plates after developing and printing, and to serve as a standard of density for any shadow pictures which might appear. In this way close approximation of the sensitive plate to the eye was obtained, and all motions of the patient's head, which could hardly have been prevented during the necessarily prolonged sitting, were completely neutralized. For now the plate itself would move in a like direction and to the same extent, and prevent any distortion or clouding of the impression. Eye motions were practically excluded by the bandage.

The Crookes tube was placed back of the head, about fourteen inches from and parallel to the plate, which was exposed to the rays for nearly forty minutes. It was my intention to produce an overexposure, so as to reduce as far as possible the disturbing influence of the cranial bones.

In this way a front-face view was secured, which I take pleasure in submitting to you herewith. The success of this experiment is due in great measure to the complete apparatus and technical skill of Mr. M. F. Martin, in whose *x*-ray studio, at 110 East Twenty-sixth Street, the work was begun and finished. I wish to express again my sense of obligation for his interest in the case.

Holding the radiographs side by side and in contact, the wall of the orbit is seen as a narrow shadowy outline. The soft parts and the globe appear very much lighter. On the left side a number of small, approximately round, and denser spots appear—the shot-pellets themselves. It will be seen that all of them are apparently close to or in contact with the wall of the orbit. None is seen in the light space corresponding to the globe. On the right side, however, this is not the case. Here we find two foreign bodies, one near the floor of the orbit, the other on a line with the middle of the eye and possibly in its interior. To decide this it was necessary to determine the depth of penetration and locate each shot in its relation to the anterior surface of the globe. A view at right angles to the first, a profile view, was wanted. It was obtained by having the patient lie on his side, with his right cheek resting on a large photographic plate. The Crookes tube was placed opposite the left temple, under the same conditions as before. The exposure lasted thirty-five minutes, and produced a picture of remarkable clearness. It will be seen on comparing this with the front view, that the two foreign bodies in the soft parts of the right orbit are located back of the eye, which here appears as a grayish-white disc. In addition, we see the shot (five in number) which entered the left side of the face at different levels, one in the lower and one in the upper jaw, and two in the brow. We must bear in mind that the *x*-rays penetrated the structures of the skull from the left side, projecting shadows from this as well as from the right side upon the plate. We have, as it were, one picture superimposed on the other.

The nearer a body is to the plate, the smaller and denser the shadow. This enables us to say definitely on which side of the head each and every shot pellet lies, and, by comparison with the first view, to locate it quite accurately. It appears that both eyes were traversed by shot with such force that the posterior wall of the globe was perforated and the missiles lodged in the depths of the orbit. Unfortunately, the extensive laceration and intra-ocular hemorrhage have so nearly destroyed the eye that little can be done to restore sight. The patient can make out motions of the hand at three feet in the right eye; the left has only perception of light.

To sum up the principal points in which this method modified and improved upon the older ones, and which are of importance if radiography is to be of any practical use in this branch of clinical diagnosis, the following facts are evident: The whole extent of the eye and of the orbit is included in the skiagraph. Two views at right angles to one another are taken for purposes of combination. In the one, the closest possible approximation to the eye is effected by having two plates bandaged to the eye. The shadows thrown by the bones of the skull are eliminated as much as possible by extreme overexposure. When for any reason we cannot obtain two views, we may be able to dispense with the profile picture and to compute the distance of the foreign body from the plate by a calculation, in which the known factors are the diameter of the body itself, that of its shadow picture, and the distance from the sensitive plate to the Crookes tube. The *x*-rays diverge from the focal point of origin and produce a central projection of shadows, as do light rays coming from a finite distance. The same optical law holds good for both.

[1] Transactions Am. Ophth. Soc., vol. vii., p. 703.

However unavailing our therapeutic efforts may have been in this particular case, these skiagraphs show, I think, that we have in Roentgen photography, modified in the manner above described, a simple and accurate method for determining the presence and, what may be even more important, the exact position of foreign bodies in the eye, and that, under more favorable circumstances, their removal may be rendered possible by its application.

66 West Seventy-Sixth Street.

THE FUNDAMENTAL PRINCIPLES OF THE GALVANO-CAUTERY.[1]

By HORACE CLARK, (Harv.) A.B., M.D.,

BUFFALO

The galvano-cautery is an instrument of precision to a greater extent than is commonly supposed. Along with a spray-producing apparatus it is frequently found as a part of a general office outfit. The text-books are largely responsible for this misinformation. They advise the cautery as a remedial or curative measure, without specifying how to use it. Granted that each operator must learn by experience the refinements of cautery technique, there are certain gross principles applicable to the proper use of the instrument which should be more generally understood.

(1) First, as to the degree of heat to be used. Every storage battery is provided with a rheostat—an apparatus to regulate the degree of heat to be carried

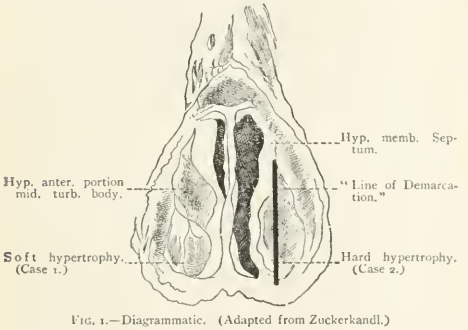

Fig. 1.—Diagrammatic. (Adapted from Zuckerkandl.)

to an electrode; but how many times has the rheostat been handled to-day simply as a means of making the cautery work, the operator not having the remotest idea whether a dull red, bright red, or white heat was required for the result he had in mind?

Case I.—A man about to take the stump in the recent campaign desired to be relieved of a disagreeable odor which came from one of his nostrils. The nostril indicated was patent, the other nearly closed. The latter fact had not been observed. The odor came from pent up secretion on the occluded side, and found its way out through the open one. The anterior end of the offending lower turbinated body was found to be in a condition of soft hypertrophy—red, smooth surface, secretion pretty clear. This condition is approximately understood by the term hyperplasia. This was reduced with the cautery at a red heat. The result was practically the same as will be indicated in the next case, although considerably more swelling and exudation were present. (The urgency of the case led me to more liberal use of the cautery than is generally advisable.) The course of a case like this is about equal to that of an ordinary head cold. This measure is also prophylactic to head cold; for the turbinated tissue becomes firm and capable of resisting further engorgement to the extent of occlusion, as by excessive nutritive activity from irritation of miscellaneous nature. If a white heat had been used in this instance, in any but a superficial way, an enormous blister would have resulted. Very probably the pressure of contained serum upon the underlying sensory nerve filaments would have caused severe local or reflex pain.

Case II.—A woman who was too poor to bear the expense of repeated visits from a distant town came to me to have her nose opened, as she said. The occlusion was due principally to the inferior turbinated bodies, which were in a condition of hard hypertrophy. Their color was grayish-pink, without lustre. The surface was not quite smooth. In drawing the probe the tissue rose slowly in the track of the indentation and was covered with a gray, pasty secretion. I decided to use the cautery, the idea being to destroy the tissue to a depth sufficient to render the nostrils patent. A white heat was used. The patient was sent home with the information that her nose would probably not close up again completely; that after a few days a "scab," as she would understand it, would come away, probably followed by a tinge of bleeding; and that thereafter she would have no further trouble. She was instructed to report a week later. The case had gone on as stated, and both nostrils were found to be free and clear. The point here is that a dull red heat would only have given the patient a sore nose, and a moderately red heat would have had so little effect as to render subjection to operation and subsequent inconvenience positively bad practice.

I mentioned destruction of tissue to a sufficient depth. How is information as to that matter to be stated? If a case like the one just mentioned is watched, "a line of demarcation"—if I may be permitted to use that term—will be seen after the first two or three days, approximately indicative of the extent to which the destructive process has gone. By noting this depth, remembering the character of the tissue, and comparing the same with that of other cases of the same or similar nature, a fairly good estimate can be made of what to expect and how to go about it. The harder and grayer the tissue, the less the resultant disturbance to the patient from burning; also the more marked this "line of demarcation." In general, as to the degree of heat to be used, the proposition holds good to decrease the amount of heat as the tissue is softer. There are, of course, exceptions to this rule, but it holds fairly good.

(I would not be understood to mean that the conditions described always require the use of the cautery. The cold snare, scissors, knife, etc., are sometimes preferably to be chosen. Chromic or glacial acetic acid, "London paste," so-called, or other destructive agents, have their use, along with or independent of the actual cautery; but these are matters beyond descriptive effort. They relate alone to the experience and judgment of the special surgeon.)

(2) In cautery work it is always best to do but one side at a time. The reasons are obvious. But both nostrils should be opened, and without undue interval. The idea to be borne in mind is the principle of division of labor. An excessive amount of air taken in through one nostril, no matter how large the opening may be, is a source of irritation and excites overnutritive activity. Both nostrils should be open, in order to present as large a surface as possible to warm, moisten, and cleanse the inspired air. For reasons relating to the ear, they should both be open. When there is a mixed condition it often happens that a soft hypertrophy, for example, of the posterior portion of one of the turbinated bodies, will take care of itself after the reduc-

[1] Read before the surgical section, Buffalo Academy of Medicine, February 2, 1897.

tion of the hard hypertrophy. (This section is meant to be simply diagrammatic.)

(3) The preparation of the part is a matter of importance. After being properly cleansed on general surgical principles, it should be dried before the local anæsthetic is used (cocaine or eucaine) and afterward dried again. It is usually unnecessary to use a cocaine spray for anterior cautery surgery, nor is a great wad of saturated cotton required for topical application. A thin piece, wrung nearly dry, nicely adjusted to the part with a probe, is sufficient. The length of time for the cotton to remain is a variable quantity. Ten to fifteen minutes for a ten-per-cent. solution of cocaine, and two or three minutes less for a eucaine solution of the same strength, is usually sufficient. Sometimes insensibility to pain is all that is required or desired. That, too, is a variable quantity according to the character of the tissue. Too much shrinking may be an actual hindrance to operation, and leaves the operator at a loss how far to go; for example, in cases of polypoid thickening, when the cautery is chosen as against the snare or other instrument. But the point I want to make is that in the majority of cases the part should be made bloodless, or as nearly so as possible. Ischæmia and insensibility to pain are not necessarily required to be coexistent. I believe this matter is of great importance. If it were not that it does not produce ischæmia, the new preparation for local anæsthesia could happily replace cocaine entirely. I refer to eucaine. It is equally good for anæsthesia and solutions are more stable. It is entirely soluble in "crystal-water" solutions; faucet water should be boiled. In many operations, when extreme shrinkage is not desirable and the tissue is practically bloodless, eucaine is even more desirable than cocaine. The desideratum is to combine with it some substance which will produce an ischæmia in addition to its own anæsthetic property.

(4) As to repetition of the use of the cautery, it is always well to hedge a little in answering that question. Not that it is an uncertain instrument, but the tissue upon which it is used is uncertain. Given a lower turbinated body in practically a uniform condition throughout, so far as can be ascertained. The cautery is applied equally. The result may be a face as firm and flat as if a piece of putty had been cut through with a sharp knife. Or it may present elevations here and there. (One of the latter may be just opposite to a protuberance or hypertrophied portion from the septum, harmless perhaps in this particular case if not in contact. Therefore the destructive agent has been sufficient for the most part, and would have been carried too far in such a case had it been pushed in the first instance, so that no elevation opposite the protuberance had resulted.) These elevations, or others, are to be met separately at another sitting.

(5) The cautery should be sparingly and cautiously used upon the septum. Incised wounds of the septum heal with surprising rapidity; but I have seen many cases of obstinate erosion caused by the ill-advised use of the cautery on this part. If there is undue bleeding from a cutting operation upon the septum, it is better to stop it in some other way than with the cautery. An operator will take great pains to grease or otherwise protect the face of an acid applicator which might touch the septum, and yet he will force the cautery electrode into a space so narrow as to burn the septum as well, thereby producing an agglutination between the parts, only aggravating the condition he sought to reduce.

(6) It is well to avoid using the cautery in the presence of a tuberculous or syphilitic diathesis. I recently saw a case in which a simple erosion upon the cartilaginous septum was transformed, by excessive irritation with the cautery, into a syphilitic ulcer; that is to say, the disease, having a predilection for the septum, manifested itself at a weakened portion. The erosion was caused by picking with the finger, crusts having adhered in the hollow of a slight undulation. The cautery had been used in the hope of forming scar tissue.

(7) As to the choice of an electrode for a given piece of work, much might be said which does not fall within the scope of this paper. The medium size flat knife is the one most generally used. The right and left curette and the point are useful instruments. I would deprecate the use of the cautery in inexperienced hands upon the middle turbinated bodies with the same freedom as may be permitted upon the lower; for the former are much more delicate, and require careful handling also, on account of their anatomical relations. The anterior ends of the middle bodies are more often the site of disease than other areas, and the curette in careful hands may be used in the reduction of these parts. The point should be used in destroying the elevations and in interrupting the blood-vessels supplying their nutrition, in the condition known as follicular pharyngitis.

(8) The cautery electrode should be quickly removed from its point of application before the heat is

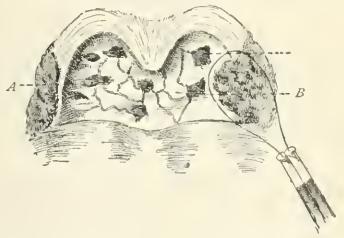

FIG. 2.—Follicular Pharyngitis. (H. C.) *A*, Pharyngitis lateralis usually accompanies this condition; *B*, Enlarged follicles with connecting arteries.

turned off, otherwise it will adhere and the tissue will be torn. This applies more particularly to the lesser degrees of heat. It is also one of the uses of the cautery, as will be presently mentioned.

(9) Aside from precautions to be taken in the subsequent care of a cauterized surface within the nose, the appearance of excessive dryness, especially upon the throat, should be considered as a contraindication to the further use of the cautery.

(10) The use of the cautery in the nasopharynx or larynx should never be attempted by untrained hands. An effort to reduce enlargements of the posterior ends of the inferior turbinated bodies by introducing an electrode anteriorly is to be interdicted as a step in the dark. I have seen many instances of damage to the cushion of the Eustachian tube as a result. The tip of an electrode must always be kept in plain sight. The hand holding the instrument must not be required to balance it, or be otherwise than perfectly free. For the latter reason the Shech handle is superior to any other with which I am familiar. It does not interrupt the line of light, as the straight handles do.

(11) Referring to the subsequent treatment of cauterized surfaces within the nose, it may be laid down as a general principle that such tissue should be allowed to take care of itself as far as possible. Accumulated secretion should be cleared away, as well for surgical reasons as for the patient's comfort; but rest is an essential factor in cautery results. When a crust has nearly separated, or is acting as a flap to obstruct free drainage, it is best removed with the electrode. The flat surface of the cold electrode is firmly laid against the crust, a dull red heat is turned on and

shut off at once. The crust is thus made adherent to the electrode and will come away with it. There is thus rarely any damage done to the underlying tissue, which is frequently the case in consequence of forcible removal with the forceps. This is also the proper way to apply the platinum wire to the tonsils. It is operated as a cold snare until a firm pedicle has been obtained. A white heat is then turned on.

(12) When a cauterized part is in close proximity to another part, the two should be mechanically separated to avoid union by adhesion. As a wedge in the lower nares I use a section of a thick rubber strap, single or double, as required. For the space between the middle turbinated bodies and the septum I insert a section of suitable length of the rubber band used upon ordinary preserve jars, with the convexity upward. These bands should be kept in strong carbolic solution. They should be washed in sterilized (or "crystal" water) and dipped in an antiseptic oily preparation before being inserted.

846 Ellicott Square.

THE AMERICAN PÆDIATRIC SOCIETY'S REPORT ON THE COLLECTIVE INVESTIGATION OF THE ANTITOXIN TREATMENT OF LARYNGEAL DIPHTHERIA IN PRIVATE PRACTICE, 1896–1897.

In this second and supplementary investigation, the aim has been to ascertain: (1) What percentage of cases of laryngeal diphtheria recovers without operation under antitoxin treatment. (2) What percentage of operated cases recovers. The report now submitted may properly be limited to answering these two inquiries.

Since the beginning of the general use of intubation, no disease has been more thoroughly observed and more fully reported than laryngeal diphtheria. Operative cases especially, whether ending fatally or favorably, have been fully and promptly put on record. The result has been a collection and tabulation of cases available for control, such as few diseases offer. There are thousands of intubation cases before the days of antitoxin, and thousands since, available for comparison. It is, then, to cases of laryngeal diphtheria, especially those requiring operative interference, that we may apply the crucial test of the value of the antitoxin treatment.

Sixty thousand circulars containing the following questions have been distributed:

Age of patient?
Diagnosis confirmed by:
- (1) Presence of other cases in the family?
- (2) Appearance of membrane elsewhere?
- (3) Bacteriological cultures?

How many days and parts of a day after the first appearance of the disease was antitoxin first administered?
- How many doses of antitoxin were administered?
- Dose of each injection in antitoxin units?
- Whose antitoxin used?

Non-operative cases—evidence of disease:
- Hoarseness?
- Aphonia?
- Stenosis?

Operative cases:
- (1) Intubation? On what day?
- (2) Tracheotomy? On what day?
- How long, in days and fraction of a day, was tube in the larynx or trachea?

Sequelæ (in recoveries):
- (1) Broncho-pneumonia?
- (2) Paralysis?
- (3) Nephritis?

Death, cause of, and on what day?
- (1) Broncho-pneumonia?
- (2) Extension of membrane to the bronchi?
- (3) Sudden heart paralysis?
- (4) Nephritis?
- (5) Sepsis?
- (6) Accidents of operation?

Recovery?
Remarks, especially on fatal cases?

These circulars were distributed throughout the United States and Canada, the following means being employed: contributors to first report, members of the society acting as agents for their respective localities, boards of health, local medical societies, and antitoxin manufacturers. At the outset, in this connection, it is a pleasure to acknowledge that the labors of the committee have been much lightened by the uniform good will of all addressed, more aid coming spontaneously than in the previous investigation. It is also a pleasure especially to acknowledge the society's indebtedness for efficient aid in distributing circulars and securing returns, to H. K. Mulford Company, Parke, Davis & Co., Lehn & Fink (Gibier's), the health departments of Chicago, St. Louis, New Orleans, Denver, San Francisco, Boston, Washington, Buffalo, Providence, Ann Arbor, Newark, Montreal, Toronto, and others.

To the New York health department are due the thanks of the society for every possible courtesy in distributing blanks and, through their inspectors, of securing returns of operative cases.

In order to reduce sources of error it was desirable to bring together a large number of cases, from widely distributed localities, from many different observers and operators, and from a period of time including all seasons of the year. All returns have been examined by the committee and only such cases accepted as bore satisfactory evidence that they were, first of all, diphtheria, and secondly, that the lesion had invaded the larynx.

A total of 1,704 cases of laryngeal diphtheria are ours for present study. A few cases (228) had not satisfactory evidence that there was laryngeal involvement; indeed some were reported through a misunderstanding of the fact that only laryngeal cases were wanted, and a few were reported in which there was no mention that antitoxin was used. These cases are of course not included in the number referred to above. Of the 228 cases, 218 recovered and 10 died.

In a total of 1,704 antitoxin-treated cases of laryngeal diphtheria, there was a mortality of 21.12 per cent. (360 deaths).

Table of All Cases, Showing Age and Result of Treatment.

Age.	Fatal Cases.	Recoveries.	Totals.	Mortality, Per Cent.
1 year and under	25	35	60	41.66
1 to 2 years	77	219	296	26.01
2 to 3 years	81	260	341	23.75
3 to 4 years	42	216	258	16.27
4 to 5 years	47	160	207	22.70
5 to 10 years	72	345	417	17.26
10 to 15 years	9	64	73	12.32
15 to 20 years	2	24	26	7.65
Over 20 years	5	17	22	22.72
Unknown	0	4	4	
	360	1,344	1,704	21.12

Cases Not Operated On.—The first inquiry of the circular was what percentage of cases of laryngeal diphtheria recovers without operation under antitoxin treatment.

Of 1,704 total cases, 1,036 were not operated upon (60.79 per cent.). Of these most did not require oper-

ative interference; a few cases were thought to require it, but operation was refused. All cases are included and it will be noted there are no eliminations.

Among the 1,036 cases not operated on, there was a mortality of 17.18 per cent. (deaths 178), or, to answer the inquiry of the circular exactly, of 1,036 cases not operated on, 82.82 per cent. recovered (or 858 cases).

As good as is this percentage of recovery in so large a number of cases of diphtheria of the severest type, it is believed it is not so good as it ought to be. Cases of laryngeal diphtheria not requiring operation, according to the testimony of consulting intubationists, are seldom heard from a second time, and less often find their way into reports. It was formerly estimated that about 10 per cent. of cases of laryngeal diphtheria recovered without operation. The present report shows that in 1,036 cases 82.82 per cent. recovered.

Cases Operated Upon.—In analyzing this class of cases, it is believed a more exact conclusion as to the value of the antitoxin treatment can be arrived at than in the non-operative.

There will be entire harmony of opinion as to the severity of laryngeal diphtheria which requires operative interference. In the early days of intubation it was customary to speak of the percentage of recoveries, and 25 per cent. and 27 per cent. were considered good results. In the last report the recoveries had crept up so high in the one hundred cases, that it seemed more natural to speak of the percentage of mortality.

In this connection it is interesting to inquire what were the best reliable statistics of intubation, taking cases as they occurred, without selection, in pre-antitoxin days. In 5,546 intubation cases collected by McNaughton and Maddren in 1892, the mortality was 69.5 per cent., or, to bring the facts into line, 30.5 per cent. recovered.

O'Dwyer's personal experience, in private consultation, brings us more nearly face to face with the old-time experience with diphtheria. Note that the following 500 cases came under the observation and care of one practitioner, a skilled operator, extended over a dozen years of time, and therefore included all types of the disease.

Exclusive of the first 100 cases of intubation, which he (O'Dwyer) regards as experimental, the results stand as follows:

2d	100 intubations—	recoveries,	27	per cent.
3d	100	"	30	"
4th	100	"	26	"
5th . . 70 on the	100	"	27	"

Total percentage of recoveries, 27.56 per cent. When he had reached 70 on the fifth hundred something occurred which carried the phraseology up over the divide, so that it was appropriate to speak of percentage of mortality. At this point in history, antitoxin arrived and interrupted forever the old series. In O'Dwyer's next 59 cases the mortality was 14 deaths, or 23.7 per cent.

In a total of 1,704 laryngeal cases there were 668 cases operated upon. In the 668 there were 182 deaths, or a mortality of 27.24 per cent. In the former report, in 553 intubated cases the mortality was 25.9 per cent. In approximate figures there is a difference between 27.25 per cent. and 26 per cent.

Summary.—Sixty thousand (60,000) circulars were distributed throughout the United States and Canada.

Time allowance, the eleven months ending April 1, 1897.

Whole number of cases in this report, 1,704; mortality, 21.12 per cent. (360 deaths).

The cases occurred in the practice of 422 physicians in the United States and Canada.

Operations employed:

(*a*) Intubation in 637 cases; mortality, 26.05 per cent. (166 deaths).

(*b*) Tracheotomy in 20 cases; mortality, 45 per cent. (9 deaths).

(*c*) Intubation and tracheotomy in 11 cases; mortality, 63.63 per cent. (7 deaths).

Number of States represented, twenty-two, the District of Columbia, and Canada.

Non-operated cases, 1,036, 60.79 per cent. of all cases; mortality, 17.18 per cent. (178 deaths).

Operated cases, 668, or 39.21 per cent. of all cases; mortality, 27.24 per cent. (182 deaths). Two facts may be recalled in connection with this paragraph. First, that before the use of antitoxin it was estimated that 90 per cent. of laryngeal diphtheria cases required operation, whereas now, with the use of antitoxin, 39.21 per cent. require it. Second, that the percentage figures have been reversed, formerly 27 per cent. approximately representing the recoveries, while now, under antitoxin treatment, 27 represents the mortality. To put it in other words, before the use of antitoxin 27 per cent. recovered; now 73 per cent. recover, and this in the severest type of diphtheria.

The present report will strike many members of the society as revealing a mortality a little too large in each of the two classes. The mortality is large, larger than the personal experience in private practice of many would expect.

The reasons for this are (1) that antitoxin is still used too late, either from procrastination on the part of the physician, or objection on the part of the friends; or (2) in a half-hearted way, which shows itself in doses from one-tenth to one-fourth as large as they should be. In truth, both the physicians and the friends of the patient are timid.

This report, it must be admitted, shows too large a mortality. In the opinion of the committee it is a larger mortality than will ever be shown again. Antitoxin is gradually being used earlier in the disease, and it will soon be used in sufficient doses.

To the society, the committee desires to say that it has sought to carry out its wishes in putting antitoxin on trial, to accept no testimony that did not bear the stamp of reliability, that it has employed the methods approved in the case of the first investigation and report, and that it has confined its work to definitely answering the main questions which the society and profession now have in mind. Points that were settled in the first report, and have since been corroborated by general medical literature, are not again taken up.

If the committee is asked to put forth the three most valuable points established in this eleven months' work, they are:

First. The mortality of laryngeal diphtheria at present rests at 21.12 per cent.

Second. That 60 per cent. approximately have not required intubation.

Third. That the mortality of operated cases is at present 27.24 per cent.

(Signed) W. P. Northrup, M.D.,
Joseph O'Dwyer, M.D.,
L. Emmett Holt, M.D.,
Samuel S. Adams, M.D.,
Committee.

The Committee Recommends: Antitoxin should be given at the earliest possible moment in all cases of suspected diphtheria.

Quality: Of the products on the market some have, by test, been found to contain one-half to one-third the antitoxin units stated on the label. Select the most concentrated strength of an absolutely reliable preparation.

Dosage: All cases of laryngeal diphtheria, the pa-

tient being two years of age or over, should receive as follows:

First dose—2,000 units at the earliest possible moment.

Second dose—2,000 units, twelve to eighteen hours after the first dose, if there is no improvement in symptoms.

Third dose—2,000 units, twenty-four hours after the second dose, if there is still no improvement in symptoms.

Patients under two years of age should receive 1,000 to 1,500 units, the doses to be repeated as above.

Progress of Medical Science.

The Relation of Hysteria to Insanity.—Neff (*Physician and Surgeon*, March, 1897, p. 103) concludes a paper on the relation of hysteria to insanity with the following summary: 1. Hysteria is the result of degeneracy, presenting mentally and physically one or more of the stigmata of degeneration. 2. It conforms to a type of psychosis. Any form of insanity may be engrafted upon hysteria, producing the so-called hysterical insanity. 3. The primary delirium of hysteria may be independent of any sensory or motor complication. More often the emotional storm follows a distinct hysterical attack. 4. Hysteria may complicate insanity, showing an analogy to its occurrence in other diseases.

Placenta Prævia.—Dr. Füth (*Centralblatt für Gynäkologie*) has collected statistics of fifty cases, showing a mortality of thirty-eight per cent. He regards it as necessary to produce premature labor as soon as the diagnosis is made. He advises some method which allows a quick stoppage of hemorrhage, while permitting dilatation of the cervix. Such means must produce prompt dilatation and be sufficient to terminate the labor. Dr. Füth advises putting a colpeurynter into the uterus and using continuous traction on the instrument; the membranes must of course be ruptured at the beginning. He does not believe in expectant methods or in tamponing, because the expectant method exposes the patient to hemorrhage and the tampon exposes to infection. Frequently the tamponing does not stop hemorrhage. This method is also best for the child, as it does not suffer from the mother's frequent hemorrhages. The colpeurynter can be applied as soon as it is possible to introduce one finger into the cervix.

Flooding at Puberty.—Dr. Bécigneul (*Journal d'Accouchements*, January 3d) reports a case of a girl of thirteen years, attacked with profuse uterine hemorrhage. The first period began with the usual phenomena, but the flow continued for a fortnight; then, after an interval of a week, it reappeared and again lasted for a fortnight. Rest, cold drinks, and ergotin were of no avail. Upon examination the uterus and ovaries appeared to be thoroughly well developed. An intra-uterine injection of water at the temperature of 113° F. stopped the flooding. Five days later, when the patient got up, the bleeding recurred, and the injection was repeated with the same result as before, though not so quickly as in the first instance. For a month the patient was kept in bed and daily injections were given. Menstruation was definitely established. This patient showed no signs of hæmophilia besides the bleeding, no cachexia of any kind, and no heart or liver disease. Diabetes, albuminuria, and inherited syphilis were excluded; there was no evidence of poisonous diet and the subject had never been attacked by any infectious disease. The uterus showed no signs of pathologic process. A negative history, such as this, appears to be the rule in "metrorrhagia of adolescence." Dr. Bécigneul thinks that the theory of reflex irritation explains nothing.

Cardiac Failure.—At a meeting of the *British Medical Association*, September 19, 1896, Dr. Grainger Stewart discussed this subject. He considers rest most important, especially rest from manual labor. The element of hope ranks next, then diet. The quantity and quality of food should be carefully adjusted to the needs of the body, and there should be great moderation in the use of liquids. Any excess in the use of alcohol should be strongly deprecated. The use of tobacco should be discontinued, and tea and coffee should be used sparingly. Massage, in the great majority of cardiac cases, diminishes the area of cardiac dulness. Repeated applications bring about a permanent diminution of the area of dulness. The saline bath (three pounds of sodium chloride with eight ounces of calcium chloride in forty gallons of water), in which carbon dioxide is liberated, produces a most striking diminution of cardiac dulness. Dr. Stewart considers digitalis as the most valuable heart tonic. It possesses greater power of contracting the arterioles than any other medicine of the group to which it belongs. Any gastro-intestinal disturbance caused by this drug may be obviated by giving it in another form. Next to digitalis he places strophanthus, which seems to act directly upon the muscular tissue of the heart, increasing contraction. It has little influence on the muscular fibres of the arterioles. Strophanthus is of greater service in an emergency than digitalis, as it acts more quickly. With other heart tonics, Dr. Stewart has had less experience. Caffeine has sometimes been serviceable, though it acts more directly upon the kidney than upon the heart. The author finds nux vomica and strychnine of great benefit when the other remedies are not well borne, and in all instances they may be given as adjuvants. Another group of cardiac remedies acts by dilating the arterioles, and this implies easier circulation, and less work for the cardiac muscles. For rapid action nitrite of amyl is valuable, while for prolonged effect the author gives the first place to sodium nitrite and nitroglycerin. These drugs give the best results in sclerosis of the blood-vessels and diseases of the aorta and aortic valves. If diuretics fail to relieve dropsy, it must be done by mechanical means. The safest and easiest way is by tapping the pleura. The author never drains the skin of the legs and scrotum by means of Southey's tubes unless it is absolutely necessary. Attention should be directed to functional or structural changes in other organs. The alimentary system, the liver, the hæmo-portal system may require special treatment. The lungs should be watched carefully for indications of œdema. We should endeavor to overcome this by rubefacients, and sometimes by stronger measures. The urinary system should be watched for albuminuria due to backward pressure, and in case it appears one should use diuretics which are non-irritating, rush cardiac treatment, and counter-irritate over the kidneys. The nervous system often requires attention. In administering hypnotics the main point is to avoid remedies which depress the heart, such as chloral and large doses of bromide of potassium. Opium, morphine, paraldehyde, sulphonal, and trional have given the writer the best results. In advancing inflammatory conditions Dr. Stewart prefers to avoid tonics and exercise entirely, and prescribes arsenic and the iodide of potassium, often with the carbonate of ammonium. In the degenerative changes he employs tonics and exercises with the most scrupulous watchfulness.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 15, 1897.

"THE FAITH WHICH HEALS."

UNDER this title ("*La Foi qui Guérit*"), one of the last of Charcot's essays has recently been republished by the *Progrès Médical*. In it the question of faith healing as a legitimate therapeutic measure is discussed calmly and judicially. The aim of the physician being the cure of disease, anything by means of which this end can be reached is worthy of scientific study. The fact, which admits of no doubt, that many persons, condemned by competent physicians to a life of incurable suffering, have been cured by means of prayer, led Charcot to investigate the subject, with the view of determining if possible the extent and limitations of the therapeutic miracle. He does not pretend that science is yet in position to explain all the puzzling facts embraced under the general term miraculous, but he holds that the frontiers of the supernatural in the therapeutic miracle are steadily receding, and he doubts not that eventually the complete solution of what but a few years ago was one unfathomable mystery will be reached.

As a fair sample of the whole, he takes the well-known case of the Demoiselle Coirin, who was cured miraculously after fifteen years of suffering. Her troubles began in 1716, following a fall from a horse, in which she struck her left side against a heap of stones. She began soon after to have vomiting of blood, and three months later the left breast became hard, swollen, and purplish in color. This became gradually worse and finally opened, giving exit to blood and other discharges. It was looked upon as a cancer, and the surgeons advised that the breast be amputated, but the mother would not give her consent to the operation. Two years after this a paralysis appeared in the left side, and this with the "cancer" persisted without any remission until the year 1731. In the summer of this year a pious woman made a nine-days' prayer for her at the tomb of the blessed Pâris, and brought her some earth from the tomb and also a garment which had been laid upon it. After putting on this garment the paralytic was able to turn herself in bed; the next day the earth was applied to the "cancerous" ulcer, and the secretions dried up; and the night after this the circulation was suddenly restored in the paralyzed limbs. The *restitutio ad integrum* was not, however, instantaneous, for the cicatrization was not complete until the expiration of eighteen days; six weeks elapsed before the atrophied legs had acquired sufficient strength to enable the woman to go out of doors, and another week before she was able to mount into a carriage.

Even fifteen years ago, Charcot says, the interpretation of all the elements of this curious observation would have offered many difficulties. The hysterical nature of the vomiting of blood and of the paralysis was then recognized, but it had not then been so clearly demonstrated that hysterical contractures or paralysis may be accompanied by muscular atrophy. The mammary affection was evidently an instance of the hysterical breast, and "cancerous" ulcers of the skin are a not so very rare form of dermato-neurosis.

The interesting cases reported by Dr. Fowler in the MEDICAL RECORD of February 15, 1890, in which mammary tumors were cured by psychical measures, are also referred to as illustrative of this method of therapy, with the religious element excluded. The more we investigate the facts of faith healing, says the writer, the more evident is it that this mode of cure obeys natural laws. For example, a study of the reported cases of the alleged miraculous cure of organic lesions, such as ulcers, shows that the suddenness of the cure is more apparent than real. Thus, in the case of the Demoiselle Coirin, the purely hysterical manifestations, that is, the circulatory disturbances and the paralysis, disappeared instantaneously, but the complete cicatrization of the ulcerated surface occurred only after a considerable interval, and the atrophy resulting from the long disuse of the paralyzed limbs required a normal time for its repair.

As the result of his studies, Charcot believed that not all persons are proper subjects for miraculous healing, but only those whose maladies are capable of being influenced by the action of the mind on the body—that is to say, the hysterical. Suggestion, either from outside or of autochthonous origin, is the therapeutic agent. And in suitable subjects—that is, the hysterical of either sex—the influence of the mind on the body is sufficiently powerful to bring about recovery from maladies which, but a short time ago, owing to our ignorance of their nature, were regarded as incurable. But even though we are unable to accept a supernatural explanation of such cures, we must acknowledge their existence, and ought, as conscientious physicians, to avail ourselves of them when the other resources of our art fail us.

SECOND ANTITOXIN REPORT.

THE American Pædiatric Society's supplementary report on the use of antitoxin in laryngeal diphtheria, to be found in the columns of this issue of the MEDICAL RECORD, is worthy of close study.

Laryngeal diphtheria requiring operative interference furnishes the best test of the methods of treatment. There is entire harmony of opinion as to its severity, and its statistics before and after the advent of the antitoxin are more reliable than those of most other well-observed diseases. The report contains an

analysis of 668 cases operated upon, with a mortality of 27.24 per cent. As the report mentions, early statistics of intubation, in pre-antitoxin days, could show only 27 per cent. recovery. Other factors remaining constant, the use of antitoxin has carried the percentage from 27 per cent. recovery up over the divide till it now reads 27 per cent. mortality.

The next point of importance is the percentage of cases escaping operation under antitoxin treatment. It was formerly believed that 90 per cent. of laryngeal cases required operation; now, with the use of antitoxin, 39 per cent. require it.

The returns from physicians show, for the most part, an earlier use of antitoxin in diphtheria treatment and an increasing confidence. There exists, however, a certain amount of timidity. Doses from one-tenth to one-fourth the amount required have been administered, in some cases 200, 400, and 500 antitoxin units being used, whereas the dose required is from 2,000 to 2,500.

It is believed that the percentage of mortality will gradually decrease. This decrease will depend upon three factors:

First, a better quality of strong antitoxin will be found in the market.

Second, the serum will be administered earlier.

Third, appropriate doses (2,000 units in laryngeal cases) will be employed.

The report bears the impress of painstaking labor, and constitutes an addition to the literature of the subject. The American Pædiatric Society has developed collective investigation to a high state of usefulness.

THE MORPHINE HABIT WITH MEDICAL MEN.

In a work on the morphine habit, lately published in Paris, much interesting information is given concerning morphinism and morphinomania, some of which will be new to American readers. It is stated that Germany, France, and the United States are the countries in which the vice is most widespread, but that it has its victims in Russia, Sweden, and Turkey, and that even in the extreme East morphine as a narcotic is said to be supplanting opium. Statistics are furnished of one thousand cases, collected from all parts of the world—six hundred and fifty men and three hundred and fifty women. These statistics show that of the male morphinists the medical profession supplies the largest number, forty per cent. Men of leisure come next, with fifteen per cent.; then merchants, eight per cent.; while peasants, clergymen, and politicians occupy the lowest positions on the list. Women of means are the most numerous class among the females, forty-three per cent.; followed by wives of medical men, ten per cent. In Germany there are entire villages whose inhabitants are all addicted to the use of the drug, but the general belief that the morphine habit is more extensively practised in Paris than in any other city is contradicted. Morphinomania is said to occur with the greatest frequency between the ages of twenty-five and forty.

The direct action that morphine exerts on the organs of generation in both sexes, producing impotence in the male and amenorrhœa in the female, is too well attested to need argument.

The prognosis of morphinomania is stated to be favorable, although relapses are frequent.

MEDICAL RANK IN THE ENGLISH ARMY.

For some time past great dissatisfaction has existed among the medical men of the English army, and the controversy on the subject has reached so far that the national press has taken it up. This discontent shows no signs of abatement, but is rather becoming more bitter, and so much is this the case that at the present time it is found to be almost impossible to obtain the requisite number of candidates to fill vacancies. In the event of a large war matters would be still more serious, as the army service staff and corps are much below their proper strength. This trouble does not arise from a question of money; the pay of the army medical officer is relatively good; his position, too, as defined by the army authorities, is fairly satisfactory, with the exception that he dislikes the title surgeon placed after his military rank. This objection, however, can be but a trivial one, and it has been suggested that in order to remove that stumbling-block the United States mode of styling army medical officers should be adopted. The real cause of grievance "lies in a nutshell"—it is simply a matter of social status. The medical officers think and think rightly that they should be placed on precisely the same footing as the combatant officers. The combatant officers imagine that the medical officers are not their equals in social position, and snub them. As a rule, it may be said that almost without exception a man to be an officer in the English army must possess a good private fortune. So he is brought up luxuriously, educated expensively, and mixes with men of means. On the other hand, the medical man, though probably more talented and better educated, has not been brought up in the same way. He is often a poor man, who has risen by his brains and energy, and has not had the opportunity to acquire much polish. The sooner this ungenerous prejudice passes away, the more satisfactory will it be for the wellbeing of the English army.

THE REGULATION OF VACCINATION.

At the session of the Paris Academy of Medicine, held at Paris on the 30th of March, a paper on the measures to be taken in the absence of a compulsory vaccination law was read by M. Hervieux. It is a fact worthy of notice, and to which it may not be out of place to refer here, that England, the land in which the discovery of vaccination originated, is one of the few civilized countries of the world where the regulations as to vaccination have been allowed to fall into a somewhat lax state. In Germany, for instance, the laws relating to vaccination are most stringent and more strictly adhered to than in England. As a consequence, death from small-pox is almost unknown in that empire, and is yet another striking proof of the

efficacy of vaccination. It appears from a perusal of M. Hervieux's paper that in France the laws regulating vaccination are not thoroughly and simultaneously applied, hence small-pox is more or less rife. However, if the suggestions of M. Hervieux are adopted and the regulations revised according to his ideas of what should be, the reproach of not paying sufficient attention to the vaccination laws will be removed from France.

News of the Week.

The Tsar of Russia has most graciously consented to allow his name to be placed at the head of the list of patrons of the Twelfth International Medical Congress.

Congress of American Physicians and Surgeons.—The following is a list of officers chosen by the component societies of this congress:

Pædiatric—President, L. Emmet Holt, New York; first vice-president, Henry Koplik, New York; second vice-president, C. G. Jennings, Detroit, Mich.; secretary, S. S. Adams, Washington; treasurer, F. A. Packard, Philadelphia.

Association of American Physicians—President, F. C. Shattuck, Boston; vice-president, G. Baumgarten, St. Louis; recorder, I. Minnis Hays, Philadelphia; secretary, Henry Hun, Albany; treasurer, W. W. Johnston, Washington.

Physiological—President, Prof. Russell H. Chittenden, New Haven, Conn.; secretary and treasurer, F. S. Lee, New York.

Surgical—President, T. F. Prewitt, St. Louis; vice-presidents, J. McF. Gaston, Atlanta; M. H. Richardson, Boston; secretary, Herbert L. Burrell, Boston; treasurer, George R. Fowler, Brooklyn; recorder, De Forrest Willard, Philadelphia.

Neurological—President, G. M. Hammond, New York; vice-presidents, Philip Zenner, Cincinnati, and J. J. Putnam, Boston; secretary and treasurer, F. L. Durenn, Philadelphia.

Laryngological—President, Thomas R. French, Brooklyn; vice-presidents, T. Morris Murray, Washington, and H. S. Birkett, Montreal; secretary and treasurer, Henry L. Swain, New Haven; librarian, J. H. Bryan, Washington.

Dermatological—President, J. Nevins Hyde, Chicago; vice-president, E. B. Brown, New York; secretary and treasurer, J. T. Bowen, Boston.

Ophthalmological — President, George C. Harlan, Philadelphia; vice-president, O. F. Wadsworth, Boston; corresponding secretary, J S. Prout, Brooklyn; recording secretary, S. B. St. John, Hartford.

Genito-urinary surgeons—President, A. W. White, Philadelphia; vice-president, J. C. Bell, Montreal; secretary, W. K. Otis, New York.

Otological—President, Arthur Mathewson, Brooklyn; vice-president, H. G. Miller, Providence, R. I.; secretary and treasurer, J. J. B. Vermyne, New Bedford, Mass.

Climatological—President, E. Fletcher Ingals, Chicago; vice-presidents, Samuel A. Fish, Denver, and John C. Munro, Boston; secretary and treasurer, Guy Hinsdale, Philadelphia.

Koch's Fine Commercial Instinct.—In an editorial notice of the new tuberculin, the *Boston Medical and Surgical Journal* says that "in Koch's article, as originally published in the Berlin journal, mention is made of the commercial house charged with preparing and selling the new products. In short, the new tuberculin has become a proprietary preparation, with exclusive rights conferred on a certain firm. Koch's article, in a true commercial spirit, was withheld from publication five months, till this pharmaceutical house was ready to supply the market; then the new discovery was trumpeted through the secular press some time before the publication of the article and telegraphed abroad with the name of the firm favored with the sale of the new product. The Berlin medical press and some of the Paris medical journals have very properly denounced the whole transaction as unworthy of a man of Koch's scientific eminence." But this is apparently not the worst of the business, if the charge made by Dr. Hans Buchner is true. He asserts that the commercial house which is making Koch's remedy was told by Eduard Buchner all about a similar process for extracting the active principle from yeast. He says also that he published an article in the *Münchener medicinische Wochenschrift*, March 23d, in which he spoke of Edward Buchner's discovery, and that immediately the daily press announced Koch's alleged discovery and the article in the *Deutsche medicinische Wochenschrift* came out the following week, but dated back four and one-half months. Koch has gone to Bombay to study the plague, but when he returns he may profitably spend a day or two in clearing himself of these ugly charges, if perchance he can.

Dr. Thomas Addis Emmet has received the Lætare medal from the University of Notre Dame in Indiana.

A Medical-Practice Act has recently been passed by the Texas senate.

The Society of the Alumni of St. Luke's Hospital.—The annual dinner of this flourishing society was given at the Hotel Savoy on May 12th. Dr. Carmalt, of New Haven, is the president of the society.

The American Medical Association. — We have received a communication from Dr. H. A. Hare, calling attention to the necessity for all who wish to take part in the deliberations of the association in Philadelphia to provide themselves with proofs of good standing. No person, he says, who does not come armed with a certificate of membership in his State or county medical society will be permitted to register in Philadelphia. Yet the treasurer of the association has issued postal-card receipts to men unprovided with such certificates, saying that Dr. ——, of ——, member of the American Medical Association, has paid his dues and is entitled to register at the June, 1897, meeting. Does the treasurer of the association obtain money under false pretences, or is Dr. Hare mistaken?

Obituary Notes.—Dr. Charles R. Nellden, of Stanhope, N. J., died on May 2d, at the age of fifty-five years. He was a graduate of the Bellevue Hospital Medical College in 1864.—Dr. Cornelius Olcott died at his home in Williamsburg, on May 2d, of pneumonia. He was sixty-eight years old, and was graduated from the University of the City of New York in 1849.—Dr. Billings Farnsworth, of Norwich, Conn., shot himself in that city on May 5th. He had become despondent through the loss of some property.

The Osteopaths got a bill for their benefit through the Colorado legislature recently, but it was vetoed by Governor Adams. A new medical-practice bill which passed the lower house was strangled in the senate, so the State will have to get along with its old law for the present.

Philadelphia Neurological Society.—A stated meeting of the Philadelphia Neurological Society was held on April 26th, the president, Dr. C. W. Burr, occupying the chair. Dr. Judson reported a case of dysphagia and dysphasia resulting from a lesion of the internal capsule. Dr. A. Ferree Witmer exhibited a case of acute chorea in a woman of thirty-eight, developing in the sequence of a traumatism three years ago. Dr. Wharton Sinkler exhibited a case of trophoneurosis in a woman of about thirty-five, in whom following a burn of the left hand, five or six years ago, destructive changes took place, first and in slight degree upon that member, and subsequently upon the right hand, with loss of portions of the fingers. Dr. J. H. W. Rhein exhibited a case of ataxic paraplegia and one of spastic paraplegia following exposure to the vapor of benzin. Dr. J. K. Mitchell reported an interesting case of headache with visual hallucinations. The attacks recurred periodically during the warmer half of the year, and began with the apparition of a small figure, which gradually increased in size to the proportions of a giant, who struck the patient a severe blow upon the head, with the development of intense headache and the occurrence of an epileptiform convulsion. Dr. A. A. Eshner read a paper entitled "A Contribution to the Statistics of the Muscular Dystrophies." Among other things he pointed out the rarity of this group of disorders in colored persons. Dr. F. S. Pearce reported three cases of traumatic anæsthesia.

The National Association and the Local Society.—On March 27th the secretary of the Cleveland Medical Society received notice from Dr. W. B. Atkinson, secretary of the American Medical Association, that by reason of the action of the judicial council still standing against the local society none of its members would be permitted to register as delegates at that meeting or to take part in the proceedings of the sections. And so the double game of the association goes merrily on. Having for three years received and retained the annual dues of the Cleveland delegates, in spite of the judicial council's orders that they be refunded, and having at the same time refused them those membership privileges which their dues entitled them to, the association has established a habit. Right in the face of this notice from the secretary the treasurer for the association is now receiving the 1897 dues of the Cleveland men and giving them receipts which read on their face that the holder is entitled to all privileges of the coming meeting! And, as an additional indication of consistency, the editor of the *Journal of the American Medical Association* continues at the same time to solicit new members from among our society. Did ever before any medical organization engage in such a 'bunco game' and can it expect to retain the respect of the profession while pursuing such questionable methods? And the association deliberately shoulders all this disgrace and ignominy merely to pursue the private grudge of one of its members, who has no professional standing in his own city, who can belong to no local medical organization, and who has been repudiated very plainly by the Ohio State Medical Society. Truly the ways of the association are devious and strange.—*Cleveland Journal of Medicine.*

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending May 1, 1897: April 29th.—Surgeon A. G. Cabell, ordered to the *Monongahela*, May 15th; Surgeon D. H. Morgan has been detached from the Naval Academy and ordered to the *Monongahela*, May 15th. April 30th.—Assistant Surgeon R. G. Brodrick ordered to examination for promotion, May 3d. Assistant Surgeon F. C. Cook detached from the *Vermont*, May 8th, and ordered to the *Wilmington*, May 10th.

Disinfecting Steamer.—The disinfecting steamboat *James W. Wadsworth* will be ready for inspection on Tuesday next (May 18th), between 2:30 and 6 P.M., at the foot of West Forty-fourth Street. In addition to the steam apparatus, the boat has recently been supplied with an apparatus for disinfection by formaldehyde gas. The profession is invited to attend.

German Hospital, New York.—Dr. Otto G. T. Kiliani has been appointed attending surgeon to the German Hospital.

The Toxin Treatment of Malignant Disease.—In a recent letter to the *British Medical Journal* Dr. W. B. Coley sums up the results of his toxin treatment of malignant growths as follows: The different forms of sarcoma respond very differently to the toxin treatment. The melanotic variety is scarcely at all affected; round-celled sarcoma, especially of bony origin, seldom yields good results; the spindle-celled variety gives by far the best results. In eight out of fifteen cases treated the tumor entirely disappeared, and all of the remainder showed marked improvement. This disappearance may result in permanent cure, as is shown by the fact that four of the cases have passed the three-year limit. The results in carcinoma have been generally unsatisfactory, and it follows that this method of treatment should not be advocated except in inoperable sarcoma.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

(Continued from page 675.)

First Day—Tuesday, May 4th.

AMERICAN PÆDIATRIC SOCIETY.

President's Address.—DR. SAMUEL S. ADAMS, of Washington, took for his subject "The Evolution of Pædiatric Literature in the United States." He desired to put on record the works upon diseases of children written in this country during the past hundred years, and had therefore read every essay, pamphlet, and book to 1870. Revised foreign works are excluded as being exotic. Masterpieces devoted to diseases of women and children give too little space to children to be included.

Benjamin Rush in 1789 described faithfully influenza as it appeared in 1789, 1790, and 1791. The disease is ushered in with hoarseness, sore throat, chills, and fever; pain in the head and eyes is intense, sneezing incessant. Acute pains in the limbs are like rheumatism or breakbone fever of 1780. There are profuse sweating and quick pulse. Sometimes "the disease fell upon the bowels and went off in diarrhœa." There were recurrent attacks. During the prevalence of that epidemic he inoculated twenty children with small-pox and "never saw that disease exhibit a more favorable appearance."

Caldwell in 1796 was the first to write an inaugural monograph on pædiatrics. It was "an attempt to establish the original sameness of three phenomena of fever described by medical writers under the several names of hydrocephalus internus, cynanche trachealis, and diarrhœa infantum." He says: "I have called them phenomena or symptoms because I do not consider them as primary diseases. I shall treat them as the dependent effects, not as original cause of that febrile state of the system by which they never fail to be accompanied. Without the previous existence of general fever these phenomena cannot occur. They shall be considered as genuine and distinctive offspring of arterial action, morbid in its nature, excessive in its violence, and by causes of peculiar tendency determined to the encephalon, the trachea, or the intestines."

These diseases are the "immediate result of an evacuating process which never fails to diminish the impetuosity and tumult of febrile action." The arguments supporting the new theory were that the diseases are general, not local; that the topical affections are preceded by general fever; that the morbid processes are evacuant; that they are due to an impetus of the blood subjected to febrile action, and that the same remedies are efficacious in all three diseases. "These ideas of etiology and pathology were certainly original and his clinical pictures complete."

As Caldwell was America's first author on diseases of infancy and childhood, a few historical notes are given. When nine years old he knew only his alphabet, but began the study of classics at twelve years. He began his medical studies in the University of Pennsylvania in 1792, when in his twenty-first year. His scholarship was thorough and accurate. During the yellow-fever epidemic in Philadelphia in 1793 he was the only student to remain and was placed in charge of the Bush Hill Hospital. He opposed Rush and others as to the contagiousness of yellow fever.

Rush records that while in the army Caldwell was "overtaken by a shower, was wet to the skin while laboring under a high fever; the fever left him in consequence of the shower bath and never returned." Rush cited this as reduction of fever by unavoidable hydrotherapy.

In 1806 James Stuart, M.D., presented to this country the first recorded necropsy of "a case of cholera infantum, apparently benefited by the use of nitric acid." "The omentum had nearly disappeared, the stomach was distended, the pylorus contracted, large intestine contracted, mesenteric glands obstructed," etc.

In 1810 appeared the first book on management and feeding of infants. It was by a woman who concealed her identity. The title was "The Maternal Physician: A Treatise on the Nurture and Management of Infants. From the Birth until Two Years Old. Being the Result of Sixteen Years' Experience in the Nursery. Illustrated by Extracts from most Approved Medical Authors. By an American matron, Philadelphia, 1810."

The author was attracted by the great number of obituaries and felt that mismanagement was the cause. She advocated daily cold baths, advised cow's milk when mother's milk failed, and assailed "paps and other crudities." She cut the frænum of the tongue in all children, and advised cutting the gums with a razor. She believed in the contagiousness of dysentery and treated the disease with emetic doses of ipecac. She is entitled to the credit of being the first American pædiatric author.

In 1812 Jackson recorded a clear account of a necropsy in cholera infantum.

In 1814 Edward Miller wrote an article on "The Cholera, or Bilious Diarrhœa of Infants." In this is the first record of cold baths in the treatment of fever. He injected cold or iced water into the bowels as an "anodyne, sedative, and antispasmodic."

The second American book on diseases of children was by George Logan in 1825. He first refers to the use of splints for deformed feet. He advised healing excoriations behind the ear or at the navel, not leaving them alone as was the custom. He taught that a child must suck its food, not be spoon fed.

W. P. Dewees in 1825 published a treatise on medical and physical care of children. He decried the dress of the day, the torturing swaddling clothes that allowed no motion of limbs or body. Dewees had clear ideas of substitute feeding. He advised two-thirds milk, one-third water, and a small quantity of loaf sugar. He too proscribed all other mixtures, and insisted on small amounts at a time. Milk was to be heated but not boiled. He was not far from Pasteur. He gives the morbid anatomy of cholera infantum and recommends injections of warm water and salt. Scarlet fever he regarded as epidemic but not contagious, and treated it by cold sponging.

Flint in 1826 emphasized the idea that "physical culture is to the body what moral culture is to the mind."

Reynolds, of Massachusetts, in 1833 pointed out dangers of a studious life, overcrowding of rooms, cramped positions, excess of duties, etc. It was not until three years later that Germany presented a work on protection of health in schools.

Samuel Jackson in 1833 recorded a case of a girl, eleven years old, cured of scarlet fever by the ice-water treatment. The pulse fell from 160 per minute to 120 and all bad symptoms abated.

J. Forsyth Meigs in 1848 gave us "A Practical Treatise of Diseases of Children," with intelligent discussion of physical signs and treatment up to date.

Charles D. Meigs in 1850 published his lectures and proclaimed against undue drugging of children.

Dr. Arthur Meigs in 1885 gave us "Milk Analysis in Infant Feeding."

Surgical diseases of childhood and early life were first treated of by Dr. John Watson, of New York, in 1853. He discusses injuries to joints, atrophy of limbs, and especially atrophy of muscles.

Dr. A. Jacobi, the institutor of pædiatric lectures and clinics, the first professor of pædiatrics in this country, the recipient of the highest medical honors at home and abroad, has been writing from 1857 to 1897. His books and essays are numerous. "Catarrh of the Infantile Larynx," "Importance of Premature Closure of Fontanelles and Sutures," and other essays are familiar. He is not skeptical as to effects of drugs. Uncertain diagnosis is the real trouble.

Contemporaneous with Dr. Jacobi is Dr. J. Lewis Smith, whose reputation as an author has not waned during forty years. The first edition of his "Diseases of Children" appeared in 1869. Since that time radical changes have occurred in infant feeding, in the views of diphtheria *versus* croup and its treatment.

Sachs, of New York, in 1895 gave the first "Treatise of the Nervous Diseases of Children."

In the same year Dr. T. M. Rotch published "Pediatrics." To him must be accorded the honor of inaugurating an accurate method of feeding.

In 1896 Dr. L. E. Holt "emerged from the dead house with a real live book," "Diseases of Infancy and Childhood." He closes the century with a masterpiece.

A Case of Tic Convulsif.—Dr. J. C. Wilson narrated a case of the disease in a boy of fifteen years. He was a poorly nourished child, not well developed, son of a neurotic mother. The photographs showed the boy in the various stages of attack. The spasms occurred at intervals of ten minutes and continued fifteen seconds. Hyoscine and neurotics did little good. As masturbation was a factor in the case, circumcision was performed. There was some improvement afterward.

Diaphragmatic Hernia.—Dr. W. D. Booker presented specimens from a case of congenital diaphragmatic hernia, associated with recurrent attacks simulating asthma dyspepticum. The child had eight or ten undigested stools daily, though breast fed. The diet was changed to cow's milk with some improvement. Respiration was labored and forty or fifty to the minute, more if excited. A number of spasmodic attacks of asphyxia occurred and finally death resulted in such an attack. On autopsy all of the small intestine was found in the left pleural cavity, also a portion of the liver. In nearly all diaphragmatic herniæ the opening is upon the left side. The author suggested that the embryonic development of a pleural and pericardial sac from the abdominal cavity may explain this frequency.

Dr. O'Dwyer stated that he had seen a similar case, in which a diagnosis of empyema was made and the truth only discovered upon surgical opening.

Two Cases of Unilateral Tremor.—Dr. J. P. Crozier Griffith reported these cases. One case had slight shortening and atrophy of the left arm which might be thought to be post-hemiplegic. The tremor was always present. As there was no increase of reflexes, central lesions are ruled out. Treatment was unavailing. The second subject, eighteen months old, was of healthy parents. The child when one year old ceased crawling and trying to speak. Its tissues became flabby and it seemed to have no control over its movements. There was no nystagmus, no genuine paralysis. There was a question if this were due to tuberculous lesions.

Dr. Rotch said that faulty nutrition would account for most of these cases, and that when it was corrected recovery would result. One should be sure not to have a neurologist make the diagnosis, as he will hunt for a central lesion and overlook nutrition.

A Frequent Significance of Epistaxis.—Dr. J. Henry Fruitnight, the author, wished to recall the fact that frequent nose bleed in children commonly accompanies chronic valvular heart disease, mitral obstruction and aortic regurgitation being the common forms. One should always examine the heart and treat its lesions. This will cure the epistaxis.

Two Cases of Meningitis, Apparently Tuberculous, with Recovery.—Dr. George N. Acker reported these cases. They presented persistent vomiting, irregular respiration, and irregular pulse, classical signs of tuberculous meningitis. One had dulness at the apices of both lungs with small râles. There were also green undigested stools. The real diagnosis was enterocolitis. The second case, a mulatto boy of nine years, had shown scrofula and had chills and fever. His temperature was 103° F. There were delirium and retraction of the head. He had pneumonia.

Dr. Jacobi said that those who apparently recovered might die later, showing lesions of tuberculosis. He cited a recovery from tuberculous meningitis, but the man is now in an insane asylum.

Dr. Holt cited a case of death from simple meningitis, in which tubercles were found elsewhere than in the brain. He also mentioned a boy who had double hip-joint disease, but died six months later of amyloid disease and showed no tubercles.

Dr. Jacobi said lumbar puncture would help in the diagnosis.

Dr. Dillon Brown mentioned the use of tuberculin and ophthalmoscopic examination.

Congenital Laryngeal Stenosis.—Dr. Joseph O'Dwyer related a case in which the larynx was of the size of a crow quill. By dilating with sounds and later with the tip of his finger, the larynx was brought to normal size. He wished to emphasize the value of sense of touch to the surgeon, and call attention to dilatability of the young larynx.

AMERICAN ORTHOPÆDIC ASSOCIATION.

Address of the President.—Dr. Samuel Ketch, of New York, president of the association, delivered an address, taking for his title "The Work and Influence of the American Orthopædic Association." He called attention to the fact that just ten years ago the American Orthopædic Association was formed, and it was interesting and instructive to review the work which had been done. He stated that 323 papers had been read, including 35 on hip-joint disease, 19 on knee-joint disease, 2 on disease of the ankle-joint, 2 of the wrist-joint, 3 of the shoulder, 1 of the elbow, 49 on Pott's disease, 20 on lateral curvature, 2 on round shoulders, 6 on torticollis, 2 on sacro-iliac disease, 14 on congenital dislocation of the hip, 43 on club-foot, 6 on infantile paralysis, and 7 on spastic paraplegia, besides a large number on various other subjects embraced in orthopædic surgery. This was a record of which the association could justly be proud and its influence had been felt in the medical world. Ten years ago there were very few medical schools where any attempt was made to teach orthopædic surgery, and only three where there was a systematic course of instruction. To-day it had become a well recognized specialty in almost all schools, and through the work of this association the position of orthopædy had become assured, had been taken from the hands of the quack and the instrument-maker, and placed in the domain of scientific research. Through the influence of this association other societies devoted to the special study of orthopædics had been formed in

this country and abroad, and there was promise of the establishment of an orthopædic journal. He was glad to note also that more and more attention had been given to the study of the etiology and pathology of orthopædic diseases, and that the relations of orthopædy to general medicine and surgery were broader and more catholic in spirit; and felt that with the recent aids to diagnosis and research greater advances would be made in the future. He urged that the influence of the association be exerted against the work of ignorant instrument makers and venders of surgical appliances, and that efforts be made to secure if possible legislation to protect the unfortunate cripples who might fall into their hands—also that those members of the association who were teaching should impress more and more upon their students the importance of early recognition of symptoms in joint and spinal disease and other deforming conditions.

In conclusion a fitting tribute was paid to the memory of those members of the association who had died during the past year: Dr. Henry G. Davis, the pioneer in this country of the treatment by traction of joint diseases; Dr. George W. Ryan, of Cincinnati, Ohio; Mr. N. Grattan, F.R.C.S. Ed., of Cork; Dr. Harry Hodgen, of St. Louis, Mo.; and Dr. A. Sydney Roberts, of Philadelphia.

Erosion of the Knee-Joint with Conservation of the Epiphyseal Cartilage.—Dr. Harry M. Sherman, of San Francisco, stated that his paper was simply a report of three cases to illustrate a method of procedure which was somewhat experimental but not altogether new, viz., the removal of the epiphyses for knee-joint disease without disturbing the epiphyseal cartilages. The effect of the removal of these cartilages in the growing bones of children was well known. As Koenig has said that primary tuberculosis of the epiphysis rarely attacks the diaphysis, and as it was impossible to know how extensive the disease in the epiphysis might be, it was important to remove it entirely without disturbing the barrier between it and the diaphysis. Of the three cases two presented with the knees extremely flexed with contraction of the posterior tissues and dislocation of the tibiæ backward. The flexion was corrected by apparatus until the posterior tissues were lengthened sufficiently to allow the bones to be placed in line after removal of the epiphyses. The epiphyses were removed in both cases and the patellæ, but the cartilages left intact. Both subjects left the hospital with the limbs in a straight position, but flexion occurred while the children were under observation and in spite of plaster splints, in one case there being erosion of the skin anteriorly from pressure. This seemed to be due not to a return of contracture in the soft parts but an unequal growth of bone. Dr. Sherman presented skiagraphs showing the formation of new bone. The third case was different, as he saw it very early and treated the boy conservatively for two years. As there was no improvement and as the disease seemed to be located in the head of the tibia, he removed the epiphysis, leaving the cartilage. He then found that there was disease also in the diaphysis, which he removed, forming two cavities with the portion of cartilage between. A portion of this had sloughed, but sufficient had remained to form new bone and continue the growth, so that now the child was perfectly well with full function of the joint and only two and a half centimetres' shortening. He showed a skiagraph of this case also.

Dr. Charles L. Scudder thought the suggestions offered by Dr. Sherman were excellent, that in his opinion the long-continued use of apparatus was often detrimental, and that if by this means the early investigation of a local lesion was possible it was a great advance. As regards flexion after excision, he thought that a slight degree of flexion, say 5° or 10°, was preferable to having the limb perfectly straight, that the patient could sit easier and walked with less limp.

Dr. R. W. Lovett had been interested in the paper because he had had no experience in early excisions in knee-joint disease. He had had considerable experience in late excisions, and thought the results remarkably good. The conservative treatment had been very satisfactory in his hands. At the Children's Hospital the indications for operation were to open abscesses, and then if extensive bone disease was found to excise. Arthrectomy had not proved satisfactory.

Dr. W. R. Townsend said he thought excision of the knee in children was rarely necessary, as they usually did well under conservative treatment, while on the other hand in adults the rule was that an excision became necessary in a comparatively short time.

Dr. Blanchard remarked that his experience had been quite different, and that his adult patients did better than the children.

The President said that while theoretically it was desirable to remove early a local tuberculous focus, practically it had been found very difficult to do this, and the results obtained by the German surgeons, especially in the hip, had been far from satisfactory. He could bear testimony to the fact that flexion frequently returned after excision at the knee and many times to a degree equal to the original. He believed that the conservative treatment in children was very favorable and should be thoroughly tried before resorting to any operation.

Dr. Sherman in closing said that these cases were all late operations and that he had referred to the question of focal operations only incidentally. He would exclude the hip from these operations on account of the impossibility of knowing how far to go. He felt that the question of treating a tuberculous bone lesion conservatively or by operation depended upon the ability to estimate the vitality of the patient.

Report on Cases of Traumatic Spondylitis.—Dr. Arthur J. Gillette, of St. Paul, said that he used the term traumatic because the conditions described followed an injury immediately. The first case was that of a man in good health who slipped upon the sidewalk and shortly afterward became paraplegic with an area of anæsthesia extending almost to the nipple line. Five months later, when he first saw him, these conditions were still present, and in addition there was slight prominence of the spine in the dorsal and lumbar regions. There were rigidity and pain more severe than usual in chronic disease of the vertebræ. Treatment gave only partial relief. Later he developed tuberculosis of the lungs, which ran a rapid course. A post-mortem revealed a diseased condition of every vertebra, the crest of the ilia, the ribs, and sternum, in addition to the tuberculous lesions in the lungs. The second case was that of a very vigorous man of thirty-five who "sprained his back" severely by lifting, a few months previous to the examination. At that time there were inability to walk, exaggerated reflexes, and ankle clonus, slight prominence in the dorsal spine and rigidity of the muscles. In attempting to apply a plaster jacket the patient had an alarming attack of syncope, and following this attempt all the symptoms became worse and the paraplegia increased until the sphincters were involved. Symptoms of basilar meningitis also appeared. A few weeks later there was a sudden attack of coughing and dyspnœa and evidences of pleural effusion were found, while the head symptoms were relieved. It seemed to him that these symptoms could be produced only by the rupture of an abscess, which had been pressing on the cord, into the pleural cavity, and the autopsy a few weeks later showed that this was the case. There was also extensive disease of all the dorsal and lumbar vertebræ. The third case was

that of a woodsman who "sprained his back," but was not obliged to stop work at once. When he was seen a few weeks after the injury there was slight prominence of the first two lumbar vertebræ. He grew worse in spite of treatment, suffering great pain in the lower cervical and dorsal region, where a kyphos subsequently developed. Death occurred after a number of months and the autopsy showed extensive disease in a large number of vertebræ.

Dr. R. W. Lovett reported a case which he had seen September 5, 1896. A young man, on April 3, 1896, had been injured by having a wagon, weighing twenty-six hundred pounds, run over his pelvis. He was confined to bed only a week or two and had no medical attendance, then went about on crutches though suffering considerable pain. He presented the appearance of a man suffering from severe lumbar Pott's disease with lordosis and shortening of the trunk, but none of the usual symptoms of Pott's disease were present. The diagnosis of spondylolisthesis was made and a plaster jacket applied. The jacket was renewed every two months, and in April of this year the patient was discharged as all signs of irritation and pain had disappeared, although the deformity, as shown by the photographs submitted, was still very marked.

Dr. Lovett had been surprised at the good result obtained.

Dr. N. M. Shaffer was inclined to think that there had been no true dislocation in Dr. Lovett's case, and thought that probably the injury had produced an inflammation at the junction of the last lumbar vertebra and the sacrum, and that the deformity was due to the reflex muscular spasm.

The President stated that he had seen a case which had presented symptoms very similar to those of Dr. Gillette's cases, viz., prominence in the dorsal region of the spine, paraplegia, and severe local pain, when the autopsy showed no lesion of the vertebræ whatever.

Dr. Taylor, of Philadelphia, asked if a section of the cord was made, and suggested that it might have been a case of syringomyelia.

The President replied that there was no external evidence of that disease, but he had not been able to get a report upon the cord from the pathologist to whom he had sent it.

The Treatment of Torticollis.—Dr. E. G. Brackett, of Boston, read a paper with this title. He said that he desired in his paper to emphasize a part of the treatment of this affection which he thought had been rather neglected, viz., massage and manipulation after operation, to stretch the contracted muscles, exercise those which had become weakened from disuse, and to overcome the faulty habit of carrying the head. He thought there might be a few cases which could be cured by this treatment alone, though in one which he reported it was a failure, and he thought in almost every case an operation to overcome the obstruction was necessary first. But the use of massage and manipulations persistently would obviate the prolonged application of apparatus, as he showed by reports of two cases. A curious feature of one case, which he had never seen mentioned, was the occurrence of attacks of syncope whenever the head was overcorrected beyond a certain point. This took place at the time of the operation, and had persisted ever since. He could explain it only by the possibility of pressure on the vagus from the changed relations of the parts.

Dr. L. W. Hubbard spoke highly of exercises and manipulations after operation for torticollis, and reported a case in a woman of twenty-eight years, which showed the good effects of this plan of treatment.

Dr. Shaffer said some time ago he had made a thorough trial of treating these cases without operation, and had become convinced that success was rarely possible. He believed that the after-treatment by exercises was very important.

Dr. Steele found such exercises and manipulations as recommended by Dr. Brackett rather difficult to carry out, and he had been in the habit of employing suspension and with good results.

THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

President's Address.—Dr. E. Fletcher Ingals, of Chicago, after reciting briefly the history of the association since its organization in 1884, called attention to the great increase in our knowledge of the climatological possibilities in the United States, and urged the members to extend their studies to the effect of climate on various other diseases in addition to those of the respiratory and circulatory organs. The remainder of the paper was devoted to the antiseptic treatment and the limitation of climatic treatment of pulmonary tuberculosis. He briefly cited several cases illustrative of the benefits to be derived from the various antiseptics and from an antiseptic atmosphere, and urged upon the profession the inutility of sending patients at all advanced in the disease away from home, excepting under the most favorable circumstances. The paper closed with the following conclusions:

"In addition to tonics, supporting and anodyne remedies, various antiseptics appear to possess great value in relieving pulmonary tuberculosis, but in order to get good effects it is imperative that the system be as nearly saturated with them as possible. They should be given at first in small doses, but the amount should be steadily increased until the maximum dose is obtained, care being always taken not to disturb the digestive organs. For example, with the oil of cloves we may begin with five drops given in capsules from three to five times daily, after each meal and in the middle of the forenoon and middle of the afternoon, the medicine always to be followed by a glass of milk. The second day the dose should be six drops; the third, seven; and so on until a dose of twenty-five or thirty drops is given each time.

"Creosote can seldom be given in sufficient quantities to have any material effect, because of the disturbance of the digestive organs which it is liable to cause, and because of its coagulating effect upon all albuminoids. The same may be said of carbolic acid.

"The carbonate of creosote is much more bland, and may be given in doses of from five to sixty drops after each meal with the greatest benefit.

"Guaiacol may be given in much the same way as the oil of cloves, though in somewhat smaller doses, but it is usually less easily borne than the carbonate of creosote or oil of cloves, and often cannot be tolerated in sufficient quantities. The carbonate of guaiacol may be used in much the same way as guaiacol itself, but most patients seem unable to take it in sufficient doses. Oil of cloves and carbonate of creosote are the most satisfactory antiseptics for internal administration.

"Iodine may be used as recommended by Shurley with undoubted benefit, but it causes considerable pain and is open to the objection that it necessitates too constant attendance of the physician. It may also be used advantageously as an inhalant.

"Patients should not be sent from home unless their financial and social position is such as to render the journey and sojourn easy and agreeable.

"In the first stage of the disease, patients should as a rule go to a high altitude, where the atmosphere is as warm as practicable. In the second stage they should be sent to a medium altitude. In the third

stage, if sent anywhere, it should be to a low altitude, and in most instanes to a dry atmosphere.

"When sojourning in a favorable climate the patient should be out of doors as much as practicable during the pleasant portion of the day, but should avoid excessive heat, excessive cold, and unusual fatigue.

"Patients who have been improving under any course of medication should not discontinue it upon going to a different climate, but however valuable any remedy may appear it should not be continued if it becomes clear that it is deranging the digestion.

"Of anodynes to check cough, hyoscyamus, camphor, cannabis indica, stramonium, and conium are of most value, because they can generally be taken in sufficient quantities without disturbing the digestion, whereas opiates are usually deleterious in whatever form they may be employed.

"The majority of patients sent from home in the later stages of pulmonary tuberculosis are injured by the journey and their lives correspondingly shortened, though in a small percentage a very great benefit is obtained."

Dr. R. G. Curtin, in discussing the president's address, said that he was much interested in the study of the climate of the City of Mexico. He was a delegate to the Pan-American congress, and considered it one of the most unhealthy cities of the world. He stated that the city had a very high death rate, and gave as a cause the location of the city in a valley which received the sewage. Dr. Curtin's reason for speaking of this fact was to carry out the idea of Dr. Solly's remarks, that something besides elevation should be considered in the location for cases of tuberculosis.

Dr. J. B. Walker believed that the oil of cloves had not only an influence in modifying the general nutrition, but also that it was beneficial in cell nutrition.

Dr. Solly believed that the oil of cinnamon is perhaps a little better antiseptic, as the oil of cloves is not so well tolerated by the stomach.

Dr. Ingals, in closing the discussion, said he could not agree with Dr. Solly that the effects of change of location are purely mental; he believed also that the bicarbonate of creosote could be taken in large quantities if started in small doses. He had not used the oil of cloves as an inhalant, and stated that he did not expect to attack the bacillus locally by an inhalation. He was familiar with the views of some that the antiseptics were useful in benefiting the nutrition, and he thought they did benefit the blood by increasing the destructive qualities of the blood for microbes.

Choice of a Summer Residence.—Dr. F. I. Knight, in a paper with this title, compared the New England coast resorts, and said they presented differences of temperature, moisture, wind, and other climatic conditions. He said that to be cool in summer on the New England coast one must be where the south wind blows directly from the sea. As the general direction of the line of the east coast runs mostly northeast, the coast would have the south wind from the water if it were not for the interference of the two capes, Cape Ann and Cape Cod. North of Cape Ann as far as Hampton, N. H., and north of Cape Cod, especially between Cohasset and Boston, the south wind comes overland and is a hot wind; whereas north of Hampton, N. H., and south of Cape Ann toward Boston, on what is called the north shore (*i.e.*, of Massachusetts Bay), he said the south wind comes from the sea; therefore these places are cooler than the former. He spoke also of the island resorts, where the quality of sea air is experienced more constantly and the temperature is more equable, but which differ considerably one from another in average temperature. He stated that the Isle of Shoals was much cooler than Block Island or Nantucket.

Dr. Bowditch, in discussing Dr. Knight's paper, said that the curiously dry quality of the atmosphere on the Maine coast, in spite of the fact of its being on the sea, was so striking that he thought phthisical patients would do well there, and although he had never dared to recommend it for such patients because he had found that mountainous regions were better. still, if a patient wished to try it, he should not hesitate in telling them to do so.

Dr. Solly, in discussion, said he was very glad to hear Dr. Knight's remarks about these home climates; that in Colorado it was often necessary to send patients back East for the summer; that it was a question very important to know where to send them, and that he had been studying the New England climate in that regard. He wished it were possible to secure meteorological reports of these places.

Dr. Alton thought there had been too much generalizing in the matter of climate, and that it would be well to study minutely approximate localities.

Dr. Babcock, in discussing the paper, expressed his belief that the effect of climate in the treatment of tuberculosis is largely due to whether or not the patients are able to spend much time in the open air, and that if patients are to be sent away in the summer they should be sent to climates which are stimulating, and that they must go to localities where they can remain in the open air.

Dr. Taylor stated that the reason why tuberculosis was at one time so prevalent along the Maine coast was on account of the insufficiency of the food, its quality, and its preparation, and that since the improvement in these details tuberculosis is far less prevalent.

Dr. Bonney stated that inasmuch as he had lived in Maine for a number of years, he had observed that there was a considerable difference in the character of the soil in portions of Maine from that in New Hampshire or Massachusetts. He said there was much surface moisture after a rain storm, and that it took much longer for the moisture to dry than in Massachusetts. He spoke of the ready disappearance of the fogs, which came on after a delightful day and would entirely disappear in the morning.

Dr. Knight, in closing the discussion, remarked that the coast of New England was hardly to be recommended except in the summer and autumn. He said in regard to the prevalence of such a disease as tuberculosis that it should be borne constantly in mind that it does not exist until introduced, and that it is rather the propagation and development that are to be favored by climatic conditions.

Climate or Environment as a Factor in the Repair of Neurasthenia and Melancholia.—Dr. J. Madison Taylor, in a paper with this title, expressed his personal convictions, based upon cases in his own practice and elsewhere. The paper was designed to elicit comment as to the experience and conviction of other climatologists. The profession is dependent for statistics on this subject upon contributions from those physicians who reside in countries and situations valuable from a climatic point of view. The author's convictions were: 1. That change of climate is of relative insignificance in the treatment of neurasthenic states, although changes of situation quite frequently are of more or less importance. 2. The most important element of change has to do with environment, including not only change of place, but of persons and things. 3. It is important to outline what constitutes the essential points in this change of environment, so that the average practitioner may keep in mind such imperative conditions and modifications as the varying needs of the individual, his domestic and financial status, make necessary.

The paper made special reference to the undesirability of radical changes inconsistent with the customary life of the patient, and laid stress upon the distinct harm wrought upon a highly sensitive organization thrown out of balance by a prolonged residence on the seacoast or in high mountain regions. It called attention to the hurtfulness of rushing about from place to place in obedience to morbid impulses, the outcome of agitation due to disease.

Diseases of the Nervous System Affected by Climate; Climate Defined.—Dr. Sanger Brown, in a paper read by title, stated that benefits derived from change of climate are due: 1. To incidental influences, such as relief from responsibility, change of scene, an outdoor life, and regular habits. 2. To the influence of the climate in the promotion of the general health. 3. To the direct effect of the climate upon the disease itself as the healing influence upon the lungs popularly attributed to inhalation of the atmosphere of certain districts. The author briefly recapitulated: "In debilitated states of the nervous system, attended with such disturbances of function as simple melancholia, neurasthenia, neuralgia, insomnia, neuroses incident to the menopause and hysteria, a high altitude and the seashore are contraindicated, and while generally in such cases a clear cold climate is most beneficial, a few cases do better in a mild inland climate. After a certain degree of improvement has taken place, this may frequently be advanced by sea or even mountain air."

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

A Report of Post-Mortem Examination of Some Cases of Movable Kidney.—Dr. Francis S. Watson read the first paper. In thirty-eight subjects chosen at random in dissecting-room, he found eight cases of movable kidney, a large proportion. Four cases were of males, four of females. In four cases both kidneys were movable; in three cases the right; in one the left. The perirenal fat was much diminished in five of the eight. Hydronephrosis was found in none. Ptosis of other organs was found in four of the eight. In two cases rotation on the long axis was easily performed. In two others, in which the peritoneum was much relaxed, this rotation was impossible on account of transverse bands of peritoneum. These bands the writer had not found noticed in the literature of the subject and had not found them before himself, and did not know just how much, if any, significance was to be attached to their presence. The age of the subjects varied from forty to eighty-four years. In the subject eighty-four years old there was marked evidence of tight-lacing, and the kidney was very freely movable. The enlargement found in these cases the writer thought due to congestion and not to a hydronephrotic condition from backing up of urine from obstruction of the ureters. In only one case observed (and that not of these eight reported) was there hydronephrosis, and in that there was also a renal calculus, which was perhaps the cause of the hydronephrosis. Tying the ureter causes congestion but not hydronephrosis, and after tying and then releasing we get large quantities of urine passed, more than could be caused by the mere obstruction. In rotation of kidney we get twisting of the vessels and ureter. The blood-vessels can stand a greater degree of twisting without occlusion than the ureters. In downward displacements, if the peritoneum is much relaxed and the ureter is free, we get little or no kinking and occlusion of the ureter; but if the ureter be fixed by adhesions then it certainly gets kinked and occluded. The enlargement then is due to obstruction of the ureter caused by rotation or descent of kidney (permitted by relaxed condition of peritoneum) with fixed ureter. In regard to the polyuria observed after the periods of congestion and enlargement, Dr. Watson cited the case of urination in dogs, whose bladder is small and non-distensible. The dog can go without passing urine for some eighteen hours, if compelled to, and then within a few minutes will pass more than six times as much as the bladder can hold, this being doubtless a nervous phenomenon, analogous in its effect to a temporary tying of the ureters. He spoke also of the so-called derotation of the kidney, at the time of attacks of descent (or moving), with congestion and enlargement due to the twisting of the ureter, with pain, etc. This was accomplished by turning the patient over on the side of the affected kidney, elevating the hips, and then manipulating the kidney into place. The pain ceases and the usual free urination follows (six to twelve ounces), repeated several times within a short period.

Clinical Observations on Loose and Displaced Kidneys.—Dr. John P. Bryson, of St. Louis, said that the real pathological condition was a disturbance in the condition of the fatty capsule, with or without general enteroptosis. This involved, 1st, loosening and movement of the kidney within its capsule; or 2d, a condition in which the capsule itself is loose from its posterior attachment, so as to slip with the kidney; or 3d, a combination of both first and second conditions. Early in these cases the pain is in inverse proportion to the movability of the kidney, because it is the kidney that leaves its bed, and the vessels, not being loose, cannot follow it. The displacements of the kidney and twisting or bending of the vessels cause compression of vessels, and *ergo* congestion and swelling of kidney, and therefore the pain follows. The direction of kidney movement was in the cases observed more often a rotation than a descent, and he found more pain from the twisting of the pedicle in rotatory displacement than from bending of the pedicle in descent of kidney. In one case the kidney was displaced downward and when down rotated on its short axis so that the hilus looked upward. In displacement of right kidney there were pain in the stomach and vomiting, but he had never observed this in displacement (or any trouble) of the left kidney. This suggested some possible connection of the right kidney with the pneumogastric nerve. In another case the kidney had descended into the lower right inguinal region and was rotated on its long axis, so that the outer edge looked forward; this was due to a band of adhesion attached opposite the twelfth rib and below to the kidney on its outer inferior border. The ureter was kinked low down. There was a constant pain, of a pulling, dragging character, in the loin. The right loin was depressed and sunken in. There was some atrophy of the kidney and a slight degree of hydronephrosis. Operation: Drained through the loin and fastened the kidney as high up as possible. In this case the speaker observed a phase of the polyuria which was peculiar. When up and about the patient had oliguria; when lying down he had marked polyuria. The case was a neurotic one. The first urine of a series of frequent passings was of fair specific gravity; the later ones were very low in specific gravity. The symptoms of these cases varied in three ways: first, as to intensity; second, in some there were no symptoms referable to the kidney, but all to the stomach; third, the character of the symptoms was variable, but all were due to the same cause.

There was free discussion of the two papers of Dr. Watson and Dr. Bryson taken together, especially of the polyuria and the gastro-intestinal symptoms found in many of the cases, the polyuria in most being referred to some action (unknown as yet) of the nervous system upon the kidney, and also being regarded

as of little value as a diagnostic point of movable kidney.

Dr. Bryson in closing spoke of the claim of some authors, that very flat kidneys were more liable to become loose than others. He had observed one case bearing out this statement. Polyuria is due, 1st, to irritability of the lower part of the urinary tract, causing frequency perhaps more than true polyuria; and 2d, to kidney trouble, which was more likely to be true polyuria. He thought that the constantly repeated swelling (or congestion) and emptying, due to obstruction low down, were perhaps one cause of loosening.

Dr. Watson, in closing, said that he believed that movable kidney was usually if not always only a part of a general enteroptosis of all the abdominal organs. He also suggested further observation as to the crystalline constituents of the urine in cases of movable kidney, especially oxalates, which he thought were always present in greater or less quantity.

Some Observations upon the Surgical Anatomy of the Kidney.—Dr. George E. Brewer, of New York, read a paper with this title. During the last winter the writer had made it a routine practice to make an abdominal examination of all patients upon whom such was allowable, making first a general anterior abdominal examination and then a bimanual examination, one hand behind and the other in front. If no results were obtained the patient was turned face downward on the table, after Professor Guyon's method. A few were examined standing, but with generally poor results, on account of the rigidity of the abdominal muscles in that position. If by any of these methods the kidney could be positively identified, it was classed as a "palpable kidney;" if it could be grasped and moved, but the examiner could not feel the upper border, it was classed as "movable kidney;" if the upper border could be felt and the kidney was freely movable, it was classed as "floating kidney."

To compare the clinical findings with the position of the organ as found in the cadaver, examinations were made on bodies in the dissecting-room, and the highest point of the upper border was found in the majority of cases to be about three inches from the spinal column, and between the eleventh and twelfth ribs. Other anomalies and abnormalities of the anatomy were also observed, as detailed later. Total cases examined, 351, 200 clinical and 151 post mortem. Of the 200 clinical 142 were males, 56 females. Number of displaced kidneys in the 200 clinical cases, 11, or 5.5 per cent. Of these 9 were palpable, 1 movable, 1 floating. In the 142 males but 2 displacements were found, both on the right side, or 1.4 per cent. In the 56 female cases 9 displaced kidneys were found, or 17.3 per cent., all on the right side. Of the 11 patients with movable kidney only 1 complained of symptoms directly attributable to the kidney.

Of the post-mortem examinations 151 were made, 91 males, 56 females. In 4 the sex was not recorded. Number of displaced kidneys, 14, or 9.2 per cent.; 10 in males, 4 in females. Of the 10 in males 6 were on the right side, 4 on the left side. Of the 3 in female 2 were on the right and 1 on the left side; in one case in which sex was not recorded the displaced organ was on the right side. None of these displaced kidneys were freely movable at the time of first examination, a fact probably due to the post-mortem solidification of the perirenal fat. In only 3 cases was there evidence of the kidneys having been freely movable during life. In 6 cases the lower border of the kidney was found within one inch of a transverse line joining the two anterior superior spinous processes of the ilium.

It is thus seen that although the clinical examinations seemed to confirm the generally accepted opinion that movable kidney is more common in women, and in the great majority of cases on the right side, the post-mortem examination facts observed seem to be at variance with this view, as shown in the following table:

Displaced Kidney.	Per Cent in 200 Clinical Cases.	Per Cent. in 151 Post-Mortem Examinations.
Both sexes	5.5	9.2
Males	1.4	10.9
Females	17.3	5.3
On right side	5.5	5.9
On left side	0.0	3.2

This discrepancy may be due to:

1st. That the number of observations is too small for accurate deductions.

2d. The fact that the kidney was fixed in normal position after death by no means proves that it was not movable during life.

3d. That the data from clinical examinations are probably inaccurate.

Attention was also called to some other facts observed during the post-mortem examinations which may be of surgical interest. In one case the left kidney was congenitally absent, the right one being twice as large as normal. Great variations were observed in the distributions of the arteries to the kidney: 85 kidneys received more than a single trunk; of these 70 had 2 from the aorta, 12 had 3, 2 had 4, 1 had 5; in the last case 3 of the 5 were from the aorta, 1 from the ovarian, and 1 from the common iliac. Twenty-eight kidneys received trunks or large branches in locations other than the hilus. Of these 19 received a large trunk at the upper pole, 6 at the lower pole, all of which might easily have been torn off during a nephrectomy. Three received large trunks on the anterior surface, which again might easily be torn during operation. In one instance the spermatic artery was given off from the renal, and in two cases from the aorta above the renal and crossed the renal pedicle near the middle, and might possibly and even probably be included in a ligature of the pedicle.

Many variations and anomalies in the arrangement of the ureters were also observed which might lead to difficulties in diagnosis. For instance, in one subject four ureters were found, two from each kidney. In another subject there were two complete left ureters, one from the upper portion of the kidney being markedly diseased and coming from a diseased pelvis; the other, from the lower part of the kidney, being perfectly healthy. In two other cases the ureters were double above near the kidney, uniting below to form a single trunk.

Results after Nephrectomy for Renal Tuberculosis.—Dr. L. Bolton Bangs, of New York, said he was unable to get many remote results or reports of cases long after operation. He took as his point of reference from which to reckon, Dr. Newman's report in 1888. Opportunites for diagnosis were much better since the introduction of the cystoscope. The immediate results were brilliant, both as to mortality and relief from suffering, and the patients were provided with a promise or a hope of cure. He found one hundred and twelve cases, most of them not published in previous reports. Mortality from operation, nineteen per cent.; mortality of first few months, twenty-eight per cent. These figures agree with Pollet's, making mortality twenty-nine per cent. Thirty-three of these subjects had lived from one to eight years after operation. The "promising" cases were thirty-three in number. Those having no remote record of condition after operation were nineteen in number. The prognosis, if the operation was unilateral and early, was fairly good.

Discussion brought up the question as to the relative value of operation and palliative or hygienic treat-

ment, with the majority of the speakers favoring the latter, excepting when the condition was unbearable from pain, etc., and then operation was advised for the relief of symptoms rather than as an attempt to cure. Also the discussion brought out the difficulty and the importance of excluding other bacilli than the tubercle bacilli from the microscopical examinations of the urine, especially the smegma bacillus, which gave most trouble.

Detection of Kidney Stone.—Dr. Edward Martin, of Philadelphia, did not read his paper, but only gave an abstract from memory, calling attention to a few points of etiology and symptomatology, and showing a number of skiagraphs of kidneys with and without stones in them. Among the etiological factors he spoke of heredity, traumatism, and kidney diseases. Among the symptoms he mentioned pain as a most misleading one; deposits of large quantity of mucus in sterile urine; blood in the urine, less when the patient is quiet, more when active or jolted about, with methæmoglobin rather than oxyhæmoglobin in the urine: tenderness over the kidney, sometimes transferred, pus in urine; renal colic; palpation difficult if not impossible. Positive signs: Passage of calculi; lumbar incision, with examination of kidney direct; Roentgen rays. He had had seven pictures taken by *x*-ray process, and only one was a really good typical picture of a living subject; he had had two good cadaveric pictures. By the *x*-rays all kinds of stone could be detected, but the phosphatic stones best. These pictures were certainly a help, but not conclusive always, as they would not always "take." In one case a stone had been indicated by the picture but none found on operation.

Discussion brought out the fact that small stones were usually the most troublesome, and were just the ones that could not be well located by the skiagraph; they were often located in small diverticula of the pelvis, and often could be found only by most careful digital examination—sometimes not even then. Absolute diagnosis in all cases was as yet impossible, and many operations must still be exploratory.

Scrotal Resection Clamp.—Dr. Bransford Lewis, of St. Louis, showed a new modified scrotal resection clamp, having a screw catch at one end, made so that it could be slipped off at will without unscrewing it; with eyeholes, funnel shaped, through the blades, for the ready passage of sutures before taking off the clamp, and with the inner surfaces of the blades hollowed or gouged out to allow the infiltrating anæsthetizing fluid to penetrate the area through which the needle would pass in introducing the sutures.

Cystin Calculus.—Dr. Paul Thorndyke, of Boston, reported a case of cystin calculus of the bladder. The history covered five years, with attacks of pain, passage of gravel, and occasional stoppage of urine. The stone was crushed and removed. The principal objective sign had been the rapid and easy decomposition of the urine, with evolution of H_2S, and occasional cystin crystals in the urine. The calculus weighed three and one-half grains.

Urethro-Rectal Fistula.—Dr. James P. Tuttle, of New York, read a paper on a new operation for the relief of this condition. Dr. Tuttle spoke of the lack of material in medical literature relating to this subject, and spoke of the many books and of the fact that little definite or conclusive was reported in them; he said that cases of this disease were rare, but had heard of a number of cases besides those here reported. The condition generally originated in the urethra, and the urine escapes into the rectum much more frequently than fæces into the urethra. These fistulæ are either traumatic or pathological; the former usually result from operations, the latter from cancerous growths, ulceration of rectum, simple or syphilitic or tuberculous; extension of anal fistulæ; abscesses. Diseases of the urethra and prostate are the most frequent cause, especially stricture of the urethra with posterior ulceration, and abscesses of the prostate. There are two distinct stages, viz., the acute or suppurating, and the chronic or cicatricial.

Diagnosis: The characteristic symptoms are the passage of urine by the rectum and of gas and fæces by the urethra, and the physical objective signs obtained by examination by finger or instruments. By finger one can locate the opening in the rectum if large, or even if small one can recognize the elevated pouting orifice; by speculum in the rectum one can see the orifice and pass a probe into it, and this can be felt in contact with sound in urethra. Dr. Tuttle gave a table of differential diagnosis between this condition and vesico-rectal fistula.

Treatment: This has been varied and mostly useless. After discussing and dismissing the many other means used, the writer proceeded to outline his own operation. The principles of successful treatment are: 1st. Remove all obstruction to the passage of urine and fæces by their normal outlets. 2d. Protection of the parts from the abnormal passage of urine, of fæces, and of gas, by catheterization of bladder and (best) by forming a temporary artificial anus. 3d. Treatment of the fistulous tract itself. This is to be attempted first by stimulating or caustic agents, and, these failing, by surgical operation. These operations have been many, but few of them successful. The usual one is some modification of Sims' operation for vesico-vaginal fistula. The difficulty is in keeping the wound free from decomposing urine. Fresh urine does no harm, but when it gets into any pocket it lies there and decomposes and then infects the wound. This pocketing is very hard to avoid in these operations, especially if the fistula is a long or deep one.

Ziembecki applied a new principle in destroying the parallelism of the two orifices, rectal and urethral, by dissecting the lower end of the rectum free, and rotating it till the fistulous opening was well off to one side, and suturing it in that position. Usually the urethral side gives way first in the unsuccessful cases, and therefore Dr. Tuttle paid especial attention to preventing that. He incised the rectal sphincter, cut away cicatricial tissue, and freshened the edges of the fistula. He dissected the rectum loose to a point above the opening of the fistula. He then opened the urethra by perineal section, closed the fistula in the floor of urethra by flaps over a sound in the urethra, and left the perineal wound open. He sewed the intestinal wound up and packed, putting a catheter in the urethra and a tube in the rectum. In six weeks the case was discharged cured.

Dr. Tuttle then gave details of twenty-five cases—eight cured by operative, four by palliative measures.

AMERICAN SURGICAL ASSOCIATION.

The Influence of Anæsthesia on the Surgery of the Nineteenth Century.—Dr. John Collins Warren, of Boston, president of the association, read a paper on this subject. It seemed desirable that he should speak on this subject on this occasion, since the semi-centennial of this important discovery had just been celebrated. He then described the methods of operating before the discovery of anæsthesia. No medical man attempted to operate. Little was known about the means of controlling hemorrhage. The introduction of the tourniquet brought about great improvement in this direction. Violent prejudice existed against surgical procedures. He then briefly outlined the history of surgery. In 1774 a closer union was established between medicine and surgery. In 1737 an academy of surgeons was founded. In 1743 bar-

ber surgeons were done away with. Later surgery became a distinct branch. The speaker then outlined briefly the methods of instruction in England and in France. To show the light esteem in which surgery was held he cited the fact that in 1753 Hunter was advised to study medicine rather than surgery. Dr. Warren then described the horrors of surgery without anæsthesia and the torture of the after-treatment. Superficial wounds were strapped together tightly and deep wounds were packed full with oakum. Military surgery has contributed much to the improvement of surgical technique. The asepsis which followed in many cases must be credited to the rapidity of operating, the most rapid operators having less sepsis. Operators were advised to cut quickly in order to avoid pain. Many surgeons used caustics, thus avoiding the use of the knife. The discovery of anæsthesia was a surprise, yet history will show that it had been foreshadowed. In 1839 Velpeau wrote about escaping from pain. Dr. Warren then reviewed at length the history of the discovery of anæsthesia, such as was read by him at the recent celebration in Boston. The crucial test was in the public administration of ether. This was done. The operation was for the removal of a tumor of the jaw, a picture of which was passed around for inspection. Salient truths stand out well in reviewing the history of anæsthesia. In 1846 anæsthesia became recognized. Immediately after its recognition the number of surgical operations greatly increased; in London hospitals the number of operations performed was more than doubted. The notable increase was among the voluntary operations. He then referred to sepsis, which ran riot in 1860 at the Massachusetts General Hospital. Students to-day know nothing of the ravages of sepsis in those days. He then spoke of the great work of Lister. Hunter had aroused great thirst for knowledge through his discovery. Great advances were made; anæsthesia widened the field of research, and when it seemed that surgery was to run on to its destruction through sepsis Lister came to its rescue.

The Indications for and the Technique of Hysterectomy.—Dr. John Homans, of Boston, read a paper with this title. Under indications for hysterectomy he advised operation: 1st. In oft-recurring hemorrhage without discovered fibroid or malignant disease, when all the usual measures have been tried without permanent success. Clinical reasons prevail over histological and practical over theoretical. 2d. In malignant disease, when the operation is possible without permanent injury to the bladder or bowels. 3d. (*a*) In a case of fibroid tumor which causes much discomfort or (*b*) threatens death by hemorrhage. (*c*) Because it may increase and become burdensome. (*d*) Because it may develop a cancerous character. (*e*) Because by its pressure on the abdominal organs it may destroy life. (*f*) Because it may become cystic and thoroughly adherent. He did not mean fibroids with dilated lymph spaces, but fibroids with cysts as clear and distinct as those in ovarian tumors. (*g*) Because it may be an ever-present anxiety. (*h*) Because it may cause œdema of one or of both extremities and phlebitis, to be followed perhaps by the passage of an embolus into the circulation. (*i*) Because it may become twisted with the uterus as a pedicle and must be removed immediately to save life. He had seen this once. (*j*) Because a very sensitive single woman, in good health and active, demands its removal on account of the disfigurement it causes. (*k*) Because the operation to-day in experienced hands is almost uniformly successful. 4th. In cases of complete prolapse, particularly after the menopause, when all the usual measures for holding up the uterus have been tried and found useless. 5th. In cases of incurable chronic inversion. 6th. In cases of infection when the removal of the Fallopian tubes affected with salpingitis has not cured the patient. The French surgeons of the present day have a great deal of right on their side when they claim that the uterus is the infecting organ, and that in many cases there will be no cure till it is removed. 7th. To cure puerperal sepsis when the diagnosis is as certain as it can be.

Under technique of hysterectomy he began by describing the simplest operation for the simplest condition requiring hysterectomy, namely, for intractable uterine hemorrhage without discovered malignant or fibroid disease. In this case the vaginal route is to be followed. A circular incision around the os completely through the mucous membrane is made and also two incisions on either side parallel with the axis of the organ and about one-half inch in length. Next the bladder is peeled off from the uterus along the line of cleavage. An opening is next made with scissors, or with the ends of a pair of forceps, through the peritoneum of the anterior cul-de-sac into the abdomen and a retractor, not too wide lest it draw the ureters into the wound, is passed into the opening to keep the bladder out of the way and prevent the intestines from descending. Next an opening is made with more freedom into the posterior cul-de-sac and is enlarged with the fingers. A piece of gauze with the end hanging out or a gauze sponge with a string of silk attached is inserted between the uterus and rectum. Next the fundus of the uterus is anteverted and pulled down beneath the bladder, and a strong clamp is put on the left broad ligament parallel with the long axis of the uterus. If it is thought best to remove the ovaries it is easier to pull them down before putting on the clamps. The same procedure is gone through with on the right side and the uterus is cut away between the clamps. It is a matter of indifference whether the ovaries and tubes are removed or not. The main thing is to get rid of the bleeding mucous lining of the uterus, and, as curetting has not succeeded, we remove the whole organ.

Dr. Homans then described the technique of abdominal hysterectomy when it has been decided to leave the neck and os. The patient is placed in the Trendelenburg position. The incision is made of the required length and the tumor is delivered at once, if free from adhesions, by means of a cork screw, or by any method of traction which seems most easy. A large piece of gauze is now put in the abdomen over the intestines, and the sides of the incision above the tumor are often fastened together by catch forceps or by a temporary stitch to prevent the intestines from protruding and to keep them clean and warm. When the broad ligaments are seen he ties the left one first, passing the ligature low down and close to the uterus by means of a Cleveland needle, being most careful not to perforate the bladder; he then ties another ligature about an inch away from the first toward the ovaries and beyond the tube, or beyond the ovary and the tube and divides the broad ligament between them. He leaves the broad ligaments as long as possible, so that the seam over the stump when the operation is finished will be a short one. He now goes through the same process on the right side, and then makes a circular incision through the peritoneal covering of the uterus in front about two inches above the outline of the bladder wall, and the same distance above the rectum behind, the two incisions meeting on either side where the broad ligaments are tied, exactly as one would make a circular incision for the amputation of the thigh. These peritoneal flaps are then turned back. The uterine arteries are then looked for and tied, or the uterus is encircled at the denuded point with a small solid rubber cord, and the tumor and uterus are then cut away. The uterine cervical canal is cauterized with Paquelin's cautery, the point being

passed through the mouth of the uterus well into the vagina and being allowed to remain there several seconds. Next the muscular wall of the neck is sewed by a continuous suture of silk over the cervical canal, so as to shut out the neck from the abdominal cavity. The peritoneal flaps are then united by a light continuous suture over the stump. Attention is then turned to the ovarian and round ligament stumps and the ovarian arteries are again tied separately. There is now a sutured line running across the lower part of the pelvis, and if there is no oozing the abdomen is emptied of the pieces of gauze, the patient is lowered, the omentum is pulled down, and the abdominal wound is closed with silkworm-gut sutures without drainage. The rapidity of convalescence is in great contrast to that following the treatment of the pedicle by the clamp, which should be entirely discarded.

The technique of complete hysterectomy, "panhysterectomy," for fibroid tumors, will vary from the above-described operation only in the fact that the os and the neck are separated wholly or in part from the vaginal wall before the abdominal dissection is begun, and at the close of the operation the vaginal walls are sewed together and the peritoneal flaps which have been separated anteriorly and posteriorly from the uterus are lightly united by a suture of very fine silk.

The operation for the cure of puerperal sepsis should as a rule be done by the vaginal route, clamps being used to secure the vessels, as these insure good drainage. Should the diagnosis of general peritonitis be made, the abdominal route should be followed and the peritoneal cavity should be thoroughly washed out and drained.

On the whole the best operations for large fibroids should begin with free separation of the vesical and rectal walls in the vagina, accompanied by ligature of the uterine arteries, to be followed by laparotomy and removal of the tumor through the abdominal wound.

The X-Rays in Surgery.—Dr. J. William White, of Philadelphia, called attention to the fact that foreign bodies in the tissues would often move, so that if a body was located at one point one day, the next day it might be found at some other point. The doctor reported several cases, showing the property of a foreign body to move from place to place. In cavities, foreign bodies were shown and located by angular skiagraphs or triangulation. In the cranial cavity bullets have been located and removed. Localization is very difficult; clinical symptoms and other means of exploration assist greatly. Rubber drainage tubes in the thorax cannot always be located by skiagraphy. By this method blood effusions from bullet wounds in the lower part of the lung have been observed. In the pelvic cavity foreign bodies can be located with satisfaction by taking skiagraphs from various positions.

The speaker then referred to fractures of the skull. He thought we might be able to recognize fractures of the inner table. Fractures of the base may be detected but this is attended with difficulty. Skiagraphs in fractures of the spine had not proven very successful; he had been moderately successful when experimenting on cadavers.

Dr. White laid great stress on the value of getting views from different positions. In making skiagraphs of the ribs, one should first fix the chest by means of bandages. Skiagraphy should prove to be of especial value in fractures which are accompanied by much swelling; in fractures about joints of extremities; in epiphyseal separations where the deformity is slight; in special fractures, as, for instance, those involving the neck of the femur. Ununited fractures can be well shown. Work has been begun in studying the repair in fractures. Callus is translucent, but lime salts are opaque. In the ambulatory treatment of fractures, we may be able to note progress. Skiagraphy is of value in certain diseases of bones, as caries of spine, hip disease, osteoma, intracranial exostosis, multiple fractures of osteomalacia, central abscess of bone, osteosarcoma, etc. An actual differentiation between diseases of bone is not possible at present, but we may be able to distinguish them later. We may also include congenital luxation at the hip, various forms of talipes, Pott's disease with resulting abscess, rheumatoid-arthritis cases, arthritis deformans, periarthritis, floating bodies in the knee-joint, etc. In cavities of the body great service can be rendered by skiagraphy. Pleural effusions, patches of consolidation, cavities in the lungs have all been recognized; also pericardial effusions and intrathoracic aneurisms have been noted. It must be understood that we are merely on the threshold of this new discovery. One should remember that variations in the time of exposure will show different tissues of the body, and so certain tissues can be kept out of the picture by varying the time of exposure. Oxalic-acid calculi are almost impervious to the rays. Stones in the bladder can be clearly seen.

The speaker referred to the therapeutic effect of the *x*-ray. He mentioned a case of inoperable cancer; the rays were passed through, but he had no results to report. He is experimenting with capillary nævi, hairy moles, keloids, etc., and will continue his experiments until he finds them useless.

Dr. W. W. Keen, of Philadelphia, called attention to the medico-legal value of the *x*-ray. He did not advocate the regular use of the rays in fractures and dislocations, on account of their unreliability. He reported a case of an osteotomy done, in which bone was thoroughly broken; the day following the skiagraph showed no fracture, but a perfectly even outline of the bone.

Dr. C. B. Nancrede, of Ann Arbor, Mich., spoke of the practical methods for detecting foreign bodies. One could define a body with the skiagraph when the fluoroscope failed to show it; he did not think we could rely upon the latter. Focussing over ten minutes with a strong current is dangerous, but he thinks this danger can be obviated by the use of some unguent. He demonstrated what could be done with an apparatus costing about $70, in the hands of a person who had but little skill; one need not know much about photography to get good results, if he sent the film away to a photographer to be developed.

Dr. G. R. Fowler, of Brooklyn, discussed briefly the question of apparatus. He thought there was little to choose between a coil and the static machine. The doctor referred to the opportunities for making errors. He mentioned the case of a distinct luxation, in which a transverse skiagraph showed nothing, while the antero-posterior skiagraph showed plainly the deformity. He spoke of a case of detection of a foreign body in the œsophagus, and its easy removal by means of a pair of forceps. Sources of error may be due to defects upon sensitive paper or the plate. One should be on his guard against malpractice suits. He related an interesting case of a lady with a Colles' fracture; she had been to some studio and a shadowgraph taken which showed deformity. She had fallen into the hands of a shyster lawyer, who persuaded her to bring suit. The speaker found he could place her well hand in such a position as to produce a greater deformity than that which was supposed to exist on the side injured.

Dr. M. H. Richardson, of Boston, spoke of the diagnosis of fractures from a medico-legal standpoint. He thought it was incumbent upon physicians to exercise the greatest care, especially in fractures involving the lower extremity and in those about the wrist. Judges in Massachusetts are going to admit skiagraphs. It seemed to him that no matter of greater importance

could be brought up than the position the surgeons are to take in this matter.

Dr. Williams had never seen the slightest harm done by the *x*-rays. He reported a case of cancer of the liver; an *x*-ray examination was made, and the cancer disappeared. He does not know whether the *x*-ray caused its disappearance or not. The doctor showed a platinum tube, over the end of which was to be placed a photograph film. This was to be inserted into the rectum, behind the bladder, and by means of the Crookes tube placed in front of the abdomen a photograph obtained of the bladder contents.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Second Day—Wednesday, May 5th.

Internal Secretions Considered in Their Physiological, Pathological, and Chemical Aspects.—This session of the congress was under the joint charge of the Association of American Physicians, the American Physiological Society, and the American Pædiatric Society.

Dr. William H. Howell, of Baltimore, contributed the first paper. He said that the organs now believed to have internal secretions were the liver, pancreas, pituitary body, and suprarenals, and probably also the ovaries, testicles, and spleen. Brown-Séquard had attributed internal secretions to all tissues, and had expressed the view that all animal tissues ought to be employed as therapeutic remedies in special cases. This was but a revival of a very old medical idea.

The one clearly successful method of treatment by animal tissues is that by the thyroid extracts—a method established quite independently of the generalization of Brown-Séquard. Not only the thyroid but the accessory thyroids had been shown beyond a reasonable doubt to have important internal secretions, and the complete removal of this tissue in man is followed by serious disturbances of nutrition that are immediately or ultimately fatal. One hypothesis supposes that this secretion is antitoxic; another assumes that the secretion of the thyroid acts normally by promoting or regulating the ordinary metabolism of the body. Histologically, the small bodies known as the parathyroids bear no resemblance to the thyroid, and appear to consist of embryonic tissue. Moreover, the two tissues seem to have a different origin. The tendency of recent research is to show that the functional value of the thyroids and the parathyroids is not identical. The removal of only one of the suprarenals does not appear to give rise to notable disturbance, but the complete removal of these bodies causes extreme muscular weakness and feeble heart action, and suggests the symptoms that precede the fatal termination in Addison's disease. It has been found that the extracts of the medulla of the suprarenals when injected into the circulation cause a marked but transient slowing of the heart action and a rise in the blood pressure. This effect disappears on section of the vagi; hence it can be due only to stimulation of the cardio-inhibitory centre in the medulla. Other experiments seem to show that the substance producing this effect is formed normally within the gland. Blood drawn from the suprarenal vein if injected into the circulation of normal animals produces the same effect, although different in degree, as that produced by the injection of the extract of the suprarenals. This is not observed, however, when blood is drawn from other parts of the body and injected into the circulation.

The anterior lobe of the pituitary body evidently has a glandular structure, but the posterior lobe presents the appearance of a very rudimentary organ. Observations bearing on the function of this body have been limited to the anterior lobe. Dr. Howell said that the nature of the connection between acromegaly and disturbances of the function of the pituitary body, if any existed, had not yet been definitely made out. Semonovitch stated that by the injection of extracts of this body he had obtained a slight fall in the blood pressure and quickening of the heart action. The speaker said that recently he had been carrying on new experiments, with extracts made separately from the glandular and the infundibular lobes. The physiological effects of each had been tested by injecting the extract into the circulation of normal dogs. Extracts of the infundibular portion had a distinct and remarkable effect on the heart and blood-vessels, causing a pronounced slowing of the heart, which lasted much longer than that produced by the injection of the extract of the suprarenals. The force of the heart's action is increased and at the same time the blood pressure rises. If the vagi had been previously cut, the slowing of the heart was much less pronounced, the reduction of the heart rate being about fifty per cent. when the vagi were intact, and twenty per cent. when the vagi had been severed. When the animal is etherized, it should be noted, the effect of the injection is the same as though the vagi had been cut. The infundibular lobe is in all probability one possessing some important physiological activity, and its function is probably different, and possibly independent, of the anterior lobe. Injections of the extracts of the anterior lobe were entirely negative.

Prof. Russell H. Chittenden, of New Haven, took up the physiological and chemical aspects of the subject. He said that in its broadest sense internal secretion must be looked upon as something common to all active tissues; but the term "internal secretion" should be limited to those specific products which, being manufactured in certain glands, are plainly endowed with a well-defined physiological action. Experiment, he said, had clearly shown that the functions of the thyroid and of the parathyroids had something in common, for, in animals possessing parathyroids, the thyroid and all but forty per cent. of the parathyroids could be removed without causing the death of the animal. A marked loss of body weight had been noted when the thyroid gland had been fed to obese persons. When administered in the form of extracts to normal individuals, it produced a very noticeable effect on the metabolism of the body, leading not only to loss of body weight but to increased excretion of nitrogen and water, and a decomposition of the tissue proteids. The thyroid gland probably prevents the formation of toxic substances in the body by exerting a direct influence on the general metabolism. From the point of view of the chemist the thyroid gland is specially characterized by the presence of a compound proteid of peculiar constitution. This substance, to which Hutchinson has given the name of "colloid matter," is the active constitutent of the gland. The thyroid gland also contains a small quantity of a nucleo-albumin, together with certain extractives which, however, apparently have no physiological significance. This colloid matter is of special interest, as it contains a compound known as thyro-iodine, and more recently as iodo-thyrin. It resists the action of ordinary decomposing agents, and the gland can be boiled for many hours with dilute sulphuric acid without destroying the active principle. It is a non-proteid cleavage product, characterized by containing both iodine and phosphorus. It seems to be pretty well established that the physiological properties of the thyroid are contained in the iodo-thyrin. So far as is known, iodine is not normally present in other tissues. In human thyroids, as well as the thy-

roids of sheep, oxen, and pigs, iodine is usually present in considerable quantity, often to the extent of ten per cent. As a dose of one milligram of iodothyrin will produce a distinct therapeutic effect on goitre, it is evident that this is not due to the insignificant quantity of iodine contained in this compound. In cases of goitre only minimal and relatively small amounts of iodine are to be found, and iodine is sometimes absent in the thyroids of children. Regarding the adrenals, the speaker said that there was some evidence of the existence of two distinct physiologically active substances in these bodies.

Dr. J. George Adami, of Montreal, said that in attempting to discuss the pathological aspects of the general subject of internal secretion, the pathologist found himself in a very difficult and disheartening position, owing to the rarity with which he was able to draw conclusions from the post-mortem findings regarding the functional activity of organs during life. He considered the subject under three main heads, viz., 1, glandular inadequacy; 2, glandular overactivity; and 3, compensation. Glandular inadequacy, he said, might be due to excess of substance acted on by internal secretion of the gland, without due compensation. In the second instance there might be an excess of internal secretion, without due compensation; and in the third class there might be lesions of the gland or an altered systemic condition, unaccompanied by symptoms. In the first two divisions there were changes accompanied by symptoms of disease, but this was not true of the third class. When morbid changes were found in the pancreas in cases of diabetes, there were usually atrophy and destruction of the gland, yet there were many cases of diabetes without such changes in the pancreas. In another class of cases there was advanced atrophy of the pancreas without the occurrence of diabetes. Addison's disease might be associated with disease of the suprarenals, or with intact suprarenals, or again there might be complete or nearly complete destruction of the suprarenals without symptoms of Addison's disease.

Dr. Francis P. Kinnicutt, of New York, discussed the clinical side of the subject. He said that the number of cases of myxœdema treated with thyroid preparations was already very great. Although the myxœdematous symptoms were speedily removed by this treatment, the discontinuance of the remedy caused a return of the original symptoms after a greater or less time. It had been shown conclusively: 1, that complete recovery could be effected even after the disease had existed as long as fourteen years, and was of a very severe type; 2, that the maintenance of health could be secured only by continuous treatment during the lifetime of the patient. Equally good results were obtained from a single daily dose, or a larger dose at longer intervals, rarely, however, exceeding a week. As regards sporadic cretinism, it had been shown conclusively that the myxœdematous symptoms could be speedily removed; that the treatment was capable of developing the natural tendencies of the growth of the skeleton; and that striking improvement in the mental condition might be effected, although more slowly than the changes in the skeleton. The effect of the treatment on the growth of the skeleton and on the mentality was in an inverse ratio to the age of the patient. In young persons the growth might amount to an increase of stature of upward of a foot in the first three years of treatment. If the treatment were initiated early and systematically continued, it held out every promise that the cretin child would develop into a healthy adult. In the treatment of goitre the maximum of improvement would be obtained in goitre of the simple hyperplastic form. Large cysts were apparently unaffected by this treatment. Complete disappearance of the goitre was rarely noted. Bruns had reported sixty cases, in which fourteen subjects were cured, twenty-nine were improved, and seventeen were not benefited. Although occasional claims had been put forward in favor of this treatment in cases of exophthalmic goitre, one would not expect, from *a priori* considerations, that these cases would be improved, but rather that the condition would be aggravated. The use of the thyroid preparations in insanity had been based on their undoubted and profound influence on metabolism. The treatment had been advocated in various mental disorders, and Dr. M. Allen Starr spoke very highly of its value in a form of mental disturbance described by him as a mental depression, with anxiety and morbid fears, occurring at the climacteric. This line of treatment is, however, still in the experimental stage. In general, Dr. Kinnicutt said the treatment of obesity by thyroid preparations had been favorable, but disappointments were met with from time to time. The loss of weight is more rapid during the first few days of the treatment, and is quite considerable even without any restriction of the diet. It does not unfavorably affect the general health, but very soon after the treatment is discontinued the obesity returns. The thyroid preparations had been advocated in phthisis, and he had given this method of treatment a careful trial in his hospital wards, but without observing any effect from it. The employment of preparations of the adrenals had been recommended in Addison's disease. Of forty-eight subjects so treated, six were reported as well, twenty-two as improved, and eighteen unimproved. In two cases the symptoms were aggravated. Owing to lack of time, Dr. Kinnicutt was unable fully to consider the other organs known to possess important internal secretions.

Dr. James J. Putnam, of Boston, continued the discussion. He dwelt upon the relation of infantilism to myxœdema. He said that out of one hundred and thirty cases of acromegaly collected by Sternberg, thirty per cent. showed giant growth, and many of the latter had myxœdema. These and kindred affections were essentially toxic in origin, due to the loss or perversion of the function of certain glands, such as the pituitary body, the thyroid, adrenals, testes, etc.

Dr. William Osler, of Baltimore, occupied the remainder of the session in showing lantern views in illustration of the very remarkable results obtained from the use of the thyroid preparations in the treatment of cretinism.

President's Address.—In the evening the president of the congress, Dr. William H. Welch, of Baltimore, delivered the address, taking for his theme "The Adaptation of Pathological Processes." He said that the conferring upon him of the honor of being president of this congress he took as a recognition of the progress made in certain branches not directly connected with the practice of medicine. The term "self-regulation" was probably better than "adaptation," as descriptive of some of these processes. His purpose was not to point out the beauties or extent of adaptations in pathological processes, but rather to speak of the general mechanism of their production and the proper attitude of mind regarding them. The most wonderful and characteristic attribute of living organisms is the adaptation to external and internal conditions in such a way as tends to the welfare of the individual or the species. Marked examples of this are to be found in the preservation of the normal temperature of animals amid great variations in the surroundings; the adaptation of the heart to the varying demands made upon it; and the adjustment of the iris to varying illumination.

The mechanical theory of the purposefulness observed in nature, the speaker said, was the only one

that could be recognized in science. The explanation of the physiological adaptations furnished by the doctrines of organic evolution helps us to study pathological adaptations. Most of our precise knowledge of these subjects has been obtained during the present century through clinical observations and pathological and biological studies. In the domain of infectious diseases, wonderful and hitherto undreamed of agents of disease have been brought to light. One of the most important characteristics of pathological adaptations is that most of them have their foundation in physiological processes or mechanisms. In physiological adaptation the cells respond to changed conditions, to meet which they are especially fitted by innate properties, determined in part by natural selection and other evolutionary factors. No other weapons than these same cells does the body possess against injuries and dangers from without, but these weapons were not forged with any special reference to their adaptation to these emergencies. A heart, hypertrophied in consequence of valvular lesion, does not completely restore the normal balance of the circulation. If we look upon inflammation as an attempt to repair injury, and, therefore, as an adaptive process, with what imperfections and failures and disorders is it often associated? A new growth of bone to fill in defects is often highly beneficial, but what grave consequences may result from thickening of the skull and partial arrest of development in embryonic life? We see, therefore, that nature is neither kind nor cruel, but simply obedient to law, and therefore consistent.

The compensatory hypertrophies afford admirable illustration of certain fundamental principles regarding adaptations in pathology. They often afford an adjustment, highly beneficial, in certain morbid conditions. Given the changed conditions on the one hand, and the organization of the cells on the other, the result must follow as surely as night follows day, and this final result influences the preceding series of events no more in the one case than in the other. Our knowledge of the manner of production of the compensatory hypertrophies of the various organs and tissues stands in direct relation to our knowledge of the physiology of the same organs and tissues. The relationship between increased functional activity and hypertrophy is so evident in many cases that there is strong presumption in favor of this explanation for those glandular compensatory hypertrophies which have not as yet been clearly referred to the class of functional hypertrophies.

In order to a better understanding of the principles involved, the speaker selected compensatory hypertrophy of the heart as a concrete example. The heart, like other organs of the body, does not work ordinarily up to its fullest capacity; it is capable of doing three or four times its usual work. Its capacity to do this extra work is called its "reserve force." It has been proved experimentally that this is sufficient to enable the heart to compensate at once for a high degree of insufficiency at its orifices. But this cannot be done long without causing fatigue, even in an accommodating organ like the heart. If it is to continue this extra work long, it must receive new increments of energy. The various morbid conditions leading to cardiac hypertrophy are such as increase the volume of the blood to be propelled at each stroke, or to increase the resistance in the circulation, or both. The physiologists have given some insight into the mechanisms by which the heart responds to increased work in these circulatory disturbances. These disturbances increase the tension of the cardiac muscle in much the same way that a weight augments the tension on a voluntary muscle. It is a physiological law that within certain limits greater tension on a muscle excites to greater contraction and to increased work. We do not know exactly how increased tension facilitates greater expenditure of energy. With increased muscular tension, under a given stimulus, a point is reached where the contraction is diminished, although the actual work done is increased. Under such circumstances the heart fails to empty its chambers as thoroughly as formerly, and the result is dilatation. We thus see that dilatation often precedes the compensation. This dilatation lessens the strain on each muscular fibre, and thus enables it to shorten more with each contraction. The evidence seems to favor the view that the power of the heart to adapt itself to the work required resides in the muscle cells and not in the intrinsic nervous mechanism.

Inasmuch as greater functional activity is associated with an increased supply of blood to the part, the argument is often put forward that it is because of this hyperæmia that functional activity and growth are increased. Physiological investigation, however, seems to indicate that the cell regulates its own metabolism. Functional activity has a marked influence on increasing the quantity and affecting the quality of lymph in the active part. It is now believed that the formation of lymph is due, not simply to filtration from the blood plasma, but to diffusion and active secretion from the blood. Any satisfactory explanation of cell growth causing work hypertrophy, Dr. Welch said, must start in physical or chemical changes in the muscle or gland cell itself directly connected with the increase of function. It should be noted that some kinds of excessive work do not lead to hypertrophy. Thus the heart might beat more rapidly than normal for years without giving rise to hypertrophy. The compensatory hypertrophy of muscle seems to be due chiefly to the size of the cells, although they may in some instances undergo multiplication. Clinical experience shows that the energy available for unusual demands, that is the reserve force, is less in the hypertrophied than in the normal heart; hence, the greater liability of the hypertrophied heart to fatigue. Such fatigue is apt to give rise to relative insufficiency of the mitral or tricuspid valve.

Turning next to the consideration of adaptation as exemplified in the circulatory system, the speaker called attention to the wonderful precision with which the blood-vessels adjust themselves to changing velocities and volumes of blood. The changes in the circulation induced by the falling out of the placental system at birth, he said, were essentially identical with those resulting from the amputation of an extremity. The mechanisms by which the adjustments are secured, have, in consequence of their physiological uses, a special fitness to meet certain pathological conditions. But these mechanisms are not equally well adapted to meet all morbid conditions. The rapidity with which a collateral circulation may be established after the ligation of a large artery is known to every surgeon. This was formerly attributed to increase of pressure above the ligature, but this rise of pressure has been shown to be too small to account for the change. The changes in the walls in the anastomosing vessels seemed to the speaker best explained by the changes associated with work hypertrophy.

He then raised the question as to how far we were justified in regarding acute inflammation as an adaptive or a protective morbid process. He said that the answer depends much upon one's point of view. The more severe the inflammation the greater, as a rule, is the danger to the patient. The clinician is not likely to see any beneficial results from inflammation, but the pathologist and bacteriologist looks at the process from a different standpoint, and sees in it a protective process by which invading micro-organisms may be prevented from entering the system.

In closing, Dr. Welch said that he had arrived at

the conclusion that the healing power of nature is often incomplete and imperfect, and that systems of treatment, based upon the belief that nature is doing the best possible in disease, rest often on an insecure foundation.

AMERICAN ORTHOPÆDIC ASSOCIATION.

Wednesday, May 5th—Second Day.

Some Effects upon the Leg of Pronation of the Foot.—Dr. John Dane, of Boston, stated that during the past few years a large amount of attention had been given to the foot and the changes which it undergoes when subjected to weight, but in the present paper he desired to offer a few facts concerning the behavior of the leg caused by the changes in shape and position of the foot which have been referred to as excessive pronation. The leg has been regarded hitherto as the fixed point, and, while this might be true when the foot was hanging freely in the air, it ceased to be when the foot was placed upon the ground. This was first brought to his attention by a series of photographs taken with double exposures upon the same plate, while he was preparing a joint paper with Dr. Lovett. These showed that while the foot and toes remained stationary there was considerable change in the outline of the leg when weight was brought to bear on the foot. He had recently made further experiments in this direction, both upon normal feet and upon those which were pronated, and the conclusions reached were as follows:

1. In "pronation of the foot" the greater part of the foot remains stationary and the leg rotates upon it.

2. While in the normal foot, when weight is brought to bear upon it, the malleoli move inward and slightly downward, the normal outward rotation of the tibia and fibula is replaced by an exaggerated rotation inward, which takes place about a nearly vertical axis located near the inner border of the tibia.

3. These changes acting together produce an alteration in the obliquity of the axis of flexion of the ankle-joints sufficient to destroy the mechanism by which the normal joints are enabled to support the body weight with a minimum of muscular exertion. As a consequence flexion must be prevented and equilibrium maintained wholly by muscular force, which soon leads to irritation and fatigue of all the muscles of the leg, and especially of the peroneus longus.

4. The inversed rotation of the tibia interferes to a great extent with the operation of the mechanism by which complete extension of the knee should lock the joint and render it proof against the constant tendency of the body weight to flex it. The knee must therefore in subjects with pronated feet be kept in extension by a constant effort of muscular force, which results in fatigue and tendency to tonic spasm of the thigh muscles.

5. Owing to the constant attempt of the muscles on the outer side of the thigh to prevent the internal rotation of the lower part of the leg, they are commonly found to be tense and sensitive to pressure.

6. To compensate for this inversed rotation of the tibia and fibula there is an exaggerated inward rotation of the femur. This in turn overstretches the external rotators of the hip, causing sensitiveness and tonic spasm of the glutei and tenderness over the points of exit of the sacral nerves.

7. This explanation is wholly in accord with the clinical fact that, when by means of efficient mechanical support pronation of the foot is prevented, the pains in the calf, knee, and hip are relieved.

Dr. Lovett considered that the work done by Dr. Dane was a decided advance over the old methods, and that in the consideration of flat foot the time had come for accurate measurements. All were familiar with the backache, pains in the thighs and calf, etc., which accompany flat foot, but no rational explanation had been offered before. It was important to recognize the difference between a pronated foot and a broken-down foot. He had been interested in noticing the effect upon the back of change in the position of the feet. The change from an angle of 90° to a straight position produced considerable lordosis. Also when the feet were parallel the weight fell principally upon the third metatarsal bone, but at an angle of 90° the weight moved inward upon the first metatarsal. This was important in regard to the base position of the feet in gymnastics, which has always been with the feet at 90°. Dr. Lovett also called attention to the frequency of pronated feet in beginning lateral curvature.

Dr. Shaffer thought the paper threw light on some points, but it told how the conditions described arose but not why, *i.e.*, what was it that threw the normal mechanism out of gear. In his opinion a shortened gastrocnemius muscle was responsible for the vast majority of pronated feet, and he thought such a faulty muscular mechanism of the foot could produce the conditions described by Dr. Dane.

Congenital Dislocation of the Shoulder-Joint.—Dr. Charles L. Scudder, of Boston, reported two cases of so-called dislocation of the shoulder, one in a girl one year and three months old, and the other in a girl three years old. With both the labor was normal. In the first case during the first week it was noticed that the baby's right arm and hand were swollen. In both the position of the arm was characteristic, rotated inward, the internal condyle looking backward, and the head of the humerus felt in the infraspinatus fossa. In the first case there was no change in the bones or muscles of the upper extremity, while in the second there were considerable shortening and atrophy, and in this case no injury had ever been noticed. He was inclined to consider this a true congenital dislocation or misplacement and the other a traumatic dislocation at the time of birth, and thought a distinction should be drawn between the two, as the pathology was probably different.

A Case of Asymmetrical Development.—Dr. H. R. Shands, of Washington, presented a remarkable case of asymmetrical development in a boy, twelve years of age, an inmate of an orphan asylum. When he was two years of age it was noticed that the right side of his body seemed to be growing faster than the left and the unequal growth had continued to the present time. He called attention to the atrophied condition of the left side, even including the face, and the greatly increased right side, the boggy feel of the soft tissues, and the purple markings of the skin, which were also present to some extent upon the left side. The measurements showed the great difference in size:

	Right.	Left.
Ankle	10	
Calf	15	9
Thigh	18½	13
Forearm	8	7½
Arm	8	8
Ball of hand	8	7¼
Little finger	2¼	1½
Length of limb	28½	24
Length of foot	9½	7½

A peculiar feature of the case was the fact that the left thumb measured three and a half inches in circumference and the right only three, and that one of the toes on the left foot was larger than the corresponding foot. The right testicle had not descended. The boy had average intelligence and was a general favorite.

The members of the Pædiatric Association were asked to come in to see this interesting case, and Dr. Adler made some remarks upon it. He said that

this was the fourth case of the kind he had seen, one of which involved the lower extremities only, and he thought they were rare. No satisfactory explanation of their etiology had been given. The two conditions with which they might be confounded were acromegaly and elephantiasis, but acromegaly always affected both sides. In this case he was struck with the fact that the left thumb and one of the toes were larger than the right, and thought that it was possible the boy might develop acromegaly later. In elephantiasis only the soft parts were involved, while here undoubtedly the bones were enlarged. These cases always presented enormously enlarged blood-vessels, even the capillaries, but he thought it was rare to have the capillaries of the skin so much dilated as in this case.

Gluteal Bursitis.—Dr. E. G. Brackett reported seven cases of inflammation of the bursa under the glutei muscles. He stated that the bursa inflamed is one of those situated under the gluteus maximus and the clinical symptoms are early and persistent limp, without remissions as in hip disease; pain referred to the back of the thigh and under the knee; limitation of motion in extreme flexion, and rotation outward and flexion of the extended leg. In the severer cases slight permanent flexion may be present. There is swelling in the upper part of the buttock, which in a well-marked case has definite outlines that can be made out by palpation. The course is rather slow and the cases are of special interest because the hip-joint may become infected by extension of the disease. Two of the cases reported were not operated upon, but were treated by the expectant plan. In all of the others the plan of operation was an incision along the edge of the gluteus maximus, thorough opening and curetting of the sac, and packing of the wound, allowing it to heal by granulation. All healed kindly. In two tuberculous disease developed elsewhere within a year. In two the contents of the sac were examined and reported to be tuberculous in character.

Mechanical Treatment of Ununited Fracture of the Neck of the Femur.—Dr. Newton M. Shaffer, of New York, reported three cases, one in which treatment was begun three months after the original injury, one eighteen months after, and the third eight months after. The first and third were completely successful, and the second a failure, which he thought was due to the fact that so long a time had elapsed before treatment was begun and that the treatment was not kept up continuously and for a sufficiently long period. The method employed was traction by the long hip splint, supplemented by a surcingle around the pelvis and direct pressure over the trochanter by means of a tourniquet. The limb was kept adducted about 20° and elevated to an angle of 160°, while the patients were kept in bed for several weeks and then they were allowed to walk and stand with the aid of crutches and a high shoe on the sound limb. He urged a persistent trial of this method in cases of ununited fracture, and thought that in the majority of cases success would be obtained.

Dr. Ridlon reported four successful cases of recent fracture of the neck of the femur in old people by means of the Thomas hip splint with fixed traction, and thought that this apparatus met the indications for this treatment of this fracture better than anything which had been devised.

(To be Continued.)

The Appendix.—There are certainly some cases, not few in number, in which the appendix is so deeply embedded in the wall of the abscess, or so difficult to define at all, that to insist upon its discovery and complete removal would be to incur quite unjustifiable risk.—McBurney.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

WORK OF THE COLLEGE LABORATORIES—HERNIA CEREBRI—NON-TUBERCULOUS POSTERIOR BASIC MENINGITIS IN INFANTS—MR. LAWSON TAIT—THE LATE LEOPOLD HUDSON, J. B. BAILEY, AND GORE RING—SIR CHRISTOPHER NIXON.

London, April 23, 1897.

A report of the laboratories committee of the royal colleges shows that since December 4th over 3,000 doses of antitoxin serum of 4,000 units each, 125 doses of 1,500 units, and 499 of 1,000 each were supplied for diphtheria in the hospitals of the asylums board. Other demands have been fully met. Researches in connection with the Goldsmith's grant have been continued. These have led to the production of a serum of eight hundred units per cubic centimetre—the strongest ever prepared, surpassing even Behring's, which is only six hundred. This strong serum is the one employed by Dr. Sidney Martin at University College Hospital, and you will remember with what important results. The report promises various improvements from researches which are not yet completed.

At the last meeting of the Royal Medical and Chirurgical Society, Mr. Lawford Knaggs read a paper on a case of "Compound Depressed Fracture of the Skull, Followed by Cerebral Abscess and Hernia Cerebri," in connection with which he took into consideration the subject of hernia cerebri based on one hundred collected cases. His patient was operated on for compound depressed fracture of the left parietal bone on September 11, 1894, and though the membranes and brain were injured and the wound subsequently suppurated, healing took place and the man became an out-patient on November 28th. He was readmitted in February, with some cerebral symptoms and a protrusion of the soft parts over the bony aperture. On February 4th he was unexpectedly found at the point of death, and the swelling was explored and then opened with a penknife by the resident surgical officer. An ounce of pus was evacuated from a cerebral abscess, and the patient brought round by artificial respiration. Hernia cerebri and paresis of the right arm and leg at once developed. The former grew as large as a hen's egg in a fortnight, remained stationary for three weeks, and then shrank, and by July 7th had disappeared. He left the hospital on August 3d well, except for some remaining weakness of the forearm muscles and a hesitation in his speech; and a year later his condition remained unaltered, except that he had a fit every eight weeks. He was working as a laborer. The intracranial conditions which produce hernia cerebri were described, viz.: (1) Increased tension; (2) a softened or diffluent state of a portion of the cerebral substance; and (3) inflammation of the brain substance, which leads to an increase in bulk, to its softening, and when prolonged to its replacement by granulation tissue, and finally by cicatrix. The inflammation also impairs, suspends, or even destroys the functions of the centres implicated. The duration and size of the hernia are influenced by the extent of the inflammation. The causes are traumatism and sepsis, either separate or combined. If sepsis be avoided the inflammatory effusion is gradually absorbed and the protrusion will certainly dwindle and disappear after it has reached its maximum. The time required varies from a few days to several months, and depends on the amount of brain involved and the absence or presence of continued irritation. The results of septic infection are abscess, meningi-

tis, and diffuse inflammation, and abscess is the only one that is not always fatal. Hemorrhage and abscess may be associated with hernia cerebri, and attention was drawn to the importance of gravity in certain cases and to the sudden but transient enlargement of the tumor, which may result from trivial causes, either local or general, such as probing the wound or an attack of tonsillitis. The prognosis was stated to be good if sepsis were avoided, and it was to be borne in mind that septic infection might be a result not only of the original injury but of subsequent interference, operative or other. Treatment should be: 1. Preventive; every case of compound depressed fracture of the skull should be thoroughly treated, and the wound made aseptic. This is now generally done, and probably accounts for the rarity of the cases in current literature. 2. Non-interference should be the rule, and the tumor allowed to run its own course. 3. Operation may be necessary when abscess is present, and should aim at evacuation, not mutilation. It may be necessary to remove embedded fragments after their position has been demonstrated by skiagraphy, but it was difficult to imagine a condition in which excision could be justified.

Mr. Ballance attributed the rarity of hernia cerebri at the present time to the successful avoidance of sepsis. Provided that there was an aseptic condition, as in surgical operations, extensive injury might be done to the brain without hernia cerebri. After an accident it might be impossible to obtain an aseptic condition of the parts. He found it difficult to believe that the hernia might push through the uninjured dura mater. The cases ought certainly to be carefully treated at the onset, and he was in hopes that the surgeon might be able to deal with and render aseptic compound fractures of the base as well as those of the vault.

Dr. J. Walter Carr afterward read a paper on "Non-tuberculous Posterior Basic Meningitis in Infants." The object of the paper was to show that there was a distinct form of meningitis, occurring almost exclusively in infants, which has not at present received adequate recognition, though described by Dr. Gee and Dr. Barlow in the St. Bartholomew's Hospital Reports for 1878, under the title of "The Cervical Opisthotonos of Infants;" that it mainly affects the posterior part of the base of the brain, is entirely independent of tuberculous disease, runs a subacute or chronic course with fairly characteristic symptoms by which it can be diagnosed during life, and presents very constant and definite post-mortem appearances, although its actual causation remains at present unknown. Eleven cases observed by Dr. Carr were narrated in detail, and compared with those recorded by Dr. Gee and Dr. Barlow. The cases all terminated fatally, none in less than five weeks, while some patients lived for three months or even longer. At the necropsies (ten in number) inflammation of the pia-arachnoid was found over a very definite area at the base of the brain, hydrocephalus in all the cases, and in some closure of the openings between the fourth ventricle and the subarachnoid space. In no instance was any sign of tuberculous disease discovered, either in the cranial cavity or elsewhere. The possible causation of the ventricular effusion was considered in the paper, discussion on which was adjourned.

Mr. Lawson Tait has had to submit himself to the knife of a surgical confrère. While stooping over a patient he was suddenly attacked with acute pain about the neck of the bladder, which was followed by symptoms of impacted stone. A perineal incision was made and the calculus removed. As Mr. Tait had renal colic last year, it is probable that the stone descended from the kidney at that time. It will gratify your readers to hear he is rapidly recovering.

Mr. Leopold Hudson died lately, in his thirty-fifth year. After a distinguished curriculum and serving various offices, he attained a position on the surgical staff of his hospital (the Middlesex) and of the Children's Hospital. In the early part of last winter's session he was attacked with paraplegia, and last month cerebral hemorrhage occurred. He was a man of great ability and devotion to his work, a genial companion. He will be missed by both colleagues and students, who all regarded him with admiration and affection.

Mr. James B. Bailey, the librarian of the Royal College of Surgeons, died lately. He was much esteemed by those who frequent this important library, for his cordiality and readiness at all times to place at their disposal his profound knowledge of medical bibliography. Before taking his last office Mr. Bailey was librarian at the Medical and Chirurgical Society, and previous to then at the Radcliffe Library, Oxford. The decease of this accomplished medical librarian, at the early age of forty-eight, is a loss to the profession.

Dr. Gore Ring, of Keswick, died suddenly in church on Sunday morning, just as the service had begun.

Sir C. Nixon, the eminent Dublin physician, had a narrow escape last week. While speaking to his coachman in the coachhouse, the ground under him suddenly gave way, and he was saved from a fall into an old well some thirty feet deep only by seizing the wheel of a vehicle close by, when he was helped out of the chasm by the coachman.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 8, 1897:

	Cases.	Deaths.
Tuberculosis	215	101
Typhoid fever	5	2
Scarlet fever	232	7
Cerebro-spinal meningitis	3	5
Measles	350	7
Diphtheria	285	50
Laryngeal diphtheria (croup)	9	0
Small-pox	3	2
Chicken-pox	31	0

Chancres to Burn.—Multiple chancres are not uncommon, but Petrini's case of an Italian who had six upon the face shows an *embarras de richesse* hitherto not recorded.

He Ought to Know.—The new house surgeon, having examined the injured man, said to his wife: "I fear your poor husband is dead." "No, I ain't," said the supposed corpse. "Hush, John, be quiet," said the wife; "the gentleman must know better than you what's the matter with you."—*St. Thomas' Hospital Gazette.*

Adherent Pericardium in Children.—Of the physical signs often found, Dr. G. M. Swift says (*Archives of Pediatrics*) the following are important: 1. Marked enlargement of the heart is present in many cases, accompanied by various murmurs. 2. Systolic depression at site of apex beat. 3. Systolic retraction of lateral and posterior walls of thorax. 4. Impeded descent of diaphragm in inspiration. 5. Dilatation of the veins of the neck, with sudden emptying in diastole. 6. Absence or feebleness of apex beat.

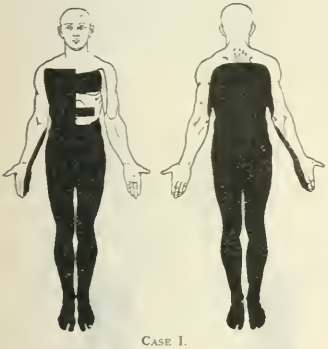
SENSORY DISTURBANCES IN LOCOMOTOR ATAXIA. A STUDY OF THE LOCALIZATION OF ANÆSTHETIC AREAS AS AN EARLY SYMPTOM.

By ALLAN BLAIR BONAR, A.B., M.D.,

NEW YORK CITY,

ASSISTANT IN NEUROLOGY IN THE VANDERBILT CLINIC; RESIDENT PHYSICIAN TO THE INCURABLE HOSPITAL, BLACKWELL'S ISLAND.

All symptoms are of value in spinal-cord diseases, and especially is this true in tabes because of its insidious onset. Areas of sensory disturbance in tabes constitute a new symptom which is not usually noticed by the patient. It has been known for some time that sensory disturbances were present in the later stages of the disease, but only lately has it been shown that areas of anæsthesia are an early and frequent symptom of locomotor ataxia. Attention has been called to these areas and their early appearance by Laehr[1] and Patrick.[2]



Case I.

Complete anæsthesia to touch. Complete anæsthesia to heat and cold in lower extremities. Impaired sensibility to heat and cold in trunk. Anæsthesia to pain all over the four extremities and trunk up to the level of the clavicles.

Out of twenty-one cases of locomotor ataxia which I have had under my care and observation in the Incurable Hospital during the last year, I find that eighteen have sensory disturbances of various kinds and degrees. The areas vary greatly in shape, size, and location.

I have examined these cases again and again, and find that the anæsthetic areas change, generally in a progressive manner, showing a greater involvement of the sensory nerves as the disease progresses. In examining a patient I have used a camel's hair brush for ascertaining tactile sensibility, a pin for pain perception, and hot and cold test tubes for sensibility to heat and cold. I have marked the areas of sensory disturbance as found upon the skin of each patient, and carefully mapped them out on the accompanying diagrams.

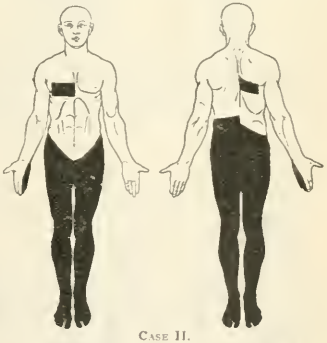
Trunk anæsthesia is absent in only two of the seventeen cases which have sensory disturbances. Tactile anæsthesia is present on the trunk to a greater or less degree in all the other cases, and is sometimes accompanied by loss of pain perception, and in a few cases by a loss or impairment of heat and cold sensibility also.

This trunk anæsthesia may be present on both the chest and the back. It may involve both sides of the chest or of the back, or only one side of each. It may also involve only one side of either the chest or the back. When only one side of the chest is affected, there is generally a corresponding area of anæsthesia on the same side of the back, but in Case VIII. there is only the small area on the left chest.

The anæsthesia on the back is always at about the same level as that on the chest. When unilateral it is sharply limited to the median line. Laehr has noted that when the trunk anæsthesia has reached the third rib it extends down the inner surface of the upper arm in a tongue-shaped area. This obtains in all except two of my cases which have trunk anæsthesia.

It will be seen from the diagrams that the anæsthesia may be broader on one side of the body than on the other, and that the superior boundary of the anæsthetic area of one side is higher than that of the other in eight of the nine cases which have anæsthesia on both sides of the chest. Laehr says that the upper borders of the anæsthesia on the two sides of the chest are nearly always on a level and that the anæsthesia extends downward.

When I first examined Case IV. the trunk anæsthesia extended on both sides from the level of the third rib downward to the umbilicus. Now the anæsthesia extends from the clavicles downward, joining that on the lower extremities, thus having extended both upward and downward. In most of the other cases the extension has, however, been downward. In some of the cases there are two distinct and separate bands, or commencing bands, on the same side of the chest or back, which condition would seem to indicate that different parts of the cord may be invaded at the same time.



Case II.

Complete anæsthesia to touch. Over the front of the legs heat and cold sensibility is impaired. Ulnar side of right hand, paræsthesia and tactile anæsthesia.

In the arms anæsthesia appears first over the ulnar distribution; in the legs it usually starts in the feet and ascends. In the lower extremities the areas of anæsthesia vary greatly from time to time, usually in a progressive manner. They vary more than the areas on the trunk. In several cases, when I first examined I found anæsthesia over the foot and lower half of the leg, like a sock, with a band of delayed or impaired sensibility just above it. In succeeding examinations this anæsthesia has ascended until, as shown

[1] Archiv für Psych., xxvii., p. 688. "Ueber Sensibilitätsstörungen bei Tabes dorsalis und ihre Localisation."

[2] New York Medical Journal, February 6, 1897.

in the diagrams, it has involved the whole of the lower extremities.

These areas of anæsthesia also change in size with the weather. In rainy or cold and damp weather the areas are larger than on pleasant and warm days.

In examining these cases again and again I have been interested in the changes found in regard to the size and location of the anæsthetic areas. One would naturally expect to find an anæsthetic area increase in size with the progress of the disease, but in several of the cases these areas have decreased in size or perhaps entirely disappeared. More often, however, a hyperæsthesia has become an anæsthesia, or the area of anæsthesia has become larger. The diagrams here pre-

CASE III.

Anæsthesia to touch. Anæsthesia to pain all over the body. Anæsthesia to heat and cold, in front, over lower two-thirds of legs and feet, and over the penis and scrotum; behind, over thighs, from just below the buttocks downward, over the legs and soles of the feet. Heat and cold sensibility very much impaired and uncertain over all the rest of the body, heat more so than cold.

CASE IV.

Anæsthesia to touch and pain. Perception of heat and cold delayed. Numbness all over trunk and legs.

CASE V.

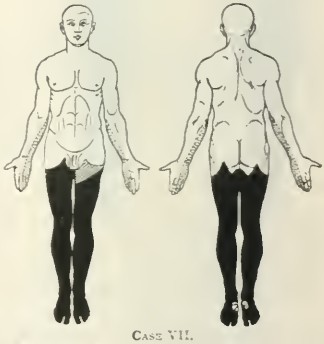
Anæsthesia to pain and touch. Pain sensibility is normal over scrotum, but lost on penis. Anæsthesia to heat and cold all over legs, below knees, and on penis and scrotum. Sensibility to heat and cold impaired over thighs in areas in which there is tactile and pain anæsthesia; heat perception is less than cold.

CASE VI.

Anæsthesia to touch. Sensibility to pain, heat, and cold is normal.

CASE VIII.

Loss of tactile sensibility.



CASE VII.

Anæsthesia to touch, pain, heat, and cold.
Anæsthesia to heat and cold only.
Impaired sensibility to touch and pain.

CASE X.

Anæsthesia to touch. Anæsthesia to pain on anterior surface of left leg. Anæsthesia to pain over all of anterior surface of right lower extremity and over the posterior surface of both legs below the knees. Anæsthesia to heat and cold over the posterior surface of both lower extremities from the sacral region downward, and over the anterior surfaces of both legs below the knees

CASE XI.

Amputation.
Tactile anæsthesia. Pain anæsthesia also over buttock and ulnar side of right hand.
Anæsthesia to pain.
Anæsthesia to heat and cold over left leg below knee (anterior and posterior surfaces).

CASE XIII.

Tactile anæsthesia.
Anæsthesia to pain and touch. Perception of heat and cold delayed. Anæsthesia to heat only, on the plantar surface of left foot.

CASE XIV.

Tactile anæsthesia. On soles of feet, total anæsthesia. *Pain sense* dulled all over body except above the superior boundary of the trunk anæsthesia. Sensibility to heat and cold is slightly uncertain over the lower extremities.

CASE XV.

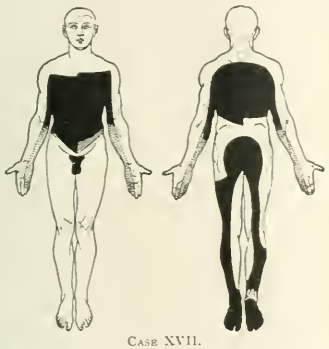
Loss of tactile sensibility.

CASE XVI.

Tactile anæsthesia. Anæsthesia to heat only, sensibility to cold normal. Anæsthesia to *heat and cold* over penis; sensibility on scrotum normal. Pain sense diminished over legs and ulnar distribution on forearms.

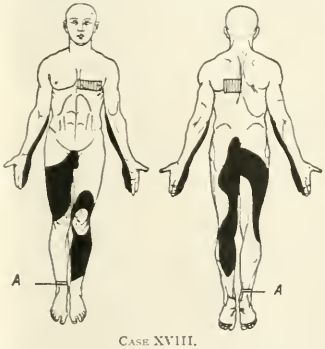
sented show the results of the last examination, made this month (April).

I have found that the borders of the anæsthesia on the chest or back are sharply defined in most cases, especially the upper border; but when the anæsthesia extends down upon the abdomen the lower border is usually poorly defined. The borders of the areas on the lower extremities are not so sharply defined as upon the chest. If, in locating the borders of an anæsthetic area, one approaches the anæsthesia by successive touches or pricks, it is noticed that the borders recede and the area is smaller than if the examination is begun in the anæsthetic area and continued outward to the normal surface.



CASE XVII.

Anæsthesia to touch.
Anæsthesia to touch, pain, heat, and cold.
Tactile sensation uncertain. General anæsthesia to pain over lower extremities and trunk below superior boundary of tactile anæsthesia on trunk.



CASE XVIII.

Sensibility to pain impaired. Anæsthesia to touch on posterior surface of lower extremities. Sensibility to pain is normal over penis and scrotum. Sensibility to heat and cold is lost over penis and scrotum. Anæsthesia to heat only, over anterior and posterior surfaces of legs below the knees.
Tactile anæsthesia only.
A, Foot amputated.

In comparing these areas of anæsthesia with the distribution of the spinal-cord segments, it is seen that in the arms and trunk they agree, and that the anæsthesia does not correspond to the distribution of the peripheral nerves. In the legs very few areas correspond to the distribution of the spinal-cord segments. Cases IV. and VII. agree with the spinal-cord segments, according to Th. Kocher's diagrams, and Cases XIV. and XVII. nearly correspond to them. The other cases do not correspond except partially.

One of the first things we notice about these cases is the fact that the sensory changes are apparently not dependent upon the duration of the disease, for there are large areas of anæsthesia and hyperæsthesia in some of the cases in which the duration has been only from two to five years, while in some others which have had tabes from twenty-five to twenty-eight years there are hardly any sensory changes at all.

Cold is more easily perceived than heat, and is often very easily felt—almost a hyperæsthesia—when there is no perception of very hot water.

In some cases at one time sensations were not localized correctly over certain areas, but this condition has been succeeded by complete anæsthesia over these same areas.

Tactile anæsthesia is found oftener than the other anæsthesiæ, but it is usually accompanied by a hyperæsthesia or anæsthesia to pain over the same area. Loss of perception of touch may be present in various combinations with anæsthesia to pain, heat, or cold over the same area. These sensory disturbances are a valuable and early symptom of tabes, as has been proven by the finding of small areas of tactile anæsthesia in a number of consecutive cases of incipient tabes which have come under my notice in the Vanderbilt Clinic. The patients very seldom are aware of the areas of anæsthesia unless they involve the hands, feet, or buttocks. They then know of them because they cannot feel objects they pick up, and at night they cannot feel the bedclothes.

Paræsthesia is an early symptom which causes a good deal of annoyance to the patient. It is present very early in the disease, and usually appears first in the feet or the ulnar distribution of the forearms. It may be limited to these areas, or it may extend until it involves the whole body. One of my cases has paræsthesia over the whole body, and another over the whole of the left half of the body only. This paræsthesia also varies with the weather.

It may be interesting in this connection to mention a new symptom of locomotor ataxia, which was first noticed by Biernacki and has been named after him. This symptom is the lack of pain when violent compression of the ulnar nerve at the elbow is made, although the usual tingling of the finger is felt. Biernacki says that this condition is present in seventy-five per cent. of his cases, and that it occurs in no other

form of organic disease that may be mistaken for tabes. It is sometimes present, however, in general paresis. I have found this symptom present in seventeen of the twenty-one cases, but in two of them it is present only on one side. Therefore the symptom is present in about eighty per cent. of my cases, which is somewhat more frequently than was found by Biernacki.

The advantages which we ought to gain from a knowledge of these areas of anæsthesia and their location in tabes are both pathological and clinical. As regards pathology, a close study of the areas of anæsthesia and of their location in a large number of cases may be of service in helping to localize more definitely the areas of the skin related to the spinal-cord segments. If these areas become better known, we may be able to locate the point of invasion of the disease more accurately.

From a study of the areas of anæsthesia in old cases—that is, in cases which have had the disease a number of years—we can get many data which will be of service in studying and diagnosing incipient cases of tabes.

A case illustrating the value of examining suspected cases of tabes for areas of anæsthesia, and the assistance the presence of such areas may be to us in making a diagnosis, has just come to my notice. The patient, a young man, had a chancre ten years ago. He now has a loss of both knee jerks and a very slight swaying of the body when the eyes are closed. There are no other symptoms. The pupils respond normally. No diagnosis was made, although tabes was suspected, until on examination an area of tactile anæsthesia was found on his chest. The presence of the area of anæsthesia confirmed the suspicions of the examiner,[1] and made the diagnosis of tabes possible.

Case I. has had locomotor ataxia six years. There is complete anæsthesia to touch over the whole of the lower extremities, over all the posterior surface of the trunk, and over the chest, on the right side, from the level of the second rib downward, and on the left side from the level of the third down to the sixth rib. There is also tactile anæsthesia over a second area on the left side of the anterior surface of the trunk, which extends outward from the median line for about four inches, and from just below the sternum downward about two inches. Tactile anæsthesia is also present over a small tongue-shaped area on the inner side of each arm, extending from the axilla downward nearly to the elbow, and also over the ulnar distribution of the right forearm. Over the lower extremities there is complete anæsthesia to heat and cold. Sensibility to heat and cold is much impaired or uncertain over the anterior and posterior surfaces of the trunk. Pain perception is lost all over the four extremities, and over both the anterior and posterior surfaces of the trunk as far up as the clavicles.

Case II., in which the disease has existed for seven years, presents complete tactile anæsthesia over the anterior surface of the lower extremities up to the groin, and over the posterior surface as far up on the left side as the lower dorsal vertebræ, and on the right side as the second lumbar vertebra. On the right side of the chest, extending from the median line outward about five inches and from the fourth to the sixth rib, there is an area in which tactile sensibility is lost. There is a similar area on the right side of the back, at about the same level, in which tactile perception is absent. Over the anterior surface of the lower extremities perceptions of heat and cold are very much impaired and uncertain. On the ulnar side of the right hand tactile sensibility is lost and there is marked paræsthesia.

Case III.—Duration of the disease, twenty-five years. There is general complete anæsthesia to pain (analgesia). Over the penis and scrotum there is also anæsthesia to touch, heat, and cold. Tactile sensibility is lost on both the plantar and the dorsal surface of each foot, the anæsthesia extending in front up to about the middle third of the legs. There is also tactile anæsthesia in a semicircular area on each buttock, in an area over the epigastrium extending about four inches on either side of the median line, and in two small areas on the back, both on the left side of the median line. There is a loss of perception of heat and cold over the lower two-thirds of the legs in front and the dorsal surfaces of the feet, and over the thighs behind from just below the buttocks downward over the legs and the soles of the feet. Over all the rest of the body sensibility to heat and cold is very much impaired, cold being more easily distinguished than heat.

Case IV. has had the disease twelve years. There is complete anæsthesia to touch and pain from the level of the clavicles downward over both the anterior and posterior surfaces of the body, excepting only a small area on the inner side of the plantar surface of each foot, where all sensations are normally felt. Over this same area there is a general numbness, and perceptions of heat and cold are much delayed.

Case V. has had tabes for ten years. There is anæsthesia to pain and touch over the anterior surface of both lower extremities, excepting over a narrow tongue-shaped area extending downward from the groin and nearly to the knee along the middle of the left thigh, and in a small circular area over the left knee, where sensations are normally perceived. On the right side this anæsthesia extends upward on the abdomen to the level of the umbilicus. On the abdomen, on the left side of the median line, there is a small area about two inches square just below the umbilicus, in which there is a loss of pain and tactile perception. On the chest there are three areas of tactile and pain anæsthesia—one on the right side, extending from the median to the axillary line and from the third rib down to just below the end of the sternum; one on the left side, extending from the fourth to the sixth rib and from the median line outward for about one and one-half inches, where there is a normal space; and external to that the third area, a continuation of the anæsthesia again to about two inches beyond the nipple. Over the posterior surface of the trunk and lower extremities there is a loss of sensibility to pain and touch from about the level of the inferior angles of the scapulæ downward, excepting only a narrow area along the inner surface of the left thigh, where sensation is normal. Sensibility to pain is normal over the scrotum, but is lost over the penis. There is anæsthesia to heat and cold over the whole of the legs below the knees, and on the penis and scrotum. On the thighs, in the areas in which there are pain and tactile anæsthesia, perception of heat and cold is diminished, cold being more easily distinguished than heat.

Case VI. has had locomotor ataxia ten years. Perceptions of pain, heat, and cold are normal. There is tactile anæsthesia all over the forearms, over the inner half of the posterior surface and the upper half of the inner surface of each arm. Tactile anæsthesia is present on the trunk from about the level of the third rib downward, the upper border being a little higher on the right side than on the left. This tactile anæsthesia is present also over the upper two-thirds of the anterior surface of the right thigh and the upper fourth of the left thigh. There is no perception of touch over the back as far down as the lower lumbar region, and down along the outer surface of the right thigh to the popliteal space. There is also a small area of tactile anæsthesia on the posterior surface of the left

[1] Dr. Pearce Bailey.

thigh, as shown in the diagram, and a still smaller area over the external malleolus of the left ankle.

Case VII.—Duration of the disease, five years. There is total anæsthesia over the anterior and posterior surfaces of both lower extremities from the junction of the upper with the middle third of the thighs downward, excepting a small area on the inner side of the plantar surface of each foot, and another small area in the middle third of the anterior surface of the left thigh. In the small area on the plantar surface of the left foot and the area on the middle third of the left thigh there is anæsthesia only to heat and cold. Over the ulnar distribution of each forearm sensibility to touch and pain is impaired. There is no trunk anæsthesia.

Case VIII. has had tabes twenty-eight years. There are no other sensory disturbances than a tenderness to pressure along the spine from the eighth to the twelfth dorsal vertebra, and the narrow interrupted band of tactile anæsthesia on the left side of the chest at the level of the nipple.

Case IX.—Duration of the disease, eight years. Death from uræmia. Over the whole of the right lower extremity, excepting a small area just below the groin, and over the external half of the anterior and posterior surfaces of the left lower extremity, there is anæsthesia to touch, heat, and cold. Perception of touch is lost over the ulnar half of the left hand. Pain sensibility is normal over the whole body. There is no trunk anæsthesia. As I was able to make but one examination of this patient before his death, I do not present the diagram of his areas of anæsthesia.

Case X. has had the disease twelve years. There is tactile anæsthesia over two areas on the chest. On the right side the anæsthetic area extends from the median to the axillary line and from the third to the sixth rib, and on the left side from the median to the axillary line and from the fourth to the seventh rib. There is also loss of tactile sensibility over the ulnar side of the left forearm, both anterior and posterior surfaces, and on the anterior and posterior surfaces of the lower extremities, as shown in the diagrams. Over the same area on the anterior surface of the left leg there is also loss of pain perception. There is anæsthesia to pain over all of the anterior surface of the right lower extremity, and over the posterior surfaces of both legs below the knees. Perception of heat and cold is lost over the anterior surfaces of both legs below the knees, and over the whole of the posterior surfaces of both lower extremities from the upper sacral region downward.

Case XI.—A woman; duration of the disease, thirteen years. Right thigh amputated at *A* for Charcot joint. There is tactile anæsthesia over the anterior surface of the trunk, from the third rib on the right side, and from the fourth rib on the left side down to the pubes, and over the posterior surface of the trunk as far down as the first lumbar vertebra. The boundaries, both upper and lower, of this anæsthetic area on the back are higher on the left than on the right side. There is also a loss of touch perception over a tongue-shaped area on the inner and posterior surfaces of each arm, extending from the axilla downward nearly to the elbow, over the ulnar side of the right hand, and over a semicircular area nearly covering the right buttock. Anæsthesia to pain is present over the whole of both forearms, the whole of the left lower extremity from the groin in front and the sacral region behind downward, and over the whole of the posterior surface of the right thigh below the sacral region. There is a loss of perception of heat and cold over the whole of the left leg below the knee.

Case XII.—A woman; duration of the disease, eighteen years. There is general hyperæsthesia to all stimuli.

Case XIII.—A woman; has had the disease five years. She is blind. There is tactile anæsthesia over an area on the left side of the chest, extending from the median to the axillary line and from the fourth to the sixth rib, and over an area on the left side of the back at about the same level, extending from the median line outward for about five inches. Over the whole of the left lower extremity and the left buttock there is anæsthesia to pain and touch, and perceptions of heat and cold are very much delayed. On the plantar surface of the left foot there is anæsthesia only to heat.

Case XIV. is blind: has had the disease seven years. There is complete loss of tactile sensibility on the chest, extending on the right side from the median to the axillary line and from the fourth rib down to the level of the umbilicus, and on the left side from the median to the axillary line and from the space below the third down to the sixth rib. On the back the area of tactile anæsthesia extends on the right side from the median to the axillary line, the superior and inferior borders being on the same level as those of the area on the right side of the chest. On the left side of the back the band of tactile anæsthesia corresponds in width to that on the left chest. There is also tactile anæsthesia over the penis and scrotum and the adjacent surface of the thighs and pubes, and over the posterior surface of the thighs in the areas shown in the diagrams. There is total anæsthesia over the soles of the feet, excepting a small area on the inner side of each foot, where sensibility is normal. Pain perception is impaired over the whole body below about the level of the third rib. Over the lower extremities sensibility to heat and cold is slightly impaired and uncertain.

Case XV. has had tabes five years. The patient is blind. The only sensory disturbance found in this case is a complete loss of tactile perception over an area on the right chest, extending from the median to the axillary line and from the fourth rib downward nearly to the level of the umbilicus, and over an area on the right back extending from the median to the axillary line and from just above the inferior angle of the scapula downward for about five inches. There is no diminution of perception of pain, heat, or cold on any part of the body.

Case XVI. is blind; has had the disease twenty-seven years. This patient has anæsthesia to touch and heat over the following areas: On the left chest from the median to the axillary line, and from just above the fourth to the sixth rib; on the left back from the median to the axillary line, and from the level of the spine of the scapula down to about the eighth dorsal vertebra; on the right back from the median to the axillary line, and from the level of the spine of the scapula downward about five inches (this area connects with a tongue-shaped one on the inner and posterior surface of the right arm): over the ulnar distribution of both forearms, over the anterior surface of the right lower extremity from the middle of the thigh downward, and on the left side from the level of the umbilicus down over the whole surface of the left lower extremity, excepting only a small area on the inner side of the knee. Posteriorly this anæsthesia extends from the lumbar region downward over the whole of the lower extremities, excepting a small area on the inner side of the left knee. Perception of cold is normal over the whole body except over the penis, where there is complete anæsthesia to heat and cold. Over the scrotum heat and cold sensibility is normal. Pain perception is diminished over the ulnar distribution of the forearms and over the legs below the knees.

Case XVII. has had tabes seventeen years. There is complete tactile anæsthesia over the right side of the chest from the third rib downward nearly to the

groin, and on the left chest from the second intercostal space downward to about midway between the umbilicus and the pubes; below this tactile perception is impaired. Over both sides of the back from about the level of the spines of the scapulæ down to the upper lumbar region, there is also loss of touch perception. This tactile anæsthesia extends downward on the inner surface and the inner half of the anterior and posterior surfaces of the arms to the elbows. There is tactile anæsthesia over the penis and scrotum, and to a slight extent on the adjacent parts, and over the buttocks and posterior surfaces of the lower extremities, as shown in the diagrams. Over the ulnar distribution of both forearms there is total anæsthesia. There is a loss of sensibility to pain over the whole of the lower extremities, the inner surfaces of the arms, and the trunk as far up as the level of the third rib.

Case XVIII.—Duration of the disease, two years. Foot amputated at *A*. There is tactile anæsthesia on the left chest over a small area about two inches wide, extending outward for about five inches from the median line at the level of the nipple, and over an area about two and one-half inches square at about the same level on the back just to the left of the median line. There is an impairment of pain perception over the ulnar distribution of both forearms, over the lower two-thirds of the anterior surface of the right thigh, over a small area on the anterior surface of the left thigh just above the knee, over the upper two-thirds of the anterior surface of the left leg, and over the irregular areas on the posterior surfaces of both the lower extremities and the buttocks. Over the penis and scrotum sensibility to pain is normal, but there is a loss of perception of heat and cold. There is anæsthesia to heat only over the anterior and posterior surfaces of both legs below the knees, sensibility to cold being normal.

Case XIX.—Duration of disease, two years. Has no sensory disturbances.

Case XX. is blind. Has had the disease four years. There is no anæsthesia.

Case XXI. has had tabes five years. There is no anæsthesia.

It is seen from these cases that sensory disturbances are both an early and a late symptom of tabes, that the areas of anæsthesia are of diagnostic value in incipient cases, and that they increase in size as the disease progresses.

I wish to thank Dr. M. Allen Starr and Dr. Pearce Bailey, attending physician to the Hospital for Incurables, for their kindness in giving me valuable advice in the preparation of this article.

April 10, 1897.

The Treatment of Hemorrhoids by Whitehead's Method.—Dr. Delorme (*Médecine Moderne*, October 31, 1896) speaks very favorably of Whitehead's treatment of hemorrhoids, which he regards as the method of election in cases of large internal or externo-internal piles forming a prominent circular mass. The author states that in eighteen patients thus treated he obtained perfectly satisfactory results; the operation was followed by primary union, there was exact apposition of the skin and mucous membrane, the formation of supple and dilatable cicatrix, and freedom from both retention and incontinence. The cure is radical provided the gut is incised above the zone of venous dilatation. The immediate hemorrhage is seldom profuse. To secure success, the incision must be made above the limits of the affected mucous membrane; the suture must be strong; the sphincters must be carefully preserved; absolute rest of the perirectal muscles must be maintained until the complete development of firm union.

GOUTINESS IN ITS RELATIONS TO DISEASES OF THE EAR.[1]

By ALBERT H. BUCK, M.D.,

NEW YORK

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY; CONSULTING AURAL SURGEON, NEW YORK EYE AND EAR INFIRMARY AND THE PRESBYTERIAN HOSPITAL.

I believe that the sentiment among otologists is quite general that while gout, or the gouty diathesis, may play a certain part in the etiology of various disturbances of the ear, the facts which thus far have been ascertained are too few or of too doubtful a character, as matter of evidence, to warrant us in establishing a distinct class of cases to which we may apply the term gouty. It is, therefore, not surprising that modern otological text-books say little or nothing on this subject. But when I came to look over the published works of some of the older English writers, for the purpose of ascertaining what particular lesions or phenomena were considered by them as being of a gouty nature, I was surprised to find that only two of them furnish any data upon which one can form an opinion in regard to this question. Thus, for example, in Wilde's treatise[2] (page 259) I find the following: "That gouty otitis may exist, I have no doubt, but I myself have never seen a well-marked example of it; neither have I yet read a description of that disease which afforded any one pathognomic [*sic*] which could be relied upon." Then, on a previous page (170), he says: "Gouty inflammation of the external ear has been fully established. Dr. Graves, who was the first to describe this affection, says that the state of congestion of the auricle seldom lasts long, and generally subsides on the occurrence of the disease in the extremities."

At a somewhat later date Toynbee, on page 362 of his work,[3] makes this statement: "The poison of gout may also give rise to deafness and other peculiar symptoms in the head." Then, by way of illustration, he gives the history of a case which he believed to be of gouty origin. As it is the only thoroughly typical case of gouty ear disease of which I have been able to find a record, I make no apology for reproducing the account here in its entirety.

Toynbee's case: "D. T——, Esq., aged fifty-four, consulted me in June, 1857. He said that for the last four or five years he had been subject to attacks of gout, which had at times caused him great inconvenience, and the disease had recently made so much progress as to make him fearful that his brain was weakened by its influence. He added that he was never really clear-headed excepting just after an attack of gout, when he supposed his blood was temporarily freed from the poison. He had rapidly aged in the course of the previous two years. An extremely distressing symptom had lately presented itself in the form of a peculiar sensation of vacancy in the ears, accompanied sometimes by a low humming sound. There was no deafness, and the patient applied to me only on account of the sensations in the ear. On examination, small deposits of gouty matter were observed in the substance of the right upper eyelid; the surface of the meatus externus was of a bright red color; the circumference of the membrana tympani and of the long process of the malleus were also red; while the surface of the tympanic membrane was very bright. Air passed freely,

[1] Read before the American Otological Society at its meeting in Washington, D. C., on May 4, 1897.

[3] "The Diseases of the Ear; their Nature, Diagnosis, and Treatment," London, 1868.

and with the natural sound, into the tympanic cavity. The hearing power was perfect. By what, therefore, could the distressing symptoms be caused? Were they the result of congestion of the nerve?—a condition which, it seemed to me probable, might render the nerve so exquisitely sensitive that the ordinary sounds ever floating in the air might become a source of excitement to the ear. Being aware also, from previous experience in similar cases, that pressure upon the external meatus so as to shut out or diminish the sound in the meatus would remove the symptom complained of, I closed with my fingers each external meatus, and the unpleasant symptoms at once disappeared. On subsequently exerting a gentle pressure on the ears by the introduction of cotton steeped in water into each, the patient was enabled to leave in comparative comfort. For the purpose of preventing the recurrence of the symptoms, it was of course requisite to diminish the congestion, for which purpose two leeches were applied below each ear, small doses of colchicum administered, and strict attention to diet enjoined. The quantity of wine was decreased from four to two glasses daily, and in lieu of beef and mutton, of which he had been in the habit of partaking very abundantly, he was ordered to live principally on poultry, game, and fish, with abundance of farinaceous food and vegetables. The result of this treatment was the removal of the distressing symptoms in the ears, and the gradual disappearance of the attacks of gout."

It is clear, from this account, that Toynbee based his belief in the gouty nature of both these lesions—those seen in the external auditory canal and those assumed by him to exist somewhere in the course of the auditory nerve—partly upon the other pathological phenomena which the patient manifested, and which would be accepted by all authorities without dispute as being of gouty origin, and partly upon the beneficial results of the antigouty treatment adopted.

So far as the older otological literature is concerned, the data given above comprise, as I have already stated, all the information which I have been able to obtain. But in Garrod's classical treatise on gout[1] I find certain statements which may be quoted here, as they bear directly upon the question of the correctness of Toynbee's diagnosis in the case just cited, as well as upon the general subject of gouty affections of the ear. In speaking of the irregular forms of gout—and it is among these that all the ear cases of this disease must be classed—he says (page 32): ". . . they occur in subjects who have never experienced a true fit, but who either inherit gout, or at least have been much exposed to its predisposing causes. When at any time we can demonstrate that these symptoms depend upon the same diathesis as leads to the inflammation of the joints, we are certainly justified in considering them irregular manifestations of gout." Farther on, he says: "On the other hand, there can be no question that the same systemic condition which ordinarily leads to the development of regular gout may at times produce symptoms altogether apart from the joints, but which are essentially of a gouty character." Then again, in speaking of eczema, he says: "Eczema is also a form of skin disease constantly met with in gouty individuals, either localized to a few spots in certain parts, as behind the ears, or on the external ear," etc. The only mention which he makes of any gouty manifestations in the deeper parts of the ear is the following: "Deposits are not unfrequently found upon the drum and the ossicles of the ear, but I have failed to discover uric acid in any which I have examined. I am inclined to regard the alterations which I have now and then seen in the bones of the ear as indicating the presence of rheumatoid arthritic disease rather than true gout."

[1] Edition of 1876 (London).

Finally, Lyman, of Chicago, in his admirable treatise on gout in the first volume of the "Twentieth Century Practice of Medicine,"[1] mentions a number of alterations in the organ of hearing which have been attributed to the arthritic diathesis; but, as no details of individual cases are mentioned, the reader cannot form an independent judgment in regard to the correctness of these deductions. Personally, however, I am confident that at least some of these alterations have been rightly attributed to goutiness.

During the past eight or nine years the conviction has been steadily growing stronger in my mind that a gouty diathesis plays an important part in a very large percentage of the cases of ear disease which we encounter in private practice. I start out with the premise that a patch of eczema, of spontaneous development, signifies the existence, in the individual possessing it, of a gouty diathesis. Garrod's statement, just quoted, is my warrant for this broad rule. As it happens, the floor of the external auditory canal is apt to be the very first spot on the surface of the body where an eczematous inflammation develops. That this should be the favorite spot for the first outbreak of an eczematous inflammation is probably due to two facts: first, that the blood-vessels in this locality are very small; and second, that rarely if ever is the skin at this spot disturbed in its quietude. Every other part of the surface of the body is moved at brief intervals, and this motion is unfavorable to stagnation of the blood-current. The spontaneous development of this condition of stagnation in the blood-current of some limited area of the skin constitutes, therefore, a valuable guidepost, pointing, as it does, at a very early stage, to the existence of that disturbed state of the metabolic processes to which the term goutiness, or a gouty diathesis, is applied. In the cases which I am about to describe as types of gouty ear disease, this lesion was invariably present at some time or other in the course of the disease. In these cases, furthermore, it will be seen how different localities or different tissues are involved at different times. Thus, for example, at one time it is the skin of the external auditory canal and auricle; at another time the dermoid surface of the tympanic membrane is involved, as well as the walls of the canal; at still another, the adjacent bone tissue is affected; and finally, at a fourth, the disease locates itself in the mucous membrane of the tympanic cavity, and particularly in that part of it which borders upon the two fenestræ. In addition to these brief histories I will give with each a running commentary upon those features which seem to me to call for some special remark.

[1] Published by Wm. Wood & Co., New York, 1895, Thomas L. Stedman, M. D., editor.

Case I.—A gentleman, about thirty years of age, and apparently in robust health, consulted me, in the spring of 1882, on account of an uncomfortable affection of both his ears. The symptoms were: a distressing irritation in both canals, occasional pain, intermittent watery discharge, and decided fluctuations in the hearing-power. Generally, he could hear perfectly well, but often, for two or three days at a time, the ears would seem to close, and then he would experience considerable difficulty in hearing. On examination, I found both auricles eczematous and the external auditory canals very much swollen. The semi-raw surface of the skin, in the latter regions, was bathed with a thin purulent secretion. Near the tympanic membranes there seemed to be an abundance of room, but farther outward the calibre was reduced to the size of a steel knitting-needle. The cause of the trouble was not far to seek. In the first place, his father was a great sufferer from gout; and in the next

place, he himself was very fond of good living, and was well known among his friends as an authority on the places where the best brew of German beer or the best Bass' ale could be obtained. Furthermore, he habitually abstained from anything like vigorous physical exercise.

I gave him momentary relief from the worst aspects of his trouble by the local application of a strong silver-nitrate solution (one hundred and twenty grains to the ounce), and I spoke to him very earnestly in regard to the important topics of diet and physical exercise.

During the past fifteen years I have seen this patient repeatedly. His ears are to-day in precisely the same condition as they were in 1882—no better no worse. Strange as it may seem, the tympanic cavities appear to have escaped entirely. At all events, when the outer passages are clear he seems to hear as well as anybody. Even an intercurrent severe attack of knee-joint inflammation—presumably gouty—has not accomplished any more than have my repeated sermons in inducing him to alter his habits in respect to eating and taking exercise.

The preceding case is a well-marked example of a class of cases with which every aural surgeon in private practice is perfectly familiar. In probably the majority of instances the eczema is not so widely diffused; it is more apt to be confined to a patch of limited extent, which rises but little if at all above the level of the surrounding healthy skin. While the lower wall of the canal is, perhaps, more oftcn the seat of such a localized patch of eczema than is any other portion of the canal, there is no part of it which may not be visited by the disease. Now and then it invades even the drum membrane itself. I have seen several instances of this, but I have preserved the records of only the two following cases:

Case II.—The patient, a lady of about fifty years of age, consulted me during the autumn of 1896 on account of the following symptoms: tinnitus, slight impairment of the hearing, and vertigo, together with sleeplessness, anorexia, and "rheumatic" pains in different parts of the body (hands, shoulders, etc.). In both external auditory canals I found circumscribed areas of eczema, and in one ear the posterior half of the membrana tympani was the seat of an oblong, dirty-looking, grayish scab, sharply limited in its outlines, and of only slight thickness. By the employment of a small and very delicately constructed ring-shaped curette this scab was readily removed, and the base upon which it rested was found to present a feebly granulating moist surface. Under a course of anti-gouty treatment the subjective symptoms nearly all disappeared, but the patch on the membrana tympani persisted for a period of several weeks, despite the fact that I applied a strong solution of silver nitrate to the granulating surface on one or two different occasions. Finally, this lesion disappeared completely (March 19, 1897), leaving the tympanic membrane perfectly smooth and pale.

Another case, which belongs in this category, was reported by me in 1891.[1]

Case III.—In this patient, an adult, I found the region above and behind the short process of the hammer, and the larger part of the posterior half of the drum membrane, converted into a mass of tolerably firm granulation tissue. At its lower and posterior border the mass represented little more than a red, succulent, very much thickened tympanic membrane, while at and around the short process the mass projected sufficiently for me to remove a portion of it with the snare. The outer canal elsewhere was only mildly inflamed, and contained but a small quantity of purulent discharge. The hearing for voice sounds was scarcely at all affected. A search was made for a fistulous opening in the vicinity of Shrapnell's membrane, but no trace of one could be found. The previous history of the case pointed rather to chronic eczema of the external auditory canal.

By the aid of the snare at first, and of chromic acid afterward, I soon succeeded in destroying all the exuberant tissue in the region of Shrapnell's membrane; the patient in the mean time employing faithfully Angelo's ear douche, with warm water, two or three times a day. In less than three weeks the tympanic membrane and the surrounding regions had very nearly resumed their natural appearance, and I question whether anybody who might then have seen the ear for the first time would have believed it possible that such gross lesions as I have described above were present in this ear so short a time previously. In only one material respect did the tympanic membrane show a departure from the normal condition: an elongated oval patch, of a silver-grayish color and sharply defined borders, occupied the greater part of the posterior half of the membrane. By suitable manipulations with the tip of the slender silver probe it was ascertained that the thickening was seemingly confined to the outer surface of the membrana tympani, and that it was perfectly flexible and dry. A patch of psoriasis is the only skin lesion which occurs to my mind as presenting a strong resemblance to the one observed in the present case.

In this last case we are warranted, it seems to me, in assuming that the gouty impulse, at least at this particular spot on the membrana tympani, was stronger than it is in those cases in which the granulation process goes no farther than to convert the skin surface into a succulent secreting area.

But the picture presented to the eye may be materially modified by the action of other factors, such as pressure upon the inflamed parts, damming up of the products of the inflammation by an obstructing mass of cerumen, etc. The following case, which I saw about twenty years ago,[1] illustrates this point, and also suggests the probability of our being able to demonstrate, at some future day, that even large deposits of chalky material (urates) may occur in the external auditory canal.

Case IV.—The patient, a very intelligent lady, thirty-eight years old, and in fairly good health, stated that during the previous five weeks she had experienced at times quite severe pain in the right ear. There had been no discharge and very little disturbance of the hearing, so far as general conversation was concerned. Her regular medical adviser had attributed the painful affection of the ear to impacted cerumen, and had syringed the canal very thoroughly with tepid water, but without beneficial effects. On examination, I found the orifice of the right auditory canal tender on pressure, and obstructed by the presence of a moderately large mass of granulation tissue springing from the mouth of what seemed to be a furuncular pocket. Beyond this fleshy mass, which I at once removed with the snare, the canal was found to be tightly plugged with a whitish mass which felt as hard as chalk. By means of the curette and forceps, I was able to break down and remove piecemeal the entire mass. It presented, throughout, every appearance of being a chalky substance, and probably represented a calcareous transformation of pus that had first undergone cheesy degeneration.[2] The inner end of the mass extended to within a few millimetres of the drum

[1] "International Clinics," April, 1891.

[1] Reported in my manual, "The Diagnosis and Treatment of Ear Diseases," Wm. Wood & Co., New York, 1880, pp. 93–95.

[2] The present report of this case, it should be remembered, is in the same words which I employed when I first published it in 1880. Farther on, it will be seen that I no longer entertain the view here put forward in regard to the mode of development of this chalky mass.

membrane. After it had been entirely removed I found that the only lesion in the osseous part of the canal, beyond a moderate degree of redness and swelling, was a circumscribed ulcer, situated posteriorly and superiorly not far from the junction of the osseous with the cartilaginous portion. On exploration with the probe I ascertained that denuded bone surface constituted the base of the ulcer. The membrana tympani appeared to be perfectly normal.

An examination of the patient's left ear, which she had always supposed to be healthy in every respect, revealed the existence of a small, pale, succulent polypoid mass, springing from the posterior wall of the osseous part of the canal, close to the drum membrane. The secretion from this mass was so scanty that no fluid could be seen in the canal except in the immediate neighborhood of the growth. Exploration with the probe showed that the polypus was simply a superficial outgrowth, not connected with any demonstrable disease of the bone. The membrana tympani appeared to be perfectly natural, and there was no appreciable redness or swelling of the walls of the canal in the vicinity of the growth.

I questioned the patient carefully with regard to the condition of her ears in the past, but could elicit no information that threw any light upon the peculiar lesions found. The pain of which she had complained during the previous five weeks was evidently due to the development of a furuncle near the outer orifice, and the mass of granulation tissue found in this location was simply the effect of continued irritation from some source or other. These lesions were evidently of comparatively recent date. The presence of the calcareous mass in the right meatus pointed clearly to a discharge of much earlier date; but it was not so easy a matter to define the location from which this discharge came. The middle ear, for instance, could safely be excluded as a source of the pus, as the patient was positive that she had never experienced any pain or discomfort in the right ear until recently, and also because the condition of the drum membrane, as found after the chalky mass had been removed, showed no trace of any recent or former inflammation of the middle ear. The discharge, therefore, in all probability, came from the auditory canal. The patient, however, it will be remembered, stated distinctly that she had never observed a discharge from either ear. In explanation of this apparently contradictory state of things, the assumption is certainly warranted that in the outer portion of the canal there must have been some obstacle which prevented the escape of pus secreted in the inner portion. Impacted cerumen would present such an obstacle, and, by greatly diminishing the rate of evaporation which would take place in the pus under ordinary circumstances (*i.e.*, in an unobstructed meatus), would favor its gradual accumulation and slow transformation, first into a cheesy and then into a chalky mass. No cerumen, it is true, was found in the canal at the time when I examined it; but it is more than probable that the thorough syringing which the ear had received at the hands of the attending physician had removed all that was there.

The question relating to the exact source of this assumed discharge, whether the latter came from the circumscribed ulcer described above, or from some previous diffuse inflammation, of which this ulcer was the last remaining trace, is one which I am unable to answer.

With regard to the treatment and subsequent progress of the case, there is very little of interest to communicate. Both ulcers healed slowly under the use of nitrate of silver (in the form of a bead) and (later) powdered iodoform. A dry eczema, affecting the orifices of the canals, continued to be present for several weeks after the ulcers had healed, and then finally disappeared. As late as during the summer of 1879 I found both canals still quite natural in appearance.

In recent years I have been disposed to attach an entirely different pathological interpretation to the lesions described in the foregoing record. I think that it is highly probable that the ulceration of the osseous portion of the right external auditory canal was a distinctly gouty lesion, such as is seen in the vicinity of certain articulations in the more severe forms of the disease, and that the chalky material which filled the canal came from this source. This lady's father and sister had both been sufferers from gout in a pronounced form, and, as will be noticed in the record, both canals showed evidences of eczema for a certain length of time after the healing of the ulcers. These two facts add strength to the hypothesis that in this particular case the main underlying cause of the peculiar lesions observed in the ears was a well-marked gouty diathesis, active only during a limited period of time.

To the minds of some it may seem strange that the chalky material observed in this case should have been found lying free in the external auditory canal, whereas the gouty tophi observed in other parts of the body are always surrounded by an envelope of skin. This difference may probably be explained in the following manner: In the neighborhood of the small joints of the fingers the skin is very strong and elastic and only loosely adherent to the underlying fibrous structures. The chalky urates may, therefore, easily accumulate at these points in quite large quantity without rupturing the skin. In the external auditory canal, on the other hand, or more particularly in its osseous portion, the skin is extremely thin and is quite firmly attached to the underlying bone. It could therefore scarcely serve as a sac for holding any such mass of chalky material as was found in the present case.

It may also seem strange to some that these chalky urates—if such, indeed, they were—should not have escaped from the external auditory canal, instead of remaining there, and gradually forming a solid mass of considerable size. The explanation which seems to me to be the most plausible is the one which I have already given above, viz., that a mass of impacted cerumen doubtless occupied the outer half of the canal at the time when the more active gouty outbreak occurred, and the presence of this obstacle prevented the escape of the solid portions of whatever secretions may have been poured out into the deeper parts of the canal.[1] One can easily understand how, under these favoring conditions, the separate particles of solid matter might, in the course of time, become pressed together into a fairly hard mass, such as was found in the present case.

In the cases of which I have thus far given brief accounts, the lesions have been limited in extent and have not, with, perhaps, a single exception (Case IV.), involved the underlying bone structures. In the following case[2] the gouty influence was so strong and so persisting that both the skin and the underlying bone became involved in the inflammation.

Case V.—The patient, a rather stout lady about thirty-eight years of age, consulted me on October 6, 1887, for what seemed to be a subacute catarrhal inflammation of both middle ears, accompanied by almost constant tinnitus, and by an unpleasant sense of fulness in the ears. From the right ear there had been

[1] This lady's regular medical adviser was in the habit of using the speculum and reflector in examinations of the ear; and, as he first pronounced the condition to be one of impacted cerumen, I think we are warranted in concluding that he based this first diagnosis upon the fact that he actually saw such a mass in the canal.

[2] Reported in part in the "International Clinics," April, 1891. Lippincott Company, Philadelphia.

a slight discharge, and the sensation of itching in this ear had at times been almost intolerable. The patient was then also suffering, and had been for several years, from well-marked diabetes insipidus. In general conversation with her I observed no evidences of impaired hearing, but on testing this function with the watch, which was a loud ticker, I found that she could hear it at a distance of only two inches on the left side and three on the right. I inquired into her habits as regards eating and exercise, and learned that she practically took no outdoor exercise whatever, and yet she had not modified her diet in the slightest degree.

An examination of the ears revealed the existence of an eczematous inflammation in both external auditory canals. The tympanic membranes showed no noticeable alterations.

I prescribed a restricted diet, more physical exercise, the use of the douche with warm water in the right ear, local applications of the oil of cade and vaseline in both ears, spraying the nasal passages with listerin and water, bi-weekly applications of a silver-nitrate solution to the vault of the pharynx, and inflations of the middle ears acording to Politzer's method. Very little, if any, improvement followed this plan of treatment. My impression is, however, that the advice about diet and exercise was not followed.

From October, 1887, to January, 1890, I saw the patient at irregular intervals. The memoranda in my case book simply show a record of ups and downs, with no special tendency on the part of the disease to grow materially worse. The discharge from the right ear, although scanty, was almost constant. On the 31st of January, however, she began to suffer from the first of a series of boils in the right external auditory canal. All sorts of local remedies—Hebra's diachylon ointment, silver-nitrate solutions of various strengths, powdered boric acid, etc., were tried, but without any beneficial effect. The sulphide of calcium, administered in small doses, seemed to do a little good, but yet not enough to warrant us in continuing its use. In the mean time the left ear had also begun to discharge, owing to the presence of a diffuse inflammation of the skin lining the inner half of the canal.

On the 14th of May I found, on the lower wall of the right meatus, not far from the outer orifice, a circumscribed patch of granulation tissue, which I touched freely with a strong (twenty-four per cent.) silver-nitrate solution. This application causcd the ulcer to heal promptly, and for about one month afterward the ear gave her very little trouble. The left ear had also, by this time, resumed a fairly quiet condition.

On the 16th of June, when I saw her for the last time before she went away to the country for the summer, there was a little tenderness at the orifice of the right canal, as if a fresh furuncle were developing; but in all other respects both ears seemed to be as free from irritation as they had been at any previous time for several months past.

On the 6th of October, when she returned from the country, I found the left external auditory canal in very much the same condition as I had seen it on the 16th of June; that is, the canal was a trifle narrower than it should be and there was more fulness of the blood-vessels than is normal. On the right side, however, the condition of the auditory canal had become very much worse. A polypoid growth, about the size of a small pea, occupied the orifice of the canal. By the aid of a bent probe it was ascertained that this growth sprang from the edge of an opening in the skin, at the bottom of which denuded bone could be felt. After the removal of this polypus with the snare, it was seen that the cutaneous walls of this deeper portion of the canal had been converted into granulation tissue which completely obliterated the calibre of the meatus. Neither on this nor on any subsequent occasion was I able to determine accurately whether any portion of the cutaneous lining of the canal had escaped this conversion into granulation tissue. Along the upper wall, down to a point close to the tympanic membrane, the skin seemed still to retain a smooth, firm surface, but I was not able to ascertain positively whether such was the fact or not. The lack of space and the facility with which such tissues bleed when manipulated are almost insurmountable obstacles in the way of a satisfactory examination. The skin covering the mastoid process was red, swollen, and tender, and the auricle was dislocated slightly forward. There was comparatively little pain at this time; no more, in fact, than would be expected from an inflammation of the surface tissues.

Although I inquired carefully into what had taken place during the interval between June 16th, when I last examined the right ear, and the date of the visit to which I have just referred, I failed to discover any facts which would warrant the belief that she was suffering from inflammation of the mastoid process of middle-ear origin, that is, an inflammation which had developed more or less independently of the long-standing disease in the external auditory canal. During this period she had experienced, it is true, a great deal of pain in and around the ear, but it could all readily have come from the presence of a deep-seated furuncle and from the rather vigorous efforts made by the different medical men whom she consulted to effect healing of the furuncular cavity.

I took her temperature (under the tongue) and found it to be normal; and I might add that on no subsequent ocasion did it rise above 99.5° F.

During the next three weeks I made various attempts to remove, or materially to reduce in bulk, the granulation tissue in the right canal, but at most I accomplished very little. On the 31st of October, therefore, she was put under the influence of ether, and I proceeded to remove, partly by means of suitably curved knives and partly by the aid of Hinton's fenestrated forceps, the larger part of the obstructing mass. In this way I obtained a clear calibre, from the tympanic membrane outward, of fully five millimetres in diameter. As the bony floor of the canal seemed to be rougher than natural, I scraped it with a sharp-edged spoon. As a last step I insufflated powdered iodoform and sealed up the orifice of the canal lightly with cotton.

Three days later I found that no unpleasant reaction had followed the operation, and that the canal still retained a calibre of about four millimetres in diameter. In the hope of stimulating these relaxed tissues to contract and resume the firm condition of natural skin, I injected into the meatus, by means of a slender glass pipette, a six-per-cent. (thirty grains to the ounce) solution of silver nitrate. The result of this procedure was directly the opposite of that which I had expected; at the end of about forty-eight hours I found the calibre of the canal completely obliterated.

By this time I had become thoroughly convinced that I was contending with forces which I could not possibly hope to overcome by mere local interference, and I expressed the opinion that it would be useless to make any further active efforts to benefit the ear in this manner; although variations in the local conditions might call for some slight therapeutic interference from time to time.

During the early part of November the patient was obliged to keep her bed on account of a rather severe attack of arthritis of the right knee. While this was in progress the pain and swelling in the mastoid region became more marked; but under the influence of

frequent poulticing, with hot flaxseed-meal poultices, the swelling and tenderness rapidly diminished and the pain became insignificant.

About one month later (early in December) I was confident that a certain amount of shrinking and a diminution in the hyperæmia had taken place in the granulating walls of the right external auditory canal. The discharge had always been scanty, and this remained unchanged. There were but two things to which I could attribute this change for the better, and these were the increased amount of outdoor exercise which her attending physician had at last succeeded in inducing the patient to take, and the greatly restricted diet which he had prescribed and which she had faithfully adopted. She had even, at his suggestion, dismissed her maid, in order that she might be forced to take many steps which ordinarily had been taken for her by this person, who had heretofore been in constant attendance.

While the right ear, as I have said, showed only to a slight degree the beneficial effects of the judicious treatment inaugurated by the regular medical attendant, the left responded in a much more decided fashion. It was during the month of October that this ear had begun to grow perceptibly worse. The calibre of the canal became smaller and smaller, and the inflamed walls seemed to be taking on the characteristics of granulation tissue, just as had occurred long before in the right canal. At intervals of a week or ten days a furuncle would appear on the lower wall of the canal near the orifice, break, and then heal up, to be followed in due time by a fresh one at or close to the same spot. The discharge was constant, but rather scanty in amount. Solutions of acetate of lead and of nitrate of silver of different strengths, powdered iodoform and boric acid, and a variety of ointments were tried in succession, but they all failed to produce any beneficial effects. As a matter of fact, they seemed rather to make the ear worse. All through this period the ear was decidedly painful, at times even more so than the right, which certainly seemed to be the more profoundly affected of the two. Then, as I have already stated, there came a decided change for the better in the condition of this left ear, a change which was certainly not due to any local treatment, but could rightfully be attributed to the restricted diet and the increased muscular activity alone. The improvement referred to manifested itself in the following ways: the formation of furuncles ceased, the swelling and discharge diminished, and the pain practically disappeared. By the 13th of December the calibre of this left canal had so increased in size that I was able to obtain a fairly good view of the tympanic membrane.

From this time onward I saw the patient not oftener than once or twice a year; the last time in 1894. Her left ear gave her very little trouble during this period, but the right one never returned to anything like a normal state. The skin of this canal remained in a granulating condition, and the hearing, which at no time had been seriously impaired, varied from time to time according to the variations in the degree of swelling of the granulating skin. The mastoid region continued to be somewhat tender when pressed upon, and there was also more or less pain in this region, but never enough to interfere with her sleep.

Death occurred in 1895, apparently from pneumonia. So far as I could learn, no material change had taken place in the condition of her ears during this last year of her life.

I can recall but one other case in which, from an apparently simple eczema of the skin lining the external auditory canal, there gradually developed a veritable mastoid osteitis, involving the more superficial portions of this bone. I entertained doubts for a long time in regard to the correctness of my diagnosis, and was more than once tempted to explore the interior of the mastoid process. At the end of eight or ten months of unsuccessful treatment I induced the patient to visit Homburg, near Frankfort, in Germany. She followed, for a period of six or eight weeks, the course of treatment which is commonly prescribed at these springs, and which is essentially the same as that recommended at Carlsbad, and she returned to New York seemingly cured of her disease.

The preceding examples may be considered as illustrating sufficiently the different phases manifested by a gouty inflammation of the external meatus. But the auricle and the external meatus are certainly not the only parts of the ear which are affected by this disease. I believe that it also invades the tympanic cavity and produces there alterations which are of the same general character as those which are observed in the external auditory canal. In the former region we cannot actually demonstrate, as is easily done in the meatus, the precise extent and general character of any given lesion, or the particular part of the cavity which it may occupy. The presence of the tympanic membrane prevents this. But our inferences in regard to these points are, nevertheless, not based upon guesswork; they rest upon substantial supports. I will give here two examples of what I believe to have been a gouty inflammation of the middle ear.

Case VI.—A young woman, about twenty-six years of age, and of not a very strong physique, consulted me on the first of February, 1896, for a slowly increasing difficulty of hearing, associated with neither tinnitus nor a noticeable sense of fulness in the ears. She was not able to say exactly when the trouble first manifested itself, but she was confident that during the previous summer and early autumn she had heard quite well. On testing her hearing I found that, for the watch, it stood: R. 3 in., L. 48 in.; and for spoken words it was so far impaired that I was several times obliged to repeat my questions before she was able to understand what I said. Both external auditory canals were normal in appearance, and the tympanic membranes showed no evidences of congestion, or of excessive atmospheric pressure from without, such as might be expected to result from tubal obstruction. An examination of the nasal and pharyngeal regions (by my associate, Dr. Robert Lewis) revealed no lesions of any importance in the nasal passages, and only a moderate degree of congestion of the mucous membrane of the naso-pharyngeal vault.

On inquiring into the patient's past history I ascertained that a few years previously she had suffered more or less from "rheumatism," and that during the past eighteen months she had been working unremittingly as a member of some sisterhood, nursing the sick, teaching a large class of boys, etc. With all this she had taken scarcely any outdoor exercise. Her sallow complexion and tired expression of countenance told very plainly the story of overwork.

So far as local treatment was concerned I restricted this to triweekly inflations of the middle ears by Politzer's method and equally frequent paintings of the congested vault mucous membrane with a three-per-cent. silver-nitrate solution. Small doses of cod-liver oil, abstention from work of any kind after 3 P.M., and as much outdoor exercise as circumstances would permit — these were the chief therapeutic measures upon which I depended for checking the advance of her deafness, and for regaining, if possible, some of the hearing which she had lost.

Improvement took place very slowly. By March 10th the hearing had risen to R. 13 in. and L. 78 in., for the ticking of the watch, and she experienced less difficulty in hearing conversation.

During the month of June she gave up her work al-

together and spent about twelve weeks at the east end of Long Island, on the seacoast. All through the summer she experienced no difficulty whatever with her hearing, and her health was excellent.

In September she returned to the city and resumed her work. But in the course of a few weeks she again began to have some difficulty in hearing; and, by the following February (1897), when she returned to me for treatment, her hearing had already become more noticeably impaired than at any time during the previous year. On questioning her I learned that she had been working harder than ever, and "had not had time" to take any outdoor exercise. The mucous membrane of the pharyngeal vault was again found to be hyperæmic, and an examination of both external auditory canals now revealed for the first time the presence of well-marked patches of eczema. Both tympanic membranes were also hyperæmic, but the eczematous patch in each of the canals did not extend as far inward as to the membrana tympani. The impairment of the hearing had progressed so far that I found considerable difficulty in making myself understood.

The treatment adopted was the same as that which I instituted when the patient first came under my care in 1896. But in conjunction with those measures I advised her to take, every morning, a full hour before breakfast, a tumblerful of hot water in which a scant teaspoonful of the Carlsbad Sprudel salts had been dissolved. I also recommended that the starchy and saccharine elements of her diet should be diminished.

The case is still, at the present time of writing (April, 1897), under observation; but already a very satisfactory degree of improvement has taken place, both in her general physical condition and in her power to hear. The tympanic membrane is no longer congested, and nothing remains of the eczema beyond one or two small sheets of cast-off epidermis which have not yet become fully detached from the living skin. At the end of five weeks she was obliged to give up taking the Sprudel salts, as they were beginning to cause a feeling of languor and weakness. In their place, accordingly, I prescribed Blaud's iron pills, thirty grains daily.

Very similar in character are the phenomena presented by the following case, of which, I regret to say, only very imperfect notes were kept.

Case VII.—The patient, a young woman of twenty-three, and previously of fair average health, consulted us on April 8, 1895, on account of difficulty in hearing. All winter long she had been working hard at her studies, being anxious to graduate with honor from one of the leading colleges for women. Slowly but steadily her hearing had grown more and more imperfect, until finally she experienced great difficulty in hearing what was said to her. Of her general health she had no special complaint to make, but her facial aspect revealed clearly the existence of well-marked anæmia.

On testing the hearing we found that she was almost totally deaf in the right ear. She could distinguish words only when they were spoken in a loud tone of voice almost directly into that ear. On the left side the hearing was still fairly useful; that is, she could distinguish words spoken in a loud tone of voice at a distance of eight feet.

The right external auditory canal was considerably narrowed by an eczematous inflammation of its cutaneous walls; and the corresponding tympanic membrane showed, in its upper posterior portions, decided evidences of hyperæmia and infiltration. (No memoranda relating to the condition presented by the left tympanic membrane were preserved, but it is more than likely that the lesions in this ear were of the same character as those observed in the right.)

An examination of the pharyngeal vault and nasal passages (by Dr. Lewis) revealed the existence of a small spur of bone on the left side of the nasal septum, and a moderate-sized mass of hypertrophied lymphoid tissue in the vault of the pharynx.

In addition to the local treatment (removal of both the nasal spur and the hypertrophied lymphoid tissue in the vault, mopping of the latter region with a fifteen or twenty grain silver-nitrate solution, inflations of the middle ears by Polizter's method), a certain amount of constitutional treatment was inaugurated. Restricted diet; decidedly increased amount of outdoor life; abstention from all studying; massage and the cold pack; the daily taking of iron and the Carlsbad Sprudel salts (a single morning dose); these were the more important constitutional measures adopted.

Under this treatment a certain amount of improvement took place, but only at a very slow rate. Toward the end of July it was found that the swollen condition of the right external auditory canal had almost disappeared, and the congested and infiltrated condition of the upper and posterior region of the tympanic membrane had diminished to a noticeable extent. Her general condition had also materially improved. But so far as her hearing was concerned, the result was certainly not satisfactory. The variations in hearing-power were very striking. For two or three days at a time she would be able to hear general conversation fairly well, and then she would go back almost to the point where she was when we first saw her.

At our urgent request her father then took her to Carlsbad, and she there underwent a stricter course of dieting and drinking of the waters than was practicable at her home near New York.

The patient was seen again on December 14th, a few weeks after her return from abroad. She reported that within twenty-four hours after leaving this port her hearing came back to her, and that all through the voyage she had experienced no difficulty in this respect; a fact which led us to infer that the treatment to which she had been subjected (by Dr. Lewis) had really accomplished more than appeared to be the fact when she left the city. She had gone through the prescribed course in Carlsbad, and up to the date named (December 14th) she had experienced nothing like a relapse. We tested her hearing, and found that she could hear the ticking of the watch fifty inches on the left side and twenty-two inches on the right. For whispered words the hearing-distance, right ear, was twenty feet. Her general health seemed to be excellent.

In January, 1896, the watch test showed: left ear, fifty-five inches; right ear, twenty-two inches. At a still later date (March 5th) the hearing, for the left ear, was found by the same test to be: left, fifty-seven inches (after inflation by Politzer's method, it rose to twelve feet); right, twelve inches (after inflation twenty-two inches). Then, a short time afterward, her hearing began again to give her some trouble, and her parents determined, upon their own responsibility, to send her for the second time to Carlsbad.

Since the date last named we have not seen the patient professionally. But through other members of the family we have learned that she visited Carlsbad, as already stated, and that during the past winter and spring her hearing has been quite good; but that occasionally she has a slight relapse, which lasts, however, only a short time.

In all these cases, which should, as I believe, be classified as gouty, the lesions actually observed in the external meatus and those rightfully assumed to exist in the tympanic cavity are doubtless one and the same in all essential respects. Dilated and therefore paretic blood-vessels; retarded circulation; escape of the watery elements of the blood both upon

the free surface and into the interstices of the tissues; proliferation of the cellular elements of the connective-tissue stroma; and the swelling or increase in bulk of the tissues thus affected—these are the alterations which a gouty diathesis commonly produces in the skin and mucous membrane of the human ear. But in rare cases, as in Case V., even the bony structures adjacent to such a limited area of gouty inflammation may become involved, and a disorganization not unlike that observed by Garrod in the knee-joint may ultimately take place. We are not yet able to state, from actual observation, what precise part the deposition of urates takes in these areas of gouty inflammation. But it is highly probable that such deposits are formed at these spots and that their presence plays an important part in exciting the inflammation and in retarding the flow of blood through the affected tissues.

In the two cases which I have reported above as illustrations of a gouty inflammation of the middle ear, I believe that we are justified in assuming that the pathological alterations must have taken place mainly in that part of the mucous membrane which borders upon the two fenestræ. In Case VI. the alterations noted in the tympanic membrane gave us, it is true, no warrant for this assumption; but, on the other hand, the comparatively rapid development of a marked degree of deafness and the subsequent gradual return of the hearing under the employment of suitable constitutional treatment can be better explained in accordance with this assumption than in any other way. In Case VII., however, the tympanic membrane furnished good evidence in favor of the belief that the most decided alterations in the mucous membrane were located at the posterior and upper corner of the tympanic cavity. But, after all, the most conclusive evidence of the gouty nature of all these lesions is that which is furnished by the results of an antigouty treatment, and by the comparatively insignificant results—indeed, sometimes even harmful in their nature—which follow purely local measures. If further evidence of the correctness of the diagnosis be needed in any given case, it may generally be obtained by a careful inquiry into the patient's mode of life as regards eating, drinking, physical exercise, etc., and also into the history of the different bodily ailments from which he may have suffered. Tophi at the finger-joints; stiffness and painful movements of the joints of the hand; "rheumatic" pains in different parts of the body; inflammation of one of the joints of the big toe; formication and heat, and afterward numbness of the skin along the outer sides of the thighs; a persistent, lame sensation, or a sensation of heat, in the top of the head; occipital neuralgia; cramps in the muscles of the calf of the leg; painful action, with more or less paresis, of the muscles of the shoulder; disturbances of digestion; depression of spirits; sleeplessness, etc.—these are among the concomitant symptoms which I find recorded in my notes of the different ear cases which I have set down as of gouty origin.

As this paper has already reached an inordinate length, I may be pardoned for not pointing out in detail the decided differences which exist between the two types of goutiness represented by Case I., on the one hand, and by Cases VI. and VII., on the other. Nor can I, for the same reason, enter upon a discussion of the question of treatment. However great may be the importance of this branch of the subject, it is somewhat foreign to the main purposes which I have had in view, viz., to arouse, if possible, fresh interest in a long-neglected subject, and at the same time to furnish at least a temporary scheme of the workings of a gouty diathesis in the different parts of the human ear. No matter how imperfect such a scheme may be, it cannot fail—if based upon actual observations—to furnish some aid to those who may afterward succeed in developing a more perfect presentation of the facts relating to this department of pathology.

COMPARATIVE DIAGNOSIS IN PULMONARY TUBERCULOSIS BY THE ROENTGEN RAYS—SERIES OF SEVENTY-THREE CASES.

By J. EDWARD STUBBERT, M.D.,

LIBERTY, N. Y.

The following cases are presented for the purpose of demonstrating that in the Roentgen rays and fluoroscope we possess accurate agents for diagnosing tuberculous changes of lung tissue in its various stages, using them not only as corroborative factors of results arrived at by auscultation and percussion, but in some instances discovering isolated foci of infection not recognizable by ordinary methods.

In addition these cases prove that the fluoroscope enables us to recognize more fully and accurately the degree, position, and relation of areas of infiltration and consolidation, and also delineates plainly the limits of these areas. It is unfortunate that as yet no satisfactory photographs have been taken of the images cast upon the fluoroscope plates.

In order that these observations might be of more value the examinations have been made by different physicians and written notes thereof taken by different nurses, it having been my desire to obviate all danger of bias due to familiarity with the results of examination by the ordinary method before using the fluoroscope, and *vice versa*. In addition, after fluoroscopic examinations have been made and notes taken in numerous cases, laymen have been requested to look into the fluoroscope and report the relative intensity of the transmitted light in different regions. Blue pencil marks were made by their direction and they have invariably coincided with the professional examinations. By reference to the following table it will be seen that in Cases X., XIV., and XLV., there was simply haziness of the infiltrated areas, and, in some cases of incipient trouble, at the apex. The first thing that is noticed may be a comparative haziness or indistinctness of outline of the clavicle on the affected side.

In cases of slight infiltration of one or two apices there is a haziness or fog between the light and the observer, the clavicle in other instances appearing to have a gauzy veil thrown over it. When there is marked consolidation the transmitted light is relatively less, the edges of the clavicle are indistinct, or the bone may be invisible. When there is present the same pathological condition at both apices it is an easy matter, by comparing the two sides, at once to decide upon which the disease has made the most progress. Comparative shadows at the apices are generally seen more distinctly from behind than in front, by directing the patient to bring his shoulders forward so as to separate as widely as possible the scapulæ and then placing the fluoroscope directly over the spinal column.

Ordinarily a practised eye can by these methods alone clearly distinguish areas of the most incipient infiltration, but, if it is desired to be more accurate in defining their limits, a metal rod may be placed evenly against the chest walls in front or behind and moved up and down with the fluoroscope until its outline becomes more distinct, which will indicate that the upper and the lower borders of the consolidation have been reached. If a pencil mark now be made along the edge of the rod and subsequently percussion practised, the area of dulness will be found between the lines.

In cases of complete dulness, say, to the second in-

terspace, with relatively less dulness for one or two interspaces below, a dark shadow will be seen over the first-named region, which will gradually shade off consecutively into haziness and normal reflex of light below, the area of haziness corresponding to the limits of relative dulness. In one or two instances slight haziness has been observed in spots which at the time showed no other physical signs of disease, but where they subsequently developed.

One case, number XXXI., is a good illustration of the appearance of a lung in which cavities exist. In cases in which the cavity is single, it appears as a bright reflex amidst an area of consolidation or shadow. This bright spot assumes the shape of the cavity. At times the observer can plainly discern a decidedly dark ring surrounding the dark spot (see case number XI.).

In Case XXVI. in which there were multiple cavities, the dense intervening tissue was shown in the form of dark streaks winding between the spots of bright reflex.

In another case, number II., the fluoroscope demonstrated a cavity which had presented no signs by percussion or auscultation, probably owing to obstruction at its outlet.

In Cases LXXII. and LXV., old pleuritic adhesions were seen as areas of absolute darkness, even more dense than the normal shadow over the cardiac region. In Case LXIX., displacement of the heart downward and to the right was easily marked out, also an old pleuritic thickening. Cardiac dilatation was discovered in one case. When I state that the exact areas in these last two cases were marked out by my house physician, William M. Bryan, without any knowledge of my previous diagnosis, the value and exactness of the fluoroscope as a diagnostic agent is well authenticated.

At different times we have outlined the convexity of the arch of the liver, which can be seen to rise and fall with expiration and inspiration. The cardiac pulsations are easily discernible.

A series of fifteen healthy cases was examined in order to familiarize the observer with normal reflexes and shadows.

A summary of the result of our investigations at the sanitarium shows:

1. Slight haziness indicates the beginning of tuberculous infiltration and may or may not be accompanied by dulness.

2. Decided shadows indicate consolidation, the extent of which is in direct relation to the comparative density of the shadow thrown on the fluoroscope.

3. Circumscribed spots of bright reflex, surrounded by narrow dark shadow rings or located in the midst of an area of dense shadow, indicate cavities.

4. Intense darkness, especially at the lower portion of the lung, indicates old pleuritic thickenings over consolidated lung tissue.

A great deal depends upon the intensity and steadiness of the light, and for this reason a motor generator is better than a vibrator, as the latter gives a flickering light. An eight-inch-spark coil was used. Considerable practice is necessary before the eye can appreciate perfectly the finer differences of shades and outlines.

At the Loomis Sanitarium the examination of patients by the *x*-ray is now as much a matter of routine as that by auscultation and percussion.

Comparative Diagnosis by Roentgen Rays.

Series of Seventy-three Cases.

Physical Examination.	*Fluoroscopic Examination.*
Case I.—Dulness left side infraclavicular space. Slight increase vocal resonance left side to fourth interspace.	Shadow over left upper lobe anteriorly to fourth interspace. To midline of scapula posteriorly.
Case II.—Consolidation right lung with crepitant râles anteriorly and posteriorly. Circumscribed area of increased vocal resonance third interspace near sternum right side.	Shadow from third interspace to base of lung. Extending from first interspace to third rib one inch from sternum, a bright light surrounded by dark ring.
Case III.—Consolidation right upper lobe. Crepitant and subcrepitant râles.	Sharply defined shadow right upper lobe. Ribs sharply defined until shadow is reached.
Case IV.—Right apex to third interspace, dulness, crepitant râles, and increased vocal resonance. Occasional crepitant râle base of right lung.	Shadow right apex to third interspace. Slight shadow base of right lung.
Case V.—Slight infiltration left side.	Shadow left side January 29, 1897. Absolutely clear February 26, 1897.
Case VI.—Infiltration right upper lobe. Crepitant and subcrepitant râles to second interspace.	Shadow to third interspace right side.
Case VII.—Dulness right and left apices. Crepitant râles left side, first and second interspaces. Increased vocal resonance left upper lobe and right apex to second interspace. Harsh respiratory murmur and crepitant râles right apex to line of nipple and extending under axilla to base of lung.	Shadow left upper lobe. Dim shadow diffused over right lung.
Case VIII.—Dulness right side to second interspace near edge of sternum. Increased vocal resonance, pleuritic friction sounds, broncho-vesicular breathing right side to third interspace.	Wedge-shaped shadow right side second interspace near border of sternum.
Case IX.—Dulness right and left apices. Increased vocal resonance, crepitant râles left side, first and second interspaces. Increased vocal resonance, broncho-vesicular breathing and prolonged expiration right side to second interspace.	Left apex dark shadow extending to second interspace. Right side, shadow to second interspace.
Case X.—Dulness, increased vocal resonance right apex to second interspace.	Very faint shadow to second interspace right side.
Case XI.—First stage affecting right lung. Second stage affecting left lung with physical signs of cavity in fourth interspace.	Shadow to fourth interspace left side. At fourth interspace a circumscribed area of light surrounded by dark ring. Shadow right side to third interspace.
Case XII.—Dulness outer third infraclavicular space left side. Increased vocal resonance, crepitant râles from left apex to fourth rib.	Shadow to fourth rib left side.
Case XIII.—Consolidation right upper lobe. Dulness, increased vocal resonance, crepitant and subcrepitant râles right side to third interspace.	Shadow to third interspace right side anteriorly and to lower angle of scapula posteriorly.
Case XIV.—Slight infiltration right upper lobe.	Faint shadow to fourth interspace right side.
Case XV.—Consolidation right upper lobe.	Distinct shadow right side to fourth interspace.
Case XVI.—Slight dulness right side anteriorly to second interspace, to midline scapula posteriorly. Exaggerated breathing and increased vocal resonance same region.	Slight shadow right side to second interspace.
Case XVII.—Dulness right upper lobe, bronchial breathing, increased vocal resonance whole right lung.	Whole right lung casts a shadow. More marked to third interspace.
Case XVIII.—Consolidation right upper lobe.	Shadow distinct to third interspace, right side.
Case XIX.—Dulness and increased vocal resonance to second interspace right side anteriorly and to midline of scapula posteriorly.	Shadow right apex anteriorly to third interspace. To midline of scapula posteriorly.
Case XX.—Dulness right upper lobe with broncho-vesicular breathing, pleuritic friction sounds, and crepitant râles.	Shadow right upper lobe to fourth interspace. To midline of scapula posteriorly.

Case XXI.—Dulness right apex to third interspace. No râles.	Shadow right side anteriorly to fourth interspace. To midline of scapula posteriorly.
Case XXII.—Slight dulness left side, also increased vocal resonance but no râles.	Shadow left side to fourth interspace.
Case XXIII.—Increased vocal resonance midline of scapula to base of left lung. Also crepitant râles. Increased vocal resonance right apex anteriorly outer third infraclavicular on forced inspiration.	Left lower lobe distinctly dark, shadow being well defined from fourth interspace to base of lung. Right apex shadowy to second interspace.
Case XXIV.—Dulness, increased vocal resonance, and crepitant râles over entire left lung.	Left side dark with good reflex above and below clavicle. Right side clear with good reflex.
Case XXV.—Dulness, broncho-vesicular breathing, and cog-wheel respiration right side to third interspace.	Shadow to third interspace right side. Very dark at apex. Left side clear.
Case XXVI.—Dulness, increased vocal resonance left side, apex to fifth rib. Cracked-pot resonance second interspace left side, mucous and crepitant râles.	A circumscribed area of light surrounded by dark ring in second interspace, left side. Lung dark to fourth interspace.
Case XXVII.—Dulness both apices, more marked left side. Bronchial breathing right second and third interspaces. No râles.	Shadow extending to third interspace left side. Shadow to second interspace right side.
Case XXVIII.—Both apices dull. Crepitant râles, increased respiration murmur, and increased vocal resonance apex to base left lung.	Distinct shadow over whole of left lung, more marked at apex. Shadow at right apex to second interspace.
Case XXIX.—Dulness left apex to second interspace, also bronchial breathing.	Shadow left apex to second interspace.
Case XXX.—Decided dulness right side to third interspace. Cracked-pot resonance second interspace right side. Relative dulness whole right lung.	Shadow whole right lung, more marked at apex. Bright spot second and third interspace. Left lung negative.
Case XXXI.—Dulness right infraclavicular space. Increased vocal resonance, amphoric breathing, and cracked-pot resonance to fourth interspace right side.	Shadow to fourth interspace right side. Bright spots second interspace right side, surrounded by dark ring.
Case XXXII.—Increased vocal resonance apex and infraclavicular space. Diminished respiration murmur, cog-wheel respiration right side to second interspace. Crepitant râles right apex.	Decided shadow right apex to third interspace.
Case XXXIII.—Dulness left lung to fifth interspace. Slight crepitation with pleuritic friction sounds left apex posteriorly.	Shadow from left apex to fourth interspace. Shadow more marked at apex.
Case XXXIV.—Dulness, bronchial respiration, increased vocal resonance right apex and infraclavicular space.	Shadow right apex to second interspace.
Case XXXV.—Dulness both apices. Increased vocal resonance to second interspaces. Crepitant râles to second interspaces both apices.	Shadow to third interspace right side anteriorly and midline scapula posteriorly. To second interspace left side anteriorly and upper angle scapula posteriorly. Faint shadow to third interspace right side.
Case XXXVI.—Increased vocal fremitus posteriorly and in axilla. Slight dulness right upper lobe to third interspace.	
Case XXXVII.—Infiltration right apex. Slight dulness to second interspace.	Shadow to second interspace right side.
Case XXXVIII.—Dulness and increased vocal resonance both apices. Relative dulness to fourth interspace right lung.	Shadow both apices. Shadow to third interspace right side.
Case XXXIX.—Dulness right and left apices. Crepitant râles and increased vocal resonance left apex. Increased vocal resonance and crepitant râles fourth interspace.	Shadow left apex very well marked. Shadow right lung to second interspace, remainder of lung hazy.
Case XL.—Increased vocal resonance right upper lobe to second interspace. Relative dulness to third interspace.	Shadow to second interspace right side anteriorly and upper angle of scapula posteriorly.
Case XLI.—Dulness right side. Broncho-vesicular breathing and increased vocal resonance to third interspace right side. Crepitant râles second and third interspaces right side.	Shadow right apex to third interspace.
Case XLII.—Dulness left side to second interspace. Increased vocal resonance and bronchial breathing with pleuritic friction sounds over right lung.	Shadow left side to third interspace. Right lung slightly hazy.
Case XLIII.—Dulness both apices. Broncho-vesicular respiration right side.	Shadow both apices, more pronounced on right side.
Case XLIV.—Dulness both apices. Crepitant râles right upper lobe to second interspace.	Shadow both apices. Both clavicles indistinct. Shadow to second interspace right side.
Case XLV.—Slight dulness, prolonged expiration, and increased vocal resonance right apex to second interspace.	Very slight shadow right apex to second interspace.
Case XLVI.—Dulness, increased vocal resonance, pleuritic friction sounds, broncho-vesicular respiration, and prolonged expiration left side to fourth interspace. Slight dulness right apex to second interspace.	Shadow left upper lobe to fourth interspace. Shadow right upper lobe to second interspace.
Case XLVII.—Dulness and increased vocal resonance right upper lobe to second interspace.	Shadow right apex anteriorly to second interspace. To midline of scapula posteriorly.
Case XLVIII.—Slight dulness and increased vocal resonance right apex and infraclavicular space.	Slight shadow right apex to second interspace.
Case XLIX.—Dulness right infraclavicular space. Slight crepitation right infraclavicular space anteriorly.	Slight shadow right upper lobe to second interspace anteriorly. To midline of scapula posteriorly.
Case L.—Duiness, increased vocal resonance, and crepitant râles left upper lobe.	Distinct shadow to second interspace left side anteriorly. To midline posteriorly.
Case LI.—Increased vocal resonance third interspace right side. Absence of respiratory murmur right axilla in line with nipple.	Right upper lobe hazy to third interspace. Reflex better left side.
Case LII.—Dulness first interspace. Sibilant râles upper angle of scapula. Pleuritic friction sounds right side posteriorly. Increased vocal resonance left side anteriorly; crepitant râles anteriorly to third interspace.	Shadow right apex; left side shadow to third interspace anteriorly and midline of scapula posteriorly.
Case LIII.—Cog-wheel respiration, increased vocal resonance right apex. Cog-wheel respiration, slight increase of vocal resonance first to third interspaces left side.	Shadow right apex. Shadow well defined to second interspace anteriorly and to midline of scapula posteriorly left side.
Case LIV.—Dulness. Decided increase of vocal resonance. Crepitant râles and deficient respiratory murmur right lung, more marked at apex. Increase of vocal resonance and broncho-vesicular respiration left apex.	Shadow both apices. Entire right lung hazy, more marked at apex.
Case LV.—Dulness and broncho-vesicular respiration both apices. Diminished respiratory murmur right apex. Crepitant râles and diminished respiratory murmur over whole of left lung.	Shadow both apices and entire left lung hazy.
Case LVI.—Dulness and increased vocal resonance right apex.	Slight veil anteriorly and posteriorly right apex.

Case LVII.—Dulness right side and in infraclavicular space and first interspace left side. Both lungs dull posteriorly, right side more so. Increased vocal resonance right side. Crepitant râles right apex. Bronchophony crepitant râles, and semiliquid râles right side opposite spine of scapula.	Right apex nearly opaque. Whole of right lung very dark. Light spot in second and third interspace right side. Shadow left side down to second interspace.
Case LVIII. — Consolidation both apices, more marked posteriorly left side.	Shadow both apices, more marked to second interspace left side.
Case LIX. — Dulness. Broncho-vesicular respiration. Increased vocal resonance left side to second interspace.	Shadow left apex to second interspace, more marked posteriorly.
Case LX. — Dulness both apices. Increased vocal resonance and cog-wheel respiration both upper lobes.	Shadow right apex to second interspace. Shadow to second interspace left side.
Case LXI.—Dulness, increased vocal resonance. Rude bronchial respiration with jerky respiration right side to nipple. Dulness, bronchial respiration, rude in character, left side to third rib.	Right side distinct shadow to nipple. Left side shadow distinct to third rib, remainder of lung hazy.
Case LXII. — Dulness, broncho-vesicular respiration, crepitant râles, respiratory murmur present, expiratory murmur absent, right side to fourth interspace. Dulness, bronchial breathing, and increased vocal resonance left lung apex to base.	No reflex left lung. Absolute shadow apex to base anteriorly. Hazy to second interspace right side anteriorly. Absolute shadow below. Shadow down to upper angle of scapula right side posteriorly. No reflex left side posteriorly.
Case LXIII. — Dulness, cog-wheel respiration, increased vocal resonance, broncho-vesicular respiration right side to third interspace. Dulness, increased vocal resonance, and bronchial breathing left side to third rib.	Shadow right side to third rib. Hazy to third interspace left side. Shadow right and left to midline of scapula.
Case LXIV.—Dulness, increased vocal resonance, faint crepitant râles, cog-wheel respiration, right side to third interspace.	Distinct shadow right apex to third rib.
Case LXV.—Dulness, increased vocal resonance, crepitant and subcrepitant râles, prolonged expiration, right side to third interspace. Dulness, increased vocal resonance crepitant râles, bronchial breathing, left side to second interspace. Broncho-vesicular breathing in third and fourth interspaces left side.	Shadow both apices, to second interspace left side, to third interspace right side. Shadow opposite heart fourth interspace almost identical with cardiac shadow.
Case LXVI.—Increased vocal resonance apex right to lower angle of scapula. Liquid râles upper angle scapula. Cracked-pot resonance left infraclavicular space.	Shadow whole of right lung. Shadow to first interspace left side.
Case LXVII.—Increased vocal resonance right apex to second interspace. Increased vocal fremitus, dulness, increased vocal resonance, crepitant râles, and broncho-vesicular breathing left side.	Shadow right side to second interspace, more marked above clavicle anteriorly. Shadow outer half left lung shading to haziness toward sternum. Line of shadow distinct below fourth interspace.
Case LXVIII.—Increased vocal resonance right lung upper lobe. Crepitation right apex.	Slight haziness right side to nipple, more marked at apex.
Case LXIX.—Increased vocal resonance, dulness right side to third rib. Pleuritic friction sounds, suppressed respiratory murmur fourth interspace to base of lung. History shows an old attack of pneumothorax with effusion left side, with hypertrophy of the heart to the right.	Shadow right apex to third rib. Shadow left side fourth interspace to base of lung (pleuritic thickening). Heart hypertropied to the right in line with and one inch above right nipple. Apex beat in fourth interspace border of sternum. Slight haziness right side to nipple, more marked at apex.
Case LXX.—Dulness to nipple, crepitant râles and pleuritic friction sounds apex to base right side. Crepitant and sonorous râles, pleuritic friction sounds left side to third rib.	Shadow from apex to base right lung. Shadow left side to third interspace.
Case LXXI.—Dulness, increased vocal resonance, crepitant râles right side to third rib.	Shadow right side to second interspace anteriorly and midline of scapula posteriorly.
Case LXXII.—Increased vocal resonance, dulness apex to second interspace right side.	Shadow right side apex to second interspace. Shadow nipple to base of lung right side.
Case LXXIII. — Dulness to third interspace anteriorly to upper angle scapula posteriorly right side. Marked vesicular tympanitic resonance first interspace, cracked-pot resonance infraclavicular space right side. Whisper resonance right apex to upper angle of scapula posteriorly right side with amphoric breathing. Increased vocal resonance, crepitant râles at spine of scapula to base of lung right side.	Circumscribed area of light surrounded by dark ring, first interspace right side. Remainder of lung hazy.

Progress of Medical Science.

The Treatment of Rheumatoid Arthritis with Methylene Blue.—Philpots (*British Medical Journal*, March 27, 1897, p. 781) relates that in several very obstinate cases of rheumatoid arthritis he has administered methylene blue, two grains twice daily after food, with the greatest of benefit, each case showing marked improvement soon after the commencement of treatment. Not only does the arthritic process appear to be arrested, but the drug has besides a favorable influence upon the general condition, improving nutrition and leading to increase in weight.

"Gonococcus" Pyæmia.—Dr. E. Finger (*Wiener med. Wochenschrift*) says that it is generally acknowledged that many complications of gonorrhœa—such as arthritis, tenosynovitis, bursitis, periostitis, endocarditis, and pleuritis—are dependent upon the presence of the gonococcus, the organisms being carried from the point of infection to some distant part. It is not generally accepted as proven that the gonococcus rarely excites superficial inflammation of the mucous membranes, the micro organisms acting far more frequently as an exciter of metastatic inflammation and suppuration in company with pyogenic cocci, streptococci, and staphylococci. Shon and Schlaginhaufer have shown that the morbid processes produced by the coccus are not at all dissimilar in some respects to those caused by the pus cocci. The pus cocci permeate the tissues rapidly and cause their rapid breakdown, while the gonococcus is least active and takes the paths of least resistance through the fissures and lacunæ of the epithelium and connective tissue. Again, the inflammation caused by the gonococcus is entirely purulent; the formation of granulation tissue is early and abundant. The gonorrhœic process tends to the formation of connective tissue and scars, in the urethra as stricture, in the prostate as destruction of the gland, in the suprarenals as thickening of the organs, and in the joints as ankylosis. The gonococcus is destroyed when exposed to a temperature of 103° or 104° F. for several hours, while the pus cocci are less susceptible to such a temperature. From these considerations it is shown that the gonococcus is less active and more easily destroyed than the pus cocci, and that the lesions produced by the former tend toward recovery more readily than those produced by the latter.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 22, 1897.

THE AMERICAN MEDICAL ASSOCIATION.

THERE is soon to be held in Philadelphia the annual meeting of the American Medical Association, at which will be celebrated the completion of the first half-century of its existence. Great preparations are being made by the physicians of Philadelphia to realize the expectation that this will be the most successful meeting the association has ever had, and we sincerely trust the result of these labors will fully meet the highest anticipations of Dr. Hare and his efficient co-workers on the committee of arrangements.

There are apparently but two dangers ahead, and we trust these can be avoided by skilful management. The first of them is the enormous list of papers with the reading of which the various sections are threatened—seventy-six papers in the section on laryngology and otology, ninety-three in the section on general medicine, and others in proportion. Of course many of these are merely announced as to be read, the authors never meaning to read them, even if they ever write them but with these aside there will be enough left to occupy every minute of the four sessions of each section, to weary every suffering member of the section, and effectually to strangle all discussion. No good to anybody can come from the hurried reading of paper after paper, shutting off the long-winded speakers in the middle of their argument, and so limiting discussion as to make it barren of any result. This is a danger to which the association is exposed in its scientific character. But what most menaces its usefulness and will always, as long as it lasts, prevent the American Medical Association from attaining the position it should occupy as the representative body of the American medical profession is the everlasting quarrelling which disturbs the general meetings and disgusts all who think the grabbing of offices is not the chief end of medical man. Of late years the great bone of contention has been the secretaryship of the association. The present most capable secretary, Dr. Atkinson, has performed the arduous duties of his office in a most efficient manner for many years, and a meeting without his genial presence might, indeed, be a medical meeting of some sort, but it would hardly seem like one of the American Medical Association. Even the father of the association himself would scarcely be more missed. Yet for years this faithful servant of the association has been compelled to sit upon the platform and listen to accusations of incompetency and worse brought against him by young men who were unheard of and undreamed of when he first took up the cares of the office which he fills with so much honor to the society. The fact that the constitution of the association makes the office of secretary a permanent one has hitherto stood in the way of Dr. Atkinson's enemies; but at this coming meeting, held in the City of Brotherly Love, the home of the secretary and the birthplace of the association, these men hope to carry through an amendment to the constitution whereby they will be enabled, if they can pack the meeting efficiently, to depose the secretary and elect another man to serve in his place. We hope for the good of the association and for the honor of American physicians that their plans may be thwarted.

THE PREPARATION FOR ANÆSTHESIA.

THE dangers attendant upon the use of chloroform or ether pushed to the production of profound anæsthesia are too well known to require cataloguing, yet they are often forgotten, despite the many warnings in the shape of sudden death on the operating-table. Many of these deaths are unavoidable, yet many again, we fear, might have been avoided by the exercise of ordinary or extraordinary care on the part of the anæsthetist. And even when there has been no question of jeopardy of the patient's life, his discomfort and that of the operator, and especially of the anæsthetizer, may have been greatly increased by the absence of these precautions.

In *Treatment* for March 25, 1897, Dr. J. W. Silk contributes an interesting article on the preparatory treatment of patients subjected to anæsthesia, in which he offers several suggestions in following which we may often save both ourselves and our patients a world of trouble. The anæsthetic is almost always better taken, he says, if the patient has been subjected for a brief period to a hospital régime, by which he means rest of body and mind, and regulation of the bodily functions by attention to the diet, confinement to bed in some cases, though not all, and removal in any case from the usual worries and disturbing influences of the every-day life. The bowels should be moved by a purge given the evening before the operation, and care should be taken in most cases to see that the stomach is empty. Starvation, however, is to be avoided, for the patient may need all his strength to withstand the severe tax upon it of the operation. A little stimulant in the shape of hot broth may be given three or four hours before the operation, but milk should be avoided as being too slow of digestion. In special cases a nutrient enema containing the yelk of an egg and an ounce each of beef tea, milk, and brandy, may be given half an hour before the patient is placed upon the operating-table.

As a general rule, Dr. Silk does not favor the giving of drugs immediately before the anæsthetic with a view of increasing the action of the latter, or of guarding against its possible evil effects. He deprecates

the routine use of morphine, believing that its advantages are illusory, and that its tendency to mask the symptoms of over-narcosis may conduce to a fatal result. It may, however, be of possible service in cases of cerebral surgery by reason of its action in contracting the vessels. It is otherwise as regards strychnine, for this drug may obviate or reduce the shock of the operation, and it is claimed by some that the tendency to sickness is lessened by its use. In the feeble, therefore, and in severe operations one-fiftieth grain may be injected immediately after anæsthesia has been induced, and the dose may be repeated toward the end of the operation, or oftener if necessary. This can do no harm and may do a great deal of good.

The use of brandy by the mouth as a preliminary to the administration of an anæsthetic is, both physiologically and clinically considered, highly irrational. It may become necessary, however, in cases of impending syncope from fright, and possibly in some few instances its administration may have a good moral effect upon the patient, but, as a general rule, Dr. Silk holds it is certainly not a desirable proceeding.

And finally, as regards the position of the patient, the best rule to adopt, the writer says (and he speaks from long experience as the anæsthetist at King's College Hospital), is to accept the position assumed by the patient as being most convenient and comfortable to himself. In the majority of cases this will be supine, but in exceptional cases, *e. g.*, empyema, the patient may prefer to be on his side, and the administrator must adapt himself accordingly. He thinks it is hardly necessary to point out that the administration of chloroform to a patient in the sitting position, as in a dental chair, is a proceeding which is quite unjustifiable. And, of course, whatever position is adopted, the greatest possible respiratory freedom must be insured, and everything in the shape of belts, stays, etc., that may tend to obstruct the breathing, must be removed.

THE EFFICACY OF ANTIDIPHTHERITIC SERUM.

A commission has lately been held in France to inquire into and to report upon the efficacy of antidiphtheritic serum, with the view to discover the most effective system in force for obtaining and distributing the serum. The commission, which commenced its task in February, 1895, has just completed its session, and has made its report. The matter in point has been closely studied both in France itself and in other countries by the commission, and its members have arrived at the conclusion that the best system is that in vogue in Germany. The sero-therapeutic institutes there are allowed the greatest possible liberty; they can prepare serum more or less active, following their own methods, with this limitation: the government reserves to itself the right of prescribing the manner in which the serum shall be presented to the public. Its quality must be up to a fixed standard, and with the object of protecting the druggists and the public the serum is submitted to the scrutiny of a State board, composed of the bacteriologists of Berlin, who verify the assertions of the manufacturers and affix on the flasks containing the serum the mark of the State board. The commission rejected the French system, yet, on account of the great difficulties connected with the application of the German system to France, it has been decided not to recommend its adoption.

News of the Week.

Sickness among School Children.—Diphtheria and scarlet fever are unusually prevalent in Jersey City, especially in the hill section. Moved by the occurrence of a few cases of small-pox in New York, the board of education in Jersey City has given orders that all the pupils in the school shall be revaccinated.

A Prolific Family.—With the advent of a daughter to the Duke and Duchess of York, the number of grandchildren and great-grandchildren of Queen Victoria is now an even thirty.

Jubilee Lightning.—Many British and Irish medical men, as well as some in the colonies, are living in the anxious anticipation of receiving knighthood or perhaps even a baronetcy from the Queen by way of marking the completion of her sixty years of faithful service in the employ of the British government. There are even whispers of another medical peer, but that would really be almost too good to be true.

A Persistent Spitter.—A man named Bradbury, who had previously been arrested and fined $5 for spitting on the floor of a San Francisco street car, was arrested a second time a few days ago for the same offence, and was sentenced to imprisonment for twenty-four hours. He protested against the "outrage," holding with a New York civil justice that it is the inalienable right of a free-born American citizen to expectorate whenever and wherever he pleases.

Clinics Abandoned.—Five clinics in the Brooklyn Throat Hospital have been discontinued, the reason given being that they were for the treatment of diseases in no way related to the throat, and were consequently not provided for in the charter of the institution.

The Prince of Wales' Hospital Fund.—It is reported in *The Sun* that the jubilee fund for the benefit of the London hospitals, which was under the special patronage of the Prince of Wales, promises now to fall far short of the desired and expected amount, not more than one-sixth of the needed sum having been as yet subscribed.

Another Medical Senator.—After a protracted struggle in the Kentucky legislature, that body, on its sixtieth ballot, elected Dr. William J. Deboe as United States senator. During the sessions Dr. William G. Hunter led in the race, but always lacked from one to five votes. Both of these gentlemen are well-known and reputable physicians. Dr. Hunter is now a member of the national house of representatives.—*The Lancet-Clinic.*

The Colorado State Medical Society. — The annual meeting of this society will be held on June 15–17, 1897, in Denver. The president of the society is Dr. Robert Levy, and the secretary Dr. Herbert B. Whitney, both of Denver.

Dr. Lucy Waite, the wife of Dr. Byron Robinson, has been elected head physician and surgeon to the Mary Thompson Hospital of Chicago. The hospital is devoted to the diseases of women and children; it was established thirty years ago, and has a capacity of eighty beds.

Philadelphia County Medical Society.—A stated meeting of the Philadelphia County Medical Society was held on May 12th, the president, Dr. James Tyson, in the chair. Dr. J. Madison Taylor made a report as chairman of a committee on the Health Protective Hospital for Contagious Diseases. The proposal is to build a hospital for the reception of patients with contagious diseases who can afford to pay and do not desire to avail themselves of the privileges of the municipal hospital for contagious diseases. Dr. Edwin Rosenthal read a paper on "The Municipal Hospital of Philadelphia," in which he pointed out the merits and the demerits of this institution, and concluded with a warm plea for the establishment of a pay hospital for contagious diseases. In this he was sustained by Dr. Benjamin Lee, secretary of the State board of health. Dr. H. Augustus Wilson described and exhibited a portable door attachment for applying suspension. The device is an exceedingly simple one, and is constructed on the principle of the painter's jack, and should greatly extend the applicability of a useful means of diagnosis and treatment.

The Late Dr. Clark Wright.—The West End Medical Society at its regular meeting, May 1, 1897, adopted the following resolutions:

"We, the members of the West End Medical Society, have learned with regret of the death from pneumonia, on March 16, 1897, of our late fellow-member and associate, Dr. Clark Wright.

"As a physician he was endowed with high scholarly attainments, a thorough knowledge of his profession, and a kind and sympathetic nature. As a friend he was endeared to all who knew him by his genial and happy manner, and by his readiness to extend a helping hand. Be it

"*Resolved*, That this expression of our regret and appreciation of our loss be entered on the minutes, and that a copy thereof be sent to the family and that it be published in the medical journals of this city.

"Alexander H. Travis, M.D,
"F. Spencer Halsey, M.D.,
"*Committee.*"

Vital Statistics of Philadelphia.—For the week ending May 8th there were reported to the Philadelphia board of health 418 deaths, of which 122 occurred in children under the age of five years. The whole number was 71 less than that of the previous week, and 9 more than that of the corresponding week of the preceding year. The individual causes of the largest number of deaths were as follows: Pneumonia, 64; pulmonary tuberculosis, 32; heart disease, 30, apoplexy, 20. There were reported during the week 102 cases of scarlet fever, 94 of diphtheria, and 77 of typhoid fever.

The Health Department of Baltimore has decided to make systematic bacteriological examinations among pupils of the public schools whenever a case of diphtheria is reported from any one of the number. The first examination was made a short time ago, and the bacillus of the disease was found to be present in the throats of several pupils, who were ordered not to attend school. Dr. McShane, the health commissioner, is satisfied that by this means an epidemic has been prevented.

College of Physicians of Philadelphia.—A stated meeting of the section on general medicine of the College of Physicians of Philadelphia was held on May 10th, Dr. J. P. Crozer Griffith in the chair. Dr. D. J. Milton Miller exhibited the patient and reported a case of myxœdema in a woman, forty-eight years old, in which marked improvement followed the administration of thyroid extract. The patient was a small woman, of short stature, in whom, however, the myxœdematous symptoms had been noticed only during the last three or four years. Dr. James Tyson read an account of and exhibited a patient presenting fine crepitation over a wide extent of both lungs, together with emphysema, feeble heart, and inspiratory retraction of the intercostal spaces. There had been considerable loss of weight, but there was absolutely no cough and no expectoration. Respiratory frequency was increased, but there was no elevation of temperature or increased frequency of pulse. There was a difference of opinion as to whether the condition was pleural or vesicular. Dr. Tyson detailed also the report of a case of cirrhosis of the liver with enlargement and gall stones, characterized clinically by attacks of biliary colic, jaundice, chills and fever, and sweating.

Politics in State Asylums.—The governor of Missouri recently appointed three homœopathic physicians to the board management of State Lunatic Asylum No. 1, near Fulton, turning out the regular physicians on the board to make room for them. It is claimed that there was no popular demand for this change, and that it was made against vigorous protest solely for political reasons.

Dr. John B. Hamilton, formerly of the Marine Hospital Service under Surgeon-General Wyman, has gone to the Illinois Northern Hospital for the Insane at Elgin, to assume the duties of superintendent. We understand that, while abandoning his extensive surgical practice in Chicago, he will still be retained as editor of the *Journal of the American Medical Association.*

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending May 8, 1897. May 3d.—Medical Inspector J. C. Wise detached from marine headquarters, Washington, May

15th, and ordered to Columbus, Ohio, as delegate to the Association of Military Surgeons; Medical Inspector J. C. Wise, after duty at Columbus, ordered to the *Philadelphia* as fleet surgeon; Medical Inspector J. A. Hawke detached from the *Philadelphia* on relief, and granted three months' leave; Passed Assistant Surgeon C. H. T. Lowndes ordered to duty at marine headquarters; Surgeon C. U. Gravatt ordered to United States steamship *San Francisco* (fleet) per steamer, May 22d; Medical Inspector H. J. Babin detached from the *San Francisco*, on relief, ordered home, and granted three months' leave. May 5th.—Passed Assistant Surgeon G. T. Smith ordered to the naval hospital, New York, temporarily, May 15th; Assistant Surgeon M. S. Elliott detached from the *Columbia* and ordered to the *Indiana*. May 6th.—Medical Inspector J. M. Flint ordered to examination for promotion, Washington, May 12th.

Obituary Note.—Dr. Elizabeth Gable, one of the assistant physicians in the insane department of the Philadelphia Hospital, died on May 7th, at her home in York County, Pa.

Priority in Medical Degrees for Colored Women.—Dr. George T. Brown, of Euclid, N. Y., writes: "With regard to the matter of priority in the granting of medical licenses to colored women, I would say that Dr. Sarah M. Logum, daughter of the late Bishop Logum of the A. M. E. Church, received the medical degree from Syracuse University in February, 1876, thus antedating Dr. Wakefield by more than twenty years."

The Next Hosts of the American Medical Association.—Denver has nearly raised the $15,000 in promises needed to entertain the American Medical Association if it accepts the invitation to meet in that city in 1898. The other cities which hope to entertain the association that year are Columbus and Omaha.

Prof. Albert v. Kolliker, of Würzburg, hopes to celebrate, on July 6th next, the eightieth anniversary of his birth and also his fifty-year jubiläum as a medical teacher.

The German Public Health Association.—The twenty-second annual meeting of this association will be held at Carlsruhe on September 14th and three following days. Among the subjects on the programme are a discussion on the abuse of alcohol, on the adulteration of foodstuffs, on the disinfection of dwellings, and on the hygiene of baths and health resorts.

Resignation of the Health Commissioner of Cincinnati.—Dr. J. W. Prendergast, in a letter written on April 22d to the board of administration of Cincinnati, said he felt that, in view of the charges of blackmail preferred against him by a drug manufacturer of New York, his usefulness as health officer of the city was impaired, and he therefore, although innocent, resigned. The resignation was accepted and Dr. J. M. Withrow was appointed to the vacancy. Dr. Prendergast was charged with attempting to extort a bribe from the manufacturer, on the ground that certain of the latter's preparations were impure, and that as health officer he could protect him from prosecution by the Pure Food Commission.

Dr. Otto G. T. Kiliani has been appointed surgeon to the German Hospital in this city.

Pension Examining Surgeons.—Commissioner of Pensions Evans holds that every pension examining surgeon in the United States, irrespective of the amount of fees he receives, is beyond the pale of the civil service law and may be removed at the pleasure of the commissioner. The consequence of this decision will be, the Washington *Post* says, the removal of six hundred Democratic physicians from two hundred examining boards all over the country, and the appointment in their stead of six hundred Republicans.

The Medical College of Alabama, in Mobile, has united with the University of Alabama, and will henceforth be known as the Medical Department of the University of Alabama.

Guy's Hospital in London has received $5,000 from Baroness de Hirsch toward the cost of building a nursing-home in connection with the hospital, in memory of the late Baron de Hirsch, who died on April 21, 1896.

The New Hampshire Medical Society.—The one hundred and sixth annual meeting of this society will be held at Concord on May 24 and 25, 1897. The president of the society is Dr. Abel P. Richardson, of Walpole; and the secretary, Dr. Granville P. Conn, of Concord.

The New York Celtic Medical Society will hold its regular monthly meeting on Thursday, May 27th, at the residence of Dr. Manly. The society proposes to increase its limit of membership to thirty, and to establish an honorary membership.

Strange Organs.—Israel is reported to have recently removed, on account of sarcoma, the entire intestinal reproductive organs of a girl aged but seven months. Perfect recovery resulted in about forty days.—*Medical Age.*

From Chicago to Moscow.—A correspondent of the *British Medical Journal*, writing from Chicago, says that about fifty of the leading medical men of that city have made up a party to make a tour of the leading cities of Europe, Moscow being the principal objective point.

A Society for the Repression of Infectious Diseases has been founded in St. Petersburg by Princess Eugenie Maximilianovna von Oldenburg.

A Gift to a Hospital.—Mr. Charles H. Senff donated $10,000 to the Flushing (L. I.) Hospital, at a meeting of the trustees of that institution held a few days ago, for the construction of a surgical operating-room. This is Mr. Senff's third donation to the hospital. Several years ago he gave $5,000 for the construction of a babies' ward, and three years ago he contributed $1,500, when the institution was in need of that amount to meet current expenses.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

(Continued from page 713.)

AMERICAN ORTHOPÆDIC ASSOCIATION.

Thursday, May 6th—Third Day.

Treatment of Deformities of the Knee Resulting from Tumor Albus.—DR. JOEL E. GOLDTHWAIT, of Boston, read a paper with this title, in which he considered especially cases in which the patella has become adherent. The author said that the conditions to be met in ankylosis of the knee with deformity were very different from those at the hip. In the latter the treatment was practically the same, viz., an osteotomy, while in the knee frequently a simple osteotomy was not sufficient. In certain cases there was complete ankylosis with flexion; in others flexion with subluxation and the patella adherent to the femur, but no true bony ankylosis. In these cases forcible straightening and dislodgement of the patella by means of the genioclast were all that was necessary. Occasionally we saw cases of bony ankylosis and flexion due to neglect of treatment after excision. In these cases a wedge-shaped osteotomy was indicated. There was another set of cases, in which with flexion there was subluxation of the tibia and a displacement outward with rotation, so that the outer end of the bone fitted in between the condyles of the femur. Those cases which had interested him most were those in which the patella was adherent to the femur, but a certain amount of motion, say, 20° to 40°, existed in the joint. The limit of motion was due to the tibia striking against the patella. If in these cases sufficient force were exerted to tear the posterior capsule the limb could be straightened, but the tibia would be subluxated unless the patella were removed. In one case, that of a girl of fourteen, with 35° of motion, he had used the genioclast and then removed the patella and part of the condyles. The result had been a very long convalescence, a discharging sinus, a weak limb, and a loss of all the motion. In the last three cases, to avoid these unfortunate results, he had not touched the joint, but had gone in above and done a Macewen operation, correcting also the lateral deformity, and then putting up the limb in slight hyperextension. The convalescence had been rapid and the results very satisfactory, as the flexion was overcome and the slight motion at the knee retained. One patient, who had been obliged to wear a brace, was now going about without apparatus and only a moderately high shoe.

Excision of the Hip.—DR. R. W. LOVETT, of Boston, reported the work which had been done at the Children's Hospital during the last eighteen years. During that time eleven hundred new cases had come for treatment, and excision had been performed fifty times, or in about five per cent. of all the cases. The indications for the operation had been: 1. Failure of the general health. 2. Rapid destructive local processes, not influenced by efficient mechanical therapeutic measures. 3. Excessive pain and tenderness at a late stage of the disease. 4. The formation of sequestra in the joint. The mortality of these cases of late excision had been at least fifty per cent., and the results in the cases which could be traced were much more satisfactory than might have been expected from the extent of the disease for which the operation was done. Mechanical treatment was advocated up to the last possible moment, but attention was called to the fact that excision furnishes a possibility of excellent results even when done very late. One of the cases reported had practically normal motion, even though a large amount of bone was removed.

DR. W. R. TOWNSEND, of New York, reported the results of the operation of excision of the hip performed at the Hospital for the Ruptured and Crippled during the years 1888 to 1895 inclusive. In this time 2,295 persons with hip-joint disease applied for treatment, and 121 excisions were performed upon 119 patients, which showed what a small proportion was subjected to operation, and explained the position of the institution in regard to excision. In no case was excision done except with the view of saving life. It was never done in the first stage except in one case of double hip disease, and all but six cases were complicated by an abscess or sinus. It was resorted to only when other means had apparently failed. In some the treatment had been thorough and efficient; others had had no proper home care. A large majority of the cases was septic before the operation was done, which probably affected the ultimate result. Many of the cases he thought would have done better if amputation at the hip had been performed. Of the 121 excisions he had been able to trace 101—number of patients, 99. Of these, 52 were known to have died, 51 in consequence of the disease and 1 from drowning. Of the 52 deaths, 28 were from exhaustion, 9 from shock, and 9 from tuberculous meningitis, and in only 1 could the operation be held responsible, in which the symptoms appeared twelve days after. Thirty-seven died within six months, and 47 within one year. Of the 47 patients living, 26 were cured with varying degrees of shortening and deformity, and of the remaining 21 fully one-half was in bad condition and would probably die.

DR. SHAFFER stated that as a result of continued experience he felt that excision of the hip was rarely called for, and he appealed for more time in these cases; also for climatic change in apparently desperate cases. He had found that his country patients did much better than the city patients, and he thought every orthopædic hospital ought to have a country home.

DR. BURRELL said that in his opinion excision was indicated when the clinical evidence showed that the patient was irredeemably losing ground.

DR. SHERMAN, of San Francisco, remarked that his position on this question had changed somewhat: that formerly he had done excision much earlier than the time stated by Dr. Burrell, but now he had children under conservative treatment on whom he would have operated a few years ago. Relapses, infection, and the continuance of the disease; the shortening, and, worse than the shortening, the adduction, which frequently followed excision, had led him to take a rather more conservative position than formerly.

The Prognosis of Hip Disease under Efficient Treatment.—DR. LE ROY W. HUBBARD, of New York, read a paper with this title. He said that in the beginning of the treatment of any case of hip disease the first questions asked by the parents were: Will my child get well? Will he be deformed and limp for the rest of his life? How long must he be under treatment? These were important questions for the surgeon to answer if possible. He was obliged to confess that the longer he studied this disease the less able he felt to make a definite prognosis in any given case. Two recent cases led him to make this statement. One case seen early and having the best care and treatment, had after eighteen months developed unfavorable symptoms; while the other, which was very unfavorable at the beginning, had progressed rapidly toward a good recovery. It was important to know

whether there were any data or guides by which one could give an approximate prognosis provided the treatment could be carried out thoroughly and efficiently. The published statements were very general and of little value on this point. Regarding mortality, the statistics of Dr. C. F. Taylor and Dr. L. A. Sayre showed that in private practice children with hip disease had a very fair chance of growing up to adult life. While the shortening would vary somewhat in different cases, it would seem that with efficient treatment it ought not to exceed two inches. A subject should never get well with enough deformity to interfere with locomotion or posture. This could easily be prevented by care and attention during the treatment, correcting by rest in bed the slightest malposition as soon as it appeared. From observation and statistics he thought that even in very favorable cases two years' treatment would be required to effect a cure. Full range of motion after hip disease was rare and was not necessary for good locomotion, provided the limb was in a good position.

Laxity of the Ligaments with Congenital Hip Luxation.—Dr. Henry Ling Taylor, of New York, read a paper with the above title, in which he stated that the causes of congenital hip luxation usually given were trauma at or before birth, and anomalies of development of the bones forming the joint, which might be related to malpositions, deficiency of liquor amnii, or precocious or retarded ossification. Professor Wolff, of Berlin, had pointed out, in a case of multiple congenital dislocations reported by him, in which nearly all the joints of the body, even those not dislocated, showed excessive mobility, that the ligamentous structures about the joints were in this instance primarily at fault, and that it was probable that this would be found to be the essential causative factor in a certain number of cases of congenital luxation. Taking this hint, the reader of the paper had tested the mobility of the joints of the limbs in cases of hip luxation presenting for examination, and in two instances—in girls of four and nine years, with congenital hip luxation of the ordinary type, in the former bilateral, in the latter unilateral—he had found abnormal laxity of the ligaments of most of the joints. This was evidenced by excessive mobility and hyperextensibility; many of the fingers and toes, for example, could with little effort be made to touch the back of the hand and foot respectively. There was also considerable lateral motion at some of the hinge joints. The author knew of a similar case in the practice of a surgical friend. He concluded that congenital tenuity, elongation, or defect of the joint ligaments must be recognized, and that this condition was probably the essential causative factor in certain cases of congenital luxation.

Congenital Absence of the Radius.—Dr. Henry Ling Taylor also reported two cases of congenital absence of the radius in female infants. In the first, twenty months old, the absence was bilateral, and had been confirmed by skiagraphs. There was clubhand on both sides, which had been much improved by splinting. The fingers were well formed, and there was no deformity elsewhere except an unnatural mobility of the left knee-joint inward, with a tendency of the head of the tibia to subluxation backward. This was a delicate infant, the fourth child, all the others having been free from defect. In the second case, that of a baby two weeks old and the thirteenth child, the radius was absent on the right side only, and the right hand was clubbed; both thumbs with their metacarpals were wanting. This baby died at the age of a few months. No other case of deformity was known in the family. A *résumé* of the literature was given, with a discussion of fifty-two additional recorded cases, and reference was made to the neuro-archipterygeal and the tight-amnion theories of causation, the latter being preferred on account of analogy with absent fibula, cases of persistent thumb (like the author's first), presence of pseudo-cicatrices, and for other reasons. The paper concluded with reference to the various operations which had been proposed for the condition, and with a recommendation that preliminary corrective splinting be more persistently employed.

AMERICAN NEUROLOGICAL ASSOCIATION.

Wednesday, May 5th—Second Day.

Encephalitis with Changes in the Pia.—Dr. Alfred Wiener, of New York, read a paper on this subject and reported the case of a child, three years of age, who, after meeting with an accident, suffered from an attack of acute (non-suppurative) meningo-encephalitis. The child recovered after six months of illness. It remained perfectly well, and after an interval of three years, just subsequent to an attendance of three months at school, had a second attack which proved fatal. The autopsy and microscopical examination showed an involvement of the pia as well as the brain, and the characteristic picture of acute non-suppurative hemorrhagic encephalitis. He believed the first attack due to traumatic influences. The second attack was due either to influenza on account of the suspicious catarrhal symptoms present at the beginning of the attack, or as a result of mental strain in a child predisposed to such an attack. Special attention was called to the involvement of the pia, which represented a pathological condition often found in simple fibrinous pleurisy.

Dr. Collins spoke of a young man with encephalitis. Speech was lost. His mental condition deteriorated, and he ultimately became helpless. The left side of the body was spastic and paretic; there was no cranial-nerve palsy. The autopsy revealed cerebral œdema, some localized softening, and acute non-purulent encephalitis.

Dr. W. G. Spiller, of Philadelphia, said that the spinal form is similar to acute polio-myelitis and acute polio-encephalitis. He referred to a case with symptoms of typhoid fever, which subsequently developed eye symptoms and proved to be encephalitis. In another case with choked discs, etc., and supposed to be due to tumor, encephalitis was found post mortem.

Dr. F. X. Dercum, of Philadelphia, asked if evidence of general infection was discovered or if the kidneys were involved.

Dr. Wiener replied that there was only acute congestion of the kidneys.

Dr. Patrick presented some specimens from a similar case, in which there was external ophthalmoplegia.

Dr. Sachs called attention to the practical difficulty of differentiating between encephalitis and meningitis. The greatest difficulty seemed to be in substantiating the early diagnosis of encephalitis; not only the pathology should be made clearer, but also the diagnosis. In the majority of cases both forms may be combined.

Dr. J. J. Putnam spoke of the importance of a toxic cause. In view of the favorable prognosis in the majority of cases, he thought that this element should be considered in the etiology.

Dr. Herter mentioned the case of a child with convulsive seizures, which seemed like infantile cerebral palsy, but microscopical examination showed encephalitis.

Dr. Angell believed the differential diagnosis could be made if we bore in mind the symptoms of inflammation. When the membranes are affected, there is rigidity of the cervical muscles.

Dr. Wiener, in closing the discussion, thought with

Dr. Putnam that the violence of the symptoms was very likely due to toxic conditions.

Little's Disease—Shall We Retain the Name?—Dr. B. Sachs, of New York, said that the use of the term "Little's disease" has led to great confusion. German and French authors have criticised English and American writers for not recognizing the disease as a distinct clinical entity. The name has not been adopted by the latter for the simple reason that Little's disease cannot be considered as anything more than a mere etiological group, comprising those cases of early infantile spastic palsies which are due to difficulties during labor resulting in asphyxia neonatorum. It cannot even comprise all spastic palsies that are in evidence from the time of birth, for many of them are not due to asphyxia, but to developmental defects, more particularly of the cortical or cortico-spinal division of the pyramidal tract. Some authors would make a distinction between general rigidity and cerebral diplegias, and would call the cases of the former Little's disease, but he is of the opinion that there is no rigidity without paralysis, and the difference is simply one of degree and not of kind. The division which the reader made into pre-natal and birth palsies, which has been indorsed by Freund, should be continued, and the name Little's disease should be dismissed, since it represents no distinct clinical group, and since a number of different morbid conditions are responsible for the infantile spastic palsies or the cases of general rigidity appearing at the time of birth or shortly thereafter.

Dr. Frederick Peterson, of New York, differed from Dr. Sachs, as he had found that the greater the extent of the paralysis the greater the mental defect and the epilepsy. At times he had found extensive paralysis without mental defect or epilepsy. He referred to one hundred and thirty cases as having been reported, in which there were thirty with hemorrhage into the spinal canal.

Dr. J. W. Putnam, of Buffalo, said that cases varied in the symptoms according to their etiology. He spoke of two children in one family, in whom there was extensive paralysis. One had marked mental defect, and the other very little. Both pregnancies were attended by prolonged periods of vomiting.

Dr. Sachs, in his closing remarks, said he had not entered into the pathology of the subject, but agreed with Dr. Peterson. There is often an association of cerebral and spinal lesions, but he was not ready to believe that the majority of these cases is due to spinal defect.

The Nature and Treatment of Spasmodic Torticollis.—Dr. G. L. Walton, of Boston, read this paper. He considered spasmodic torticollis as an affection of the cortical centres for rotation of the head. The pathology is not settled. The fact that it is sometimes easily inhibited does not establish a mental origin. Gross organic lesion is not present. Long-continued habit may merge into spasm, as seen in certain occupations. Eye strain sometimes plays a part through causing faulty position (oblique astigmatism, muscular insufficiencies). In one case it followed the wearing of a glass which increased instead of relieving an oblique astigmatism. The course of the disease is progressive. The principal muscles affected are the sterno-mastoid, splenius capitis, complexus, trachelo-mastoid, and inferior oblique. The commonest form implicates the sterno-mastoid of one side and the posterior rotators of the other; less frequently the spasm is limited to the sterno-mastoid, occasionally to the posterior rotators of both sides (retrocollis), and rarely to the sterno-mastoid and posterior rotators of the same side. Treatment other than operative is ineffectual in well-established cases. Simple nerve section and nerve stretching are unavailing. The only operations to be considered are resection of nerves and section of muscles. Operations are generally too limited rather than too extensive. In most cases it will be necessary to resect the spinal accessory and the first three posterior branches of the cervical nerves. It will generally be wise to cut also the affected muscles. Muscle section alone has given good results (Kocher), but there is no reason to abandon nerve resection. Absolute cure cannot be expected in over half the cases; there are improvement in a greater proportion and failure in a certain proportion.

Dr. Dercum thought we should be conservative as to our view of the pathology. He did not regard it as limited to the cortex. In some cases the torticollis seems to simulate the occupation neuroses, and is often cortico-spinal. He did not know of a case of absolute cure following operation. He referred to a case in which the spasm recurred after extensive operation. Some were benefited by rest and the use of gelsemium in increasing doses. His habit was to advise surgical operation at once in the majority of cases. He had never seen much benefit from resection of the spinal accessory nerve.

Dr. C. L. Dana, of New York, said there were three different types or phases of the disease—one occurring in early life associated with neurasthenic or hysterical manifestations; another more serious type in middle life, which he looked upon as a degenerative neurosis; the third occurred in children at about the age of fifteen years, and was gradually progressive and incurable. The type must be considered in the treatment. He agreed with Dr. Walton as to the pathology. In a patient with the progressive type the autopsy showed degenerative process and chronic leptomeningitis of the convexity. He thought that many cases were primarily a cortical degeneration. The best treatment was prolonged rest and careful massage. Some patients are cured and others relieved. He did not believe drugs did permanent good. Surgical treatment was irrational in theory, and not of practical value in his experience, but he had never had the combined operation performed.

Dr. C. K. Mills had seen many cases. In the only successful one the patient recovered under the use of the actual cautery frequently applied and the administration of iodide and bromide of potassium. Gelsemium was the best drug. He had had various operations done, but had never seen good results. Nerve stretching was of value. He laid great stress on absolute rest. He did not believe all cases were of cortical origin. At times they might be of nuclear and degenerative origin, and partly irritative.

Dr. Richardson, of Boston, discussed the subject from the surgical standpoint. He operated only under the advice of the neurologist. There had been a sufficient number of cures to justify the operation. He referred to a patient treated by a helmet with benefit, but such a method is generally intolerable. Surgical methods should be undertaken only after all other measures have failed.

Dr. W. W. Keen, of Philadelphia, also spoke from the surgical point of view. His experience was the same as that of others. In one patient after the usual operation he proposed operation on the cortex, which was refused. However, improvement subsequently occurred. Before surgical interference we must be certain that medical treatment (particularly absolute rest) has been properly and faithfully but ineffectually carried out. In his experience operation had failed as to absolute cure. In a considerable proportion of cases relief was obtained. These operations are not dangerous to life. He was disappointed in resection of the spinal accessory nerve.

Dr. V. P. Gibney, of New York, continued the dis-

cussion from the viewpoint of the orthopædic surgeon. His experience had been largely in torticollis in young children and adolescents from injury to the sterno-mastoid. These are easily relieved. In the class of cases under discussion he knew of no form of apparatus that would take the place of operation. Apparatus might supplement operation. He had obtained no benefit from gelsemium.

Dr. J. J. Putnam believed that the essential thing in the treatment was methodical education of the muscles. He knew of one patient who cured himself by voluntary efforts. These methods required many months.

Dr. Langdon mentioned the case of a young man who recovered. The treatment was absolute rest and stupefying doses of bromide and chloral for three weeks.

Dr. W. M. Leszynsky, of New York, after briefly referring to his successful use of increasing doses of atropine injected into the spasmodic muscles, mentioned the case of a lady, thirty-five years of age, who had been under constant observation for the last eighteen months. The clonic spasm had previously existed for six months, and involved the sterno-mastoid, trapezius, and complexus. The sterno-mastoid was hypertrophied to about four times its natural size. Atropine treatment could not be carried out, owing to idiosyncrasy. Conium and gelsemium failed. After prolonged rest and tonic treatment, together with local massage, passive movements, and educational gymnastics faithfully carried out, the clonic spasm was absolutely cured, it now having been absent for nearly ten months. This had, however, been replaced by a mild form of tonic spasm, which was remittent. A peculiar feature in the case was the high specific gravity of the urine, which was due to urates. Whenever the gravity rose to 1.030 or 1.034 the spasm increased, seemingly indicating an autotoxic irritative element in the case. He believed that if these cases were treated early by the foregoing method very little would be left for the surgeon.

Dr. Prince had tried atropine without benefit. The only case treated by massage and rest ended in recovery. Some patients improved with apparatus. He thought this condition analogous to the occupation neuroses, and recommended education of the muscles.

Dr. Wharton Sinkler, of Philadelphia, considered this disease under three types: 1. Hysterical. 2. Disease or irritation of nerves. 3. Cortical. The hysterical closely simulated the organic form. In the second type he advised rest and massage, gelsemium or conium. If these measures failed, he concluded they were cortical. Therefore operation on muscles or nerves was useless.

After-Care of the Insane.—Dr. H. R. Stedman, of Boston, presented the report of the committee on the after-care of the insane.

The Definitive Encephalic Segments and Their Designations.—Dr. Burt G. Wilder, of Ithaca, read a paper with this title, the general object of which was to induce anatomists not to concur hastily in the interpretation and nomenclature of the encephalic segments that were adopted by the Anatomische Gesellschaft in 1895. The speaker urged the maintenance of the schema that has appeared in the last three editions of Quain's "Anatomy," with or without the two modifications embodied in the table on page 326 of his recent paper, "Neural Terms, International and National," viz., the use of diencephalon in place of thalamencephalon, and the recognition of the olfactory bulbi and certain other parts as the rhinencephalon. The paper was illustrated by many colored diagrams of the brains of representative vertebrates. Certain features of the German schema were strongly reprobated, and the paper concluded with the following words: "Never in the history of anatomy has there been an occasion calling more emphatically for the exercise of deliberation and independence; for the display of what Dr. F. P. Foster has so happily denominated the scientific suspension of judgment as distinguished from its popular precipitation; for the leadership of those who have regard for all and for the future rather than of them that consider only themselves and to-day."

Thursday, May 6th—Third Day.

Brain Tumor.—Dr. Philip Zenner, of Cincinnati, reported three cases of brain tumor.

Case I.—Male, aged thirty-four. Severe headache in the left parietal region: double optic neuritis: only one convulsion. Complete relief of symptoms followed trephining of left parietal region. Seven months later headache returned, left eye blind, muscles paralyzed. Eye enucleated and orbital tumor removed. Relief of all symptoms for nine months. Growth is returning.

Case II.—Male, aged thirty-three. Chief symptoms: Jacksonian attacks in left side of face, paresis of left arm and leg, left facial paralysis. Tenderness to percussion over left side of skull. Post mortem, large tumor in left hemisphere pressing upon left central convolutions. The symptoms were on the left side of the body. Sections of the medulla revealed an absence of the crossing of the pyramids.

Case III.—Tumor in right arm centre. Chief symptoms, Jacksonian attacks and slowly progressing paralysis of left arm and leg. On operation the middle part of the central convolutions was exposed, but the tumor could not be seen or felt. Autopsy revealed a deep-seated tumor (glioma) in the anterior central convolution, encroaching slightly upon the first and second frontal and the posterior central convolutions. The incision in the brain had barely missed the tumor. There was at no time optic neuritis and there were no manifestations of increased intracranial pressure. No vomiting, headache not intense, and intellect clear. There was no impairment of sensation before the operation, but hemianæsthesia immediately followed it.

It would seem that very slow destruction of the cortical motor area causes no sensory disturbance, while sudden lesions produce anæsthesia. Such facts seem to indicate that the central convolutions have sensory functions, but are only a part of the sensory area. The Jacksonian attacks in the second case were of a tonic character only. This was of importance in connection with the fact that the tumor was subcortical, such attacks occurring chiefly when the tumor does not involve the cortex.

Dr. C. A. Herter, of New York, reported a case of sarcoma of the midbrain, associated with asymmetrical hydrocephalus.

Dr. Angell had seen a similar case, but the asymmetrical hydrocephalus was secondary to a cerebellar tumor. The child is still living and the disease is quiescent. Circumference of head, twenty-two inches.

Dr. E. D. Fisher, of New York, cited cases in which the usual symptoms of brain tumor were absent. No paralysis and no optic neuritis. He had frequently seen relief of symptoms from operation without removal of tumor. Localization of tumor by percussion of skull he thought was unreliable. In slowly growing tumors the displacement of fibre tracts was so slow that paralysis did not take place.

Dr. Pershing, of Denver, related the history of a middle-aged man. General convulsions, loss of consciousness, defective vision. Quadrantal hemianopsia. No headache, no optic neuritis. All symptoms increased. Paraphasia, word deafness; coma, death.

At autopsy, tumor of left sphenoidal lobe and infiltrating growth in pulvinar.

Dr. Langdon referred to a case with many symptoms of tumor. Nothing was found at operation. All symptoms improved. He had seen tumor of pons and cyst of cerebellum with absence of decussation of motor tracts.

Dr. Fry mentioned an instance of asymmetrical hydrocephalus in which the diagnosis of cerebellar tumor was made. There was decided difference in the percussion note on the two sides. At the autopsy there was ventricular distention. In tumor of the cerebellum with ventricular distention, the peculiar cracked-pot resonance was probably due to vibration of bone separated at the sutures.

Dr. Patrick said that the majority of cases of brain tumor were of irregular type. General convulsions usually precede focal convulsions in deep-seated tumors. In operating it was proper to continue and go below after the surface of the brain was reached. Careful examination of the visual field and of speech defects were of much value in diagnosis.

The President reported four subjects recently operated upon. Three came to autopsy. The percussion note was altered in three.

Case I.—Infiltrating sarcoma in temporal fossa. Progressive motor aphasia, right hemiplegia. Aphasia was the first symptom. Headache and optic neuritis. At operation nothing was found.

Case II.—Woman under observation two months; all general symptoms. Unilateral and general convulsions. Operation. Very large infiltrating gliosarcoma over entire motor area. Removal followed by extensive hemorrhage. Death on the third day.

Case III.—Man; general symptoms and diagnosis of cerebellar tumor. At operation, cerebellum well exposed; seemed perfectly normal. Opening enlarged upward to occipital lobe, and then lateral ventricle tapped and large amount of fluid withdrawn. All general symptoms relieved for two weeks. At autopsy, tumor found in cerebellum below surface of normal tissue.

Case IV.—Child with all symptoms of cerebellar tumor, blindness, etc. At operation, occipital bone found eroded and softened. Operation discontinued on account of extensive venous hemorrhage.

General symptoms were often due to effusion in the lateral ventricles. The percussion note was not a reliable sign, and afforded no differentiation between cortical and subcortical tumors. He had seen two cases, with operation on postcentral convolution, in which ataxia of the right hand developed but gradually disappeared. He had not seen ataxia as a permanent symptom of tumor, nor had he seen asymmetrical hydrocephalus.

Dr. Herter did not regard a marked degree of asymmetrical hydrocephalus as indicative of tumor, in all cases.

Epilepsy Following Infantile Cerebral Palsy; Improvement after Craniotomy and Evacuation of Subcortical Cyst.—Dr. W. M. Leszynsky, of New York, read a paper on this subject, and reported the case of a boy, fourteen years of age. At second year left hemiplegia, preceded by convulsions and unconsciousness. Epilepsy developed at twelfth year. At first, conjugate deviation of eyes and head toward the paralyzed side, with transient loss of consciousness, increasing in frequency. Later, attacks accompanied by rigidity of left arm, then of arm and leg, and ultimately general convulsions and increasing mental enfeeblement. No clonic spasm at any time. After ineffectual medicinal treatment, exploratory operation. A large subcortical cyst was found under the Rolandic area. The cortex was extremely atrophied. The cyst was evacuated. Absence of all epileptic attacks for three and one-half months. The patient then had seven general convulsions within eighteen hours. The cyst was again emptied, and the attacks disappeared for more than three months. Again the cyst was evacuated. Since then he has had occasional mild attacks, despite the use of bromide. The speaker considered the advisability of permanent drainage.

Dr. J. W. Putnam spoke of a boy in whom convulsions followed traumatism, sixty to eighty attacks daily. Fluid was evacuated from the cyst, and for a week bandages were frequently soaked by the discharge. The wound healed, and there was no attack for several weeks. More fluid was withdrawn, and continued drainage allowed. The convulsions ceased. The patient has had no attack in two years.

Dr. Angell referred to a case of hemorrhagic meningeal cyst in a child having fifteen attacks daily. Cyst evacuated, and no attack since operation three years ago.

Dr. Pershing spoke of a man with epileptic attacks following a blow on the head. A cyst was found over the face centre and drained. No attack in a year.

Dr. Worcester had made seven autopsies in cases of infantile cerebral palsy. In six there was great asymmetry of the hemispheres. In one the lateral ventricle was greatly dilated.

The President had had no experience with permanent drainage. He had always seen symptoms return after evacuation of the cyst.

Uncommon Nasal Paræsthetic Neurosis.—Dr. Samuel Ayres, of Pittsburg, reported the case of a lady, twenty-three years of age, recently married, and of a neurotic temperament. The nasal disturbance began eight years ago, and was characterized by periodic flushings over the end of the nose. The attacks have increased in frequency, and now consist in a sense of burning in the integument of the end of the nose or over the entire cartilaginous portion. At the same time there are general restlessness and considerable mental depression. No cause can be discovered. Various remedies have been used, such as local applications and the internal administration of bromides, cannabis indica, ergotin, etc., with only temporary benefit.

Steps toward Insanity.—Dr. Smith Baker, of Utica, read a paper with this title. He said that the biological doctrine that structure determines function is as applicable to the neuron as to other basal elements. Applied to insanity, psychiatry properly becomes an important branch of it. The primary presupposition of every instance of true insanity is that it is based upon arrest of development and a nurture too faulty to correct this. One step which initiates the degenerative tendency is unphysiological marriage, and the perversive tensions and reactions which grow therefrom. Another step is vitiation by sexual overstress or nutritional perversions during the childbearing period. With the individual, defective home conditions play a most prominent part in fixating degenerative tendencies. Frequently the ordinary educational course, the universal leaning on proxies and various kinds of stimulants, are but ways of confirming all that is degenerative. Diseases and accidents are important, because of the emotional stress involved. Arrest of development at puberty is serious always. The immediate causation of the structural change seems to come through exhaustion and auto-intoxication. This must interfere with the characteristic activity of the neurons, which activity seems to be on the point of discovery as an amœboid movement of the cells or their processes. Dissociation, confusion, systematization may thus come to be founded in actual structural defect, itself the result, primarily, of emotional stress in ancestry.

Honorary Member.—Dr. E. C. Seguin, of New York, was elected to honorary membership.

New Members.—The following-named gentlemen were elected to membership: Dr. William G. Spiller, of Philadelphia; Dr. H. M. Thomas, of Baltimore; and Dr. William Hirsch, of New York.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Graeme M. Hammond, of New York; *Vice-Presidents*, Dr. Philip Zenner, of Cincinnati, and Dr. J. J. Putnam, of Boston; *Secretary and Treasurer*, Dr. F. X. Dercum, of Philadelphia; *Council*, Dr. H. T. Patrick, of Chicago, and Dr. Charles K. Mills, of Philadelphia.

THE AMERICAN OTOLOGICAL SOCIETY.

Tuesday, May 4th.

Goutiness in Its Relation to Diseases of the Ear.—Dr. A. H. Buck, of New York, read the first paper (see page 726).

Dr. J. O. Tansley, of New York, opened the discussion by taking issue with a statement made that eczema was pathognomonic of gout. He had seen in children numerous cases of eczema that could have had no connection with that disease. He always recognized cases of gouty tendency by a spot of redness in the upper posterior part of the membrana, which was not due to the congestion of the mucous membrane of the middle ear, but to the trouble in the articulations of the ossicles.

Dr. E. B. Dench, of New York, had seen one case of true hyperostosis of the canal due to eczema. He had obtained a very good effect by the use locally of cantharidis acetum.

The Differential Diagnosis between Diseases of the Sound-Conducting and Sound-Perceiving Apparatus.—Dr. E. B. Dench read a paper with this title. He stated that a physical examination alone was no guide to the state of the hearing. An ear looking considerably disorganized might have very fair hearing, while one looking nearly or quite normal might have scarcely any hearing at all. For diagnosis he divided the ear into two parts: First, the conductive; second, the perceptive. Obstruction to or interference with the conductive apparatus always gave rise to the same signs—quantitative audition it might be called. Qualitative audition was estimated by musical tones. In difficulty with the conductive apparatus the lower tones of the scale were the first lost. In perceptive difficulty the lower tones were not lost. In conductive difficulty high notes were good; in perceptive difficulty they were not. In mixed cases in which impairment was extreme air conduction was better than that by bone, except for the very lowest notes.

Dr. Theobald, of Baltimore, had been puzzled by the varied results obtained by him with the tuning-forks on the mastoid and the vertex.

Dr. Alderton, of Brooklyn, had noticed the same trouble, and had had the best results from the tuning-fork on the central incisor teeth.

Dr. Clarence J. Blake, of Boston, had found differences in different parts of the same vertical region, due to differences in thickness of the skull at different points. He thought the paper an excellent one to be read before the society on account of its treatment of physics as applied to the subject. He thought the Galton whistle was not reliable for the very high tones.

Ear Complications of Influenza.—Dr. W. P. Eagleton, of Newark, N. J., read a short paper on this subject, giving statistics of the proportion of cases of ear disease to those of influenza, and pointing out the differences in tractability between those following influenza and those uncomplicated with this disease.

Mastoid Disease.—Dr. Bacon reported synopses of twenty cases of mastoid disease in children and adults, in a paper entitled "What Symptoms Should We Consider Most Important as to the Advisability of an Operation in Mastoid Disease?" He had never seen a case without some elevation of temperature. The temperature might range lower in adults than in children. High temperature did not necessarily indicate extensive destruction. In estimating tenderness pressure should always be made over both mastoids. Redness and œdema he did not consider necessary factors and they were not to be waited for. Bulging of Shrapnell's membrane he thought always indicated mastoid disease, and was an indication to open the cells. When mastoid symptoms develop in chronic suppurative otitis media he would operate at once. He advised the following treatment in acute cases: leeches, followed by the Leiter coil and free incision of the membrana tympani, with frequent douching as long as the discharge was profuse and symptoms were acute. If the symptoms continued urgent, he would open the mastoid at once.

Dr. W. B. Johnson, of Paterson, N. J., believed that after free incision of the drum it was not advisable to use politzerization. He uses peroxide of hydrogen to wash out the discharge.

Dr. Dench stated, in regard to the matter of the temperature not always falling after operation, that it might be due to the fresh inoculation of the cut surfaces. He had not seen the least harm result from politzerization.

Dr. Tansley used normal salt solution in cleansing the ear, and thought it acted by promoting exosmosis.

Dr. Buck spoke of one of Dr. Bacon's cases, in which the continued high temperature was due to pneumonia, and mentioned a case in which the high temperature was accounted for by endocarditis.

In closing the discussion, Dr. Bacon stated that he inflated only when the inflammation had practically subsided and there was a free opening in the membrana.

Thrombosis of Lateral Sinus with Mastoid Abscess.—Dr. Alderton, of Brooklyn, N. Y., reported a case of this kind, with presentation of specimen. When the wall of the sigmoid groove was opened, horrible pus welled up and was evacuated. The case was left for twenty-four hours; then the sinus was slit up and cleaned out, upward and downward. Some improvement occurred during the next twenty-four hours; then metastatic pneumonia developed, and the patient died. On autopsy the antrum and aditus were found packed with cheesy pus. There was no congestion of the tympanic membrane. He wished to emphasize the importance of gaining access to the antrum and tympanic attic, and also of ligating the jugular vein to guard against extension of the sepsis.

Dr. Dench did not agree as to the proposal always to ligate the jugular vein. He would not do so without additional indications.

Dr. Bacon agreed with Dr. Dench in not always ligating the jugular vein, but would rather force septic material out of the vein by pressing upward.

Dr. Alderton, in closing, said he would not ligate when there was only a small localized spot on the wall of the sinus, but would do so if there was much disease of the sinus wall.

Pilocarpine in Deafness.—Dr. Bacon read a paper describing a case of extreme deafness, in which great and permanent improvement of hearing followed the use of pilocarpine hypodermatically. After removal of the ossicles the hearing was further improved. The best results of pilocarpine had been seen in cases due to syphilis, and lack of success in other cases might have been due to insufficiently long use of the remedy.

Dr. Tansley agreed as to the excellent results of pilocarpine in these cases, but did not agree as to the

absolute necessity for exhibiting the remedy hypodermatically. Many could not spare the time necessary, and equally good results might be obtained by administering it by the mouth.

Deviated Septum.—Dr. Tansley described a new method of operating on a deviated septum, which he believed simplified the procedure and was accomplished in two sittings ten days apart, and with a minimum of traumatism. He accompanied the paper with a blackboard demonstration.

Simulation of Labyrinth Disease.—Dr. Robert C. Myles, of New York, read a paper on the synechial bands of the Eustachian tube and fossa of Rosenmüller, producing symptoms simulating labyrinth disease, relieved by breaking up the adhesions with the finger, with immediate relief of the symptoms.

Dr. J. E. H. Nichols, of New York, exhibited an operative electric ear speculum, which left both hands free for manipulation.

The officers of the society were all re-elected, also the following as associate members: Drs. E. E. Doble, of Boston, Mass.; W. B. Marple, of New York; J. F. McKernon, of New York; and Eugene A. Crockett, of Boston, Mass. *Committee on Membership*, Drs. Gorham Bacon, J. Orne Greene, and J. S. Prout.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Second Day—Wednesday, May 5th.

Tumor of the Nose.—Dr. J. H. Bryan, of Washington, exhibited a case of intranasal tumor. The patient was a man of twenty-two, who had had a growth in the nose causing stenosis for four years. It first appeared in the left anterior naris, but was now visible in the right posterior. As the septum was intact in the nasopharynx, it was evident that the neoplasm had attacked and perforated the septum. An examination of a bit removed showed fibro-sarcoma, though from simple inspection he had made a diagnosis of simple fibroma. Within the past few weeks giddiness and double vision had appeared. There was no spontaneous hemorrhage, but the growth bled freely upon manipulation. Dr. Bryan invited the opinion of those present as to the most feasible operation for removal.

Dr. M. R. Ward, of Pittsburg, had operated in one case of fibro-sarcoma of the nose four years ago, and in spite of the fact that an early recurrence was prophesied his patient was well at the present time. In view of current views as to fibro-sarcoma, he thought that this long continuance of life somewhat invalidated the original diagnosis.

Dr. J. E. Boylan, of Cincinnati, thought that mere continuance of life ought not of itself to invalidate the accuracy of diagnosis.

Dr. W. E. Casselberry, of Chicago, had reported a case of simple fibroma some eight years ago. It was impossible to remove the tumor entire, so he had slit it up into segments with the galvano-cautery knife, and then snared it off piecemeal. It was harder to the feel than was the growth in Dr. Bryan's case.

Dr. Jonathan Wright, of Brooklyn, thought that the fact that in Dr. Bryan's case the nasopharynx was not invaded would point to fibro-sarcoma rather than simple fibroma, which, confined to the middle or anterior part of the nose, was practically unknown.

Dr. J. Solis Cohen, of Philadelphia, would advise, in the present case, the performance of Rouge's operation.

Dr. Thomas Hubbard, of Toledo, thought that the eye symptoms in the present case should suggest the query whether it was advisable to operate at all.

Dr. C. C. Rice, of New York, had seen one case during the last winter. He would strongly condemn cobbling in these cases with the snare. A more radical procedure was necessary.

Dr. J. N. Mackenzie, of Baltimore, said that the Rouge operation frequently failed to afford the necessary exposure of the involved area. He would therefore advise the modified Langenbeck operation, whereby the superior maxilla is separated from its median attachments and rotated outward.

Suppuration of the Frontal Sinus.—Dr. J. H. Bryan reported this case. The writer thought that frontal sinus suppuration was much more common in this country than was generally supposed. Recent grippe epidemics had brought to light a large number of cases. Many were undoubtedly due to propagation from the maxillary sinus, owing, in some instances at least, to an abnormal communication between the two cavities. Dr. Phillibroun, of Boston, had recently reported the results of examination of skulls in which the infundibulum had been prolonged to the actual entrance of the antrum, as a half-tube terminating in a valve-like fold, so that secretions from the frontal sinus would pour into the antrum and secondarily involve the latter.

Dr. Bryan then described the anatomy of the frontal sinus, and exhibited photographs illustrating its peculiarities. He said that the size of the supra-orbital ridges was no guide to the size of the sinuses. He would advocate in such cases the operation known as Luc's, whereby a drainage tube is inserted from the sinus down into the nose and the external wound on the forehead hermetically sealed up.

He then gave the clinical history of a case occurring in a woman, aged fifty-eight years, in which the Luc operation had been done. The antrum was also affected and was previously operated upon by the alveolar method. After the Luc operation on the frontal sinus, the clinical course had been uneventful for a while, but the drainage tube slipped out of the nose and soon evidences of sepsis began to show themselves. The dressing over the forehead wound was removed and a small abscess found. Pus was evacuated, and the wound was stuffed with gauze and allowed to heal by the open method. The further course was uneventful. The sepsis was probably due to retained discharge consequent upon the slipping out of the tube.

Dr. Casselberry was pleased to hear such strong advocacy of the Luc method. Intranasal management of these cases had in his hands proved very unsatisfactory. Symptoms were improved, but the discharge was not checked.

Dr. Mackenzie thought that strong antiseptic solutions should be carefully avoided in all such cases. It had been shown that bichloride solution as weak as 1 to 10,000 caused a necrosis of a thin layer of tissue. He would prefer Thompson's fluid as used in the bladder, or even a normal salt solution. The same thing could be said of drainage tubes. They should be avoided as much as possible, as they are liable to act as pus producers and carriers of infection.

Dr. Wright thought antrum disease from sinus disease a very common sequence.

Dr. J. E. Nichols would agree with Dr. Mackenzie as to the danger of using strong solutions. He thought it possible to make a differential diagnosis between primary antral disease and that secondary to frontal sinusitis. In the latter the antral pus appeared as long worm-like shreds, while in the former it was compact or in small masses.

Discussion on Atrophic Rhinitis.—The nature and symptoms of this affection were considered by Dr. W. E. Casselberry. No one theory of causation would account for all the cases observed. The disease as seen in the young child seemed to contravene Fraenkel's theory, which, however, was borne out by

the appearances found in old people. There were fetid and non-fetid cases. The atrophy might be due to one cause and the fetor to another. Two groups might be made—one of simple dry cases and the other of ozæna or fetid cases, as had been done by Greville McDonald. All stages of atrophy were observed, from a very slight grade up to a condition characterized by degeneration of the mucous glands and crust formation. The non-fetid variety occurred more frequently in old people. Ozæna was seen in early life, and as a rule the fetor was persistent, but in some instances the two types seemed to blend. There might also be a local affection of the peripheral sensory nerves. The nostrils became less sensitive to all irritants and the pharyngeal reflexes were sluggish. In some cases the process seemed to involve the nasal bones and cartilages as well as the turbinates, so that there was a suggestion of the saddleback nose. The tip of the nose is elevated, so that the anterior nares look forward rather than downward. Again, there might be a primary central trophic neurosis. A deviated septum might cause the change to be more marked on the concave side, but a correction of this deformity would often cure the affected nostril. Congenital malformations seemed to be a causative factor in some cases. They led to atrophic rhinitis from poor nasal ventilation, and consequent stagnation of secretion. Syphilis, tubercles, alcohol, and gout undoubtedly played a predisposing part. In both types of the disease the trophic changes varied in degree and distribution. Some cases were undoubtedly the sequels of preceding hypertrophy, but hypertrophy need not exhaust itself before atrophy begins. The middle turbinate might be hypertrophied and the inferior atrophied. Grünwald had referred the condition to preceding sinus disease; Bosworth to an earlier purulent rhinitis. More recently Belfanto and Della Vedova had found in the mucosa bacilli resembling those of diphtheria; Fraenkel and Loewenberg, a coccus; Abel, a bacillus named by him bacillus mucosus; Wyatt Wingrave, various hyaloid bodies. As regarded symptoms, in addition to those referable to the nose proper, impaired hearing and voice were often the first things noticed. The speaker would advise against a too free use of the cautery in hypertrophic cases, as atrophy might thereby be induced.

Dr. J. N. Mackenzie spoke of the pathology. In considering this topic one should consider, first, the nature of the structural changes; and second, the order of their occurrence. It must be remembered also that we are dealing with changes in a respiratory organ as well as in a mucous membrane. At present there is a haze of opinion regarding the matter, because of the loose manner in which the term atrophy is used, and, second, because we fail to discriminate between the different forms of atrophy and the causes which produce them. We may have simple atrophy and the atrophy of degeneration. The best term to indicate the condition we have in mind when we speak of atrophic rhinitis is sclerosis. This may result from a blood infection, such as tuberculosis or syphilis, or may come from an intoxication, particularly that of alcohol. It probably does not arise from purulent catarrh, for we have nothing parallel to such a sequence in any pathological process with which we are acquainted. The task of the future is to determine the origin of this sclerotic process. It is possible that the process may be sclerotic *ab initio*, and that it may begin in the periosteum. It is impossible to prove this. It is improbable from the lack of proof in clinical history, from the lack of anatomical observations on this point, and also from the fact that we frequently see a rapid transition in a given case from a hypertrophic to an atrophic condition.

In reply to Dr. Casselberry's objection to the theory of this transition, he would say that ozæna and atrophy are not convertible terms. In regard to the ozæna neonatorum, so-called, this might be due to intra-uterine changes, with the nature of which we are unacquainted. It is true that hypertrophy does not always terminate in atrophy, and in a given microscopical section we may see the two side by side. Atrophy is, as a rule, more pronounced when the catarrh has originally developed.

Dr. C. C. Rice, of New York, discussed the treatment. He would divide therapeutic measures into constitutional and local. Under the former he would include climate and general hygiene. He had seen several cases greatly improved by a transfer of residence from the city to the country. Sea air was undoubtedly better than mountain air. As to local measures, cleanliness and stimulation were probably the methods most generally employed. To affect the latter, electricity (both currents), cataphoresis with salts of copper and countless drugs, had been used. The latter had been used in bougie form. Stimulating inhalations and massage had their advocates. Resorcin, ethyl alcohol, peroxide of hydrogen, etc., were all used. Great care should be taken to avoid destruction of tissue. The oily preparations were of great service, both as vehicles and as lubricants. He would therefore cleanse and polish the nose with the oils. In very young children with excess of thin secretion powders might be used.

Dr. Jonathan Wright called attention to the fact that the disease was far more common in women than in men, and that its development seemed coincident with the menopause. After the menopause the condition generally improved. It had been suggested that the bacteria found in the nose in this affection might produce some ptomain, which by continued action on the nasal mucosa produced eventually the condition with which we are all so familiar.

Dr. S. O. Vander Poel, of New York, alluded to the serum therapy of Belfanto and Della Vedova. He had seen one subject of atrophic ozæna who contracted laryngeal diphtheria. Antitoxin was injected at three different times, and the patient recovered. It was a remarkable fact that thereafter the ozæna was also greatly improved, the amount of discharge having been most markedly lessened.

Dr. J. H. Hartman, of Baltimore, had for some years used the galvanic current, and was disposed to attach great value to it. It was, however, a tedious method of treatment, and it was difficult to make patients persist in its use.

Dr. James E. Logan, of Kansas City, had found the middle turbinate more frequently atrophied than the inferior, and was disposed to attach much importance to pre-existing sinus disease as a causative factor. He thought that the middle turbinate might act as a drain or dripstone for the sinus secretions. In severe cases of atrophic rhinitis, he had curetted the sinuses, with a remarkably good effect upon the atrophic rhinitis.

Third Day—Thursday, May 6th.

Simulated Sarcoma of the Tonsil, with Case.—Dr. D. Bryson Delavan, of New York, reported a case of a man of forty-three years, with a good family history and no suspicion of syphilis. For two months he had had a soreness in the left tonsil, with a moderate enlargement of the same. Later there ensued a breaking down of the tissue, leaving a central erosion, while the remainder was indurated. The cervical glands below the tonsil were somewhat enlarged. There was pain on palpation and deglutition. The patient was placed on the iodide of potassium, while a small piece of the tonsil was removed and submitted

to Dr. Hodenpyl for examination. Several other pathologists also examined the growth and pronounced it a sarcoma. Dr. Hodenpyl, however, was not sure of this, and was inclined to doubt the correctness of this view. The glandular enlargement cleared up under the iodide, while the tonsil still remained enlarged. It was removed with the cold snare. The microscope showed chronic hyperplastic changes, with a large number of endothelial cells. There was a strong suggestion, in the arrangement of the histological elements, of sarcoma, but the tonsil was only a little enlarged. Under the continued administration of the iodide the disease entirely disappeared, and the patient has remained well.

A New Method of Permanent Relief of Certain Enlargements of the Turbinated Bones.—Dr. Delavan also presented a short communication with this title. He said that the use of the cautery often produced too great loss of mucous membrane, while affording no permanent relief. Our aim should be to reduce the volume of the congested turbinates. He therefore would advocate the method of submucous incisions. For this purpose he used a small knife, first applying cocaine in the usual manner and then passing the blade under the mucosa, making a sweep through the submucous tissues and then withdrawing it, care being taken to avoid any additional enlargement of the original opening. The instrument employed was a needle rather than a knife. It was better to repeat the operation than to overdo it. There was but little pain and only slight bleeding. It was a good plan to keep the cocaine in contact with the tissues for several hours, and to let the slight hemorrhage stop of its own accord. This method of operating possessed the advantages of ease of execution, freedom from bad effects, preservation of the mucosa, and a practical adaptability to the desired end. In advocating this measure Dr. Delavan would lay no claim to originality, though he had never heard it before described. As to its ultimate results, he could not speak positively. He had one case now under observation, in which the good results had persisted to the present time and were all that could be desired.

Dr. Wright thought that this was a very reasonable procedure. He presumed that the good effects were due to the breaking up of the vascular coats, and the causation of clotting in the cavernous tissue was analogous to what was sometimes sought to be brought about in cases of aneurism.

Dr. Casselberry saw many cases in which the congestion was posterior. In such this operation would hardly do. He was willing to admit, however, that sometimes the removal of an anterior enlargement would cause a posterior one to disappear without further treatment. He also alluded to the method of submucous linear cauterization recently advocated by Dr. Norval H. Pierce, of Chicago.

Dr. Wright said that the importance of Dr. Delavan's first case should not be overlooked. Practitioners were apt to make sport sometimes when they gave a bit of tissue to a pathologist for examination and his report turned out to be untrue, as shown by the subsequent history of the case. There should be fair treatment of the pathologist by the clinician. The latter should acquaint the former with the full history of the case and every fact possibly bearing on it.

A Case of Subglottic Tumor Causing Great Dyspnœa; Removal by Tracheotomy and Curetting.—Dr. John W. Farlow, of Boston, reported the case of a woman of thirty-seven years, who four years before had suffered from severe dyspnœa. Three years ago she had come under the observation of Dr. H. W. Loeb, of St. Louis, who found a thickening of the nasal septum. The dyspnœa was so severe that a tracheotomy was done, and it was found that there was a tumor, sessile, about one and one-eighth inches long and three-eighths of an inch in transverse measurement, situated on the posterior wall of the trachea and bulging into the œsophagus. It had the thickness of a pencil, and was of a brownish color and soft consistency. At this time an operation was deemed unadvisable, owing to the supposed danger of the formation of a tracheo-œsophageal fistula. After the tracheotomy the dyspnœa greatly improved and she remained fairly well, with occasional periods of discomfort. She came under Dr. Farlow's observation in January, 1897. She then had dyspnœa and great wheezing in respiration. She had lost thirty pounds. The voice was not hoarse and the vocal cords moved freely. There was a tumor visible below the cords, filling up the trachea to a great extent, so that there was only a very small passage for the tidal air. The tumor presented as two masses on the right side and as a single one on the left, and was apparently connected with the trachea. A diagnosis of non-malignancy was made, and the growth was regarded as an enchondroma. On February 4th a tracheotomy was done (low operation), and the trachea opened above. Free access to the tumor was thus obtained, and it was removed with the curette. Bleeding was only slight. In closing the wound, the skin was sutured while the tracheal rings were not. Examination of the growth showed it to be a fibroma. Dr. Farlow alluded to the possibility of some relation existing between the thickened septum and the tracheal growth. The coexistence of the two suggested a constitutional tendency to the development of fibrous material.

Papillary Œdematous Nasal Polypi and their Relation to Adenomata.—Dr. Jonathan Wright, of Brooklyn, discussed a series of tumors, some of which had come under his own observation and others of which had been reported by writers. Full details of histological structure were given, and the general aim of the paper was to show that all grades of transition could be seen, from the simple nasal polyp up to the true adenomata.

A Case of Adeno-Carcinoma of the Nose was reported by Dr. F. E. Hopkins, of Springfield, Mass. His patient was a man of eighty-three years, with a negative family history as to tumors, but with a tuberculous taint. For twelve years he had had nasal obstruction with a watery discharge, but no pain or bleeding. A tumor was discovered in the nose, and a rough attempt at removal was made. The attempt had to be given up on account of the hemorrhage it caused. Later some masses were removed by the forceps. These were regarded as polypi. He was seen by Dr. Hopkins in April of the present year. There had been no operative interference for the past three years. He was now suffering from a sanious discharge, occasional epistaxis, and offensive odor. The eye was displaced outward. The septum nasi was forced over to the right side posteriorly. The mass was removed with the cold wire snare. Bleeding was profuse. The microscope showed cylindrical cells in tubular arrangement, but here and there arranged as acini. There were a few irregular cell masses. In general, it could be said that there was a tendency to a concentric arrangement. The amount of connective tissue was scanty.

Dr. Swain, of New Haven, called attention to the similarity of structure between the papillary adenomata seen in the nose and that of the ordinary aural polyp. He believed that the fibrous tissue present in these growths, as well as the cell elements, contributed to the papillary appearance.

Primary Lupus of the Larynx.—Dr. Emil Mayer, of New York, reported two cases that had been under his observation.

"Case I.—Male, aged thirty; born in Russia; pre-

sented himself for observation on July 18, 1896. His history was that he had been in good physical condition, excepting an attack of malaria seven years ago, until one year before the date of presentation. At that time, after a very short cough, he brought up about a wineglassful of blood. There were no further signs of hemorrhage until July 10, 1896. While sitting up at night he had a short cough, and brought up half a cupful of blood. From this time he had daily hemorrhages until he presented himself. During this time he was under the care of his family physician. There was no cough, no pain in deglutition, no pyrexia, no hoarseness. His physician, finding no evidence of pulmonary disease, referred him for laryngoscopic examination. There was a large ulcer in the centre of the epiglottis, extending over the entire laryngeal face. The edges of the ulcer were granular, covered with a grayish-white deposit, many small nodules existing on the free edge, the whole presenting a gnawed appearance. The width of the ulcer at the upper border was about eight millimetres. In the deepest portion of the ulcerated surface there was an eroded spot, presenting the appearance of the open mouth of a vessel. There was a tumefaction on the upper border of the epiglottis on each side of the ulcer. The arytenoids and the interior of the larynx were normal. Careful examination and investigation gave no evidence of syphilis. Sputum examined showed no bacilli. There was a slight consolidation at the apex of the left lung.

"Diagnosis: Primary lupus. Under applications of lactic acid, alternating with menthol and the internal applications of creosote, he improved markedly, the hemorrhage ceasing on the third day and never returning. His weight increased and he resumed his daily vocation, passing from observation August 5, 1896.

"April 16, 1897, patient present at my urgent request. States that he has been entirely well these eight months past, that he has steadily gained in weight, and excepting a slight cough of a few days' standing has no complaints. His voice is clear and strong, appetite good; he has no pyrexia and no pain, and there is no difficulty in deglutition.

"Examination: The epiglottis is thickened in every diameter; a piece is excavated out of its central portion, extending to within one-eighth of an inch from its free border. The portion of the epiglottis that is visible in this excavation is nodulated in appearance, a fresh nodule being visible on the site of the old cicatrix. The mucous membrane of the border of the epiglottis adjacent to the ulcer is puffy and very œdematous. Its œdematous folds form pouches hanging over the arytenoids, and tend to obstruct the view of the larynx. No abnormality can be detected in the larynx.

"Examination of the lungs: Besides a slight bronchial catarrh and the consolidation at the apex of the right lung, which is *in statu quo*, there is no other pulmonary affection.

"Case II.—This case was one of primary lupus of the pharynx and larynx, and was reported to this association in the year 1881 by Dr. Morris J. Asch, through whose courtesy the patient has been under the observation of the writer ever since. The history then given was:

"'Nora H—— came to me in February, 1879, complaining of sore throat and hoarseness. For four years she has suffered with it during the winters. During the past winter she has been much worse, deglutition becoming difficult, fluids passing out through the nose on her attempting to swallow them. There was a pricking sensation in the parts.

"'Examination: The uvula was destroyed. The free border of the velum and the posterior pillars were ulcerated. The anterior pillar of the right side, the right tonsil, and the roof of the mouth were thickened and covered with small fleshy tubercles and nodular masses. The anterior pillar of the left side was thickened, while the whole diseased surface presented a deeper tint than normal. On the posterior wall of the pharynx was a large radiated cicatrix, of the origin of which the patient could give no history. Patient is dysphonic; hearing is diminished. The epiglottis is thickened, with ulceration on the left side and with its cushion much infiltrated. The aryepiglottic folds and the ventricular bands are covered with small tubercles and thickened, so as to prevent a view of the vocal cords. There is also a large papillated mass at the base of the tongue on the right side.'

"Under cod-liver oil, iron, and applications of nitrate of silver the patient improved until October of that year, when she complained of a choking sensation in damp weather. There was pain in the throat. The growth had increased and there was an appearance of ulceration on the right side of the larynx. There was a white spot on the right posterior pillar, and the granulations, which had almost disappeared from the roof of the mouth, had returned. Under applications of perchloride of iron the patient improved steadily, and in May, 1881, there were no further indications of active disease.

"Two years after the case was described it was found that the epiglottis was sunken and flattened. This was believed to be due to subsequent cicatrization. About five years ago a new nodule appeared, extending from the centre of her distorted epiglottis and directly upon a cicatrized spot. This remains and protrudes like a spur. Before this an attack of pneumonia, and later an attack of pleurisy occurred, from which recovery was complete. No other throat affections save those noted have presented in all these years. Her life history has been that she has been twice married. Her first husband died of endocarditis. She has been pregnant twelve times and aborted seven. The abortions all were due to causes referable to the uterus. The children that were born were normal in every respect. Her skin and body were carefully examined from time to time. Her teeth were singularly perfect, nor has there appeared any diseased state of the eyes, ears, or scalp. No mercurials or iodides have ever been given or required. In the month of February, 1896, she began to cough and failed rapidly. Tubercle bacilli were found in large numbers, and cavities at the apices of both lungs. Under creosote and rest she improved sufficiently to go to Sullivan County, N. Y., on April 15, 1897. From time to time there appears over the right temple a lupus eruption, sometimes very red and at others almost gone."

The writer quoted from the literature of the subject, calling especial attention to the statements made that primary lupus of the larynx does not exist. The literature, however, contains fourteen other cases besides the ones here presented. These cases are all reported by competent observers, one of whom states that lupus may originate as a primary deposit in the mucous membrane without any external disease whatever. This is now established beyond all doubt. It was also shown that lupus is dependent upon the tubercle bacillus for its origin.

"The most important point is the question of diagnosis. Lupus must be differentiated from tuberculosis, syphilis, carcinoma, and leprosy.

"Symptoms: Primary lupus produces no symptoms for a long time, often occasions no inconvenience, no fever, only after a time and frequently after a long time the voice becomes husky, and sometimes dyspnœa may occur, and these bring the patients under observation; hence Marty truthfully said that lupus of the larynx must often be divined. The glands may or may not be involved. Clinically speaking, the pri-

mary disease resembles the secondary in appearance. There are four processes in this affection: The mucous membrane is pale, it is œdematous, there is ulceration, and cicatrices form. These may all be present at the same time.

"The course of the disease is chronic, without fever, a cure may be spontaneous, and often the disease reappears in the scar. The course of the disease may be rapid. Death ensues from complications, rarely from œdema of the glottis.

"Prognosis is good as far as temporary recovery is concerned.

"In regard to the cases here presented, the most important question is that of diagnosis. In the first case there were no symptoms of a throat affection; the epiglottis presented a worm-eaten appearance, with nodules. There were no bacilli and no cough, no fever, no evidence of syphilis; and finally a subsequent cicatrization and formation of the nodule in the cicatrix led to the diagnosis of lupus.

"In the second case the main point of interest is that at the time of its presentation the diagnosis of lupus was questioned, and it was declared to be syphilis. After careful observation for sixteen years, no evidence of syphilis presented in any way. The presence of a large nodule directly on the site of the old cicatrix and the eruption on the temple so absolutely excluded syphilis that the writer believes that the original diagnosis has been amply verified."

The writer's conclusions were: 1, That primary lupus of the larynx does exist; 2, that it is a painless affection and may go on for years unnoticed; 3, that tubercle bacilli are present in small numbers, although difficult to find; 4, that its similarity to syphilis in appearance is greater than to that of tuberculosis; 5, that the absence of adhesive bands is characteristic of lupus, while they were always present in late syphilis; 6, that the prognosis as to life is reasonably good.

Dr. Swain related the history of one case. It occurred in a girl, who presented in the larynx old scar tissue, of the existence of which she was totally ignorant. Tuberculin was injected, and after each injection the scars took on a pinkish color, though there were no adverse reaction and no therapeutic benefit from the tuberculin.

Dr. Wright thought that it was difficult to draw any hard and fast line between lupus and tuberculosis. Cases seemed sometimes to run over from one to the other. Many cases at first supposed to be lupus would clear up under the iodide, thus showing their true specific nature. In one particular instance in which this was the case, a few bacilli were found in the sputa, but later the case developed tuberculosis of the lungs and larynx and ran the usual fatal course. Such cases were regarded as cases of mixed infection, but the speaker was not a believer in the truth of this theory.

A Contribution to the Study of Laryngeal Phthisis.—Dr. T. Morris Murray, of Washington, reviewed the various advances made in the treatment of this affection since the publication of a paper read by him in 1894. He called attention to the good effects of a digestive preparation called enzymol, which he had applied to the larynx for the purpose of digesting off the diseased tissue. In one instance the result had been quite remarkable. He advocated the use of creosote, which he regarded as a *sine qua non* in the therapeutics of this affection.

Dr. E. Fletcher Ingals, of Chicago, stated that he had given up the use of creosote itself, and had substituted therefor carbonate of creosote. It was much better borne than creosote, and the dose could be run up even to one drachm three times daily.

Four Cases of Sarcoma of the Nasal Cavity.—Dr. J. E. H. Nichols, of New York, reported the cases, giving the clinical histories in deail.

The following papers were read by title: "The General Health and the Upper Respiratory Organs," by Dr. J. C. Mulhall, of St. Louis; "A Case of Angioma of the Tonsil, with Recurrence of the Same Three Years after Removal," by Dr. J. H. Hartman, of Baltimore; "The Advantage of Bromide of Ethyl in Adenoid Operations," by Dr. T. Melville Hardy, of Chicago; "Surgical Treatment of Acute Inflammation of the Tonsillar and Peritonsillar Regions," by Dr. H. L. Wagner, of San Francisco.

At the executive sessions the following were elected to active fellowship: Dr. J. Payson Clark, of Boston—thesis, "Nasal Polypi;" Dr. J. Edwin Rhodes, of Chicago—thesis, "Atrophic Rhinitis;" Dr. Richard Frothingham, of New York—thesis, "Benign Retropharyngeal Tumors," with a report of cases: Dr. James E. Logan, of Kansas City—thesis, "Laryngitis Rheumatica," with a report of cases. For corresponding fellowship, Dr. H. Luc, of Paris, France.

Officers.—The annual election of officers resulted as follows: *President*, Dr. Thomas R. French, of Brooklyn; *First Vice-President*, Dr. Alexander W. McCoy, of Philadelphia; *Second Vice-President*, Dr. Herbert S. Birkett, of Montreal; *Secretary and Treasurer*, Dr. Henry L. Swain, of New Haven; *Librarian*, Dr. J. H. Bryan, of Washington.

Brooklyn was chosen as the next place of meeting. The date will be selected by the council of the association.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Wednesday, May 5th.

Enucleation of Both Eyes in a Case of Exophthalmic Goitre.—Dr. J. A. Spalding, of New York, read a paper describing "The Enucleation of Both Eyes Owing to Panophthalmitis in a Case of Exophthalmic Goitre." The case was marked by sudden onset of diplopia and dizziness, followed by protrusion, first of the left, later of the right eye also; then enlargement of the thyroid, protrusion becoming excessive; pain extreme; temperature, over 100° F.; and pulse, 120. Pus in places behind cornea, iris, and choroid. Finally enucleation. The left eye improved for a while under thyroid extract, but later the protrusion returned and the eye was finally lost. On section the eye was found to be the seat of a purulent choroiditis, with swelling of the optic disc and nerve, extending some distance back from its entrance into the eye.

Exophthalmus.—Dr. Aiken reported a case of exophthalmus which appeared to have its origin in the stage of excitement during the administration of ether for a gynæcological operation. The vision was normal with correction. There was gradual improvement of the condition during two years, not due to medication in the opinion of the patient. Dr. Aiken thought the difficulty might be due to a hemorrhage in the fourth ventricle.

Pulsating Exophthalmus.—Dr. W. H. Wilder reported three cases of this nature. In the first, one eye projected twelve millimetres in front of the other and pulsated freely; pulsation was increased by bending the head forward. The heart sounds were normal, except a slight accentuation of the second sound. It had continued over one year without change. The second was a case of Dr. Ralph Isham's, originating in a crushing injury to the head by being caught between cars. A day or two after the injury it was noticed that the right eye protruded. Diagnosis, aneurism. Ligation of the right carotid was advised and performed, with temporary relief. On the return of the symptoms the left carotid was also ligated, resulting in general

improvement. The third case was one of Dr. Beard's after a similar injury, which was accompanied by bleeding from the nose and ears, and later a watery discharge. The patient had diplopia, which afterward disappeared. A bruit could be heard over the eye and vessels of the head, which disappeared on pressure on the carotids. In these cases ligation of the common carotid promises the best results the speaker thought.

Sarcoma of the Clinoid Processes.—Dr. S. M. Burnett, of Washington, D. C., reported a case of extensive swelling between the ear and the right eye, with loss of vision in that eye, followed later by total loss of sight in the left eye, with no macroscopic change in that eye. Later, exophthalmus in both eyes, gradually increasing, with emaciation in spite of good appetite, and death. Autopsy revealed sarcoma near the clinoid processes.

Dr. J. O. Fansley had had several cases of exophthalmus, of which two had been most interesting, and one of which had already been reported to the society. The other was that of a physician, and supervened on an attempt to remove dead ethmoidal tissue, which resulted in a profuse hemorrhage, controlled by packing the nasal space. Immediately the left eye began to bulge and pulsate, and a bruit developed in the head. First the left, later the right carotid was ligated, with only temporary relief. With a return to full diet and removal of the nasal plug, the subject got well.

Chronic Pseudomembranous Conjunctivitis.—Dr. Lucien Howe, of Buffalo, N. Y., exhibited a case of chronic pseudomembranous conjunctivitis, with some remarks on the pathology and bacteriology of the affection, and offered an improvement in the classification, based on the bacteriological appearances. He would divide conjunctivitis into four classes: First, catarrhal exudate, easily removed and with no special bacterial forms; second, conjunctivitis due to staphylococcus; third, conjunctivitis due to streptococcus; fourth, that due to the Loeffler bacillus; and he would make a further subdivision between the third and fourth, which would be characterized by the presence of the diplo-streptococcus.

Dr. Myles Standish, of Boston, Mass., reported a case of diphtheritic conjunctivitis. He was always suspicious of those gray infiltrations of the cornea with comparatively little conjunctivitis. The effect of antitoxin was extremely happy, the corneal erosions leaving no leucoma. A second case, with spots like phlyctenulæ near the sclero-corneal margin, later developed infiltration of the cornea near the phlyctenulæ and threatened total necrosis corneæ, but this was averted by the use of antitoxin.

Dr. G. E. de Schweinitz, of Philadelphia, Pa., stated that he had seen a case with extensive destruction of the cornea, not clinically indicative of diphtheria, but in which the presence of the Loeffler bacillus was demonstrated and antitoxin was not used. He confirmed the conclusions of Dr. Standish.

Dr. John E. Weeks, of New York, believed that the suggestions on classification were in the right direction.

Prosthetic Operation in Cicatricial Orbit.—Dr. G. C. Harlan, of Philadelphia, Pa., reported a new operation for prosthesis in cases of cicatricial orbit. Burrowing under the cicatricial tissue, he introduces a lead wire forming a complete circle under that tissue about the orbit in the line where the retrotarsal folds should be. Having thus formed a sinus, he lays it open and places in the groove a perforated lead shell. Later a glass shell is introduced and worn with comfort, the groove thus made not closing. He exhibited the lead-wire circle and lead shell; also photographs of the lead wire in place.

Ivory Exostosis of the Orbit.—Dr. W. F. Norris, of Philadelphia, Pa., described a case of ivory exostosis of the orbit, in which there was no difference in the appearance of the optic nerves, but the vision was somewhat better in the fellow eye than in the one affected. There was diplopia only in one position, none in the primary position of the eyes. On removal the tumor proved to be a large ivory exostosis springing from the os planum of the ethmoid. Fourteen months afterward all dizziness and double vision had disappeared, but an epiphora previously existing still continued.

Dr. Robert Sattler, of Cincinnati, Ohio, made a supplementary report of a case of ivory exostosis of the orbit, he having previously reported the case to the society. Eight months later the opening showed signs of necrosed bone, and an extensive opening of the sinus and neighboring parts disclosed in a cavity another tumor as large as a pigeon's egg. This was removed, and the subsequent progress of the case was all that could be desired. He exhibited the specimen.

Intra-Ocular Tumor.—Dr. Edward Jackson, of Philadelphia, Pa., reported a unique intra-ocular tumor. The eye showed changes in iris, lens, and vitreous. By illumination with strong sunlight concentrated on the eye by a nine-inch mirror and a lens, detachment of the retina was seen and a yellowish tumor. Diagnosis, probable sarcoma of choroid. Enucleation of the eye was proposed and performed. On examining the eye hardened in formalin, he found a gray tumor imperfectly stained with any reagent; it turned the knife aside almost like bone, and was evidently partly of calcareous consistence.

Retinal Angiosarcoma.—Dr. W. B. Johnson, of Paterson, N. J., exhibited a specimen, gelatin mounted, of angiosarcoma of apparent retinal origin. The patient had something the matter with her eyes when a baby, described as inflammation of the right eye. After her first parturition the eye became prominent. Two months before being seen she had pain, swelling of the eye, and no vision. When she was first seen the area of the cornea was increased, being one-eighth inch in diameter greater than that of the fellow eye, with staphylomatous elongation of the cornea and thinning of the anterior part of the sclera. The eye was enucleated. Macroscopical and microscopical examination was reported.

Dr. Sattler asked whether the growth involved any part of the orbit, and was answered in the negative.

Dr. Weeks thought that the description was enough to cause the tumor to be called a glioma. The cells were gliomatous and the foxtail remains of the vessels were characteristic of glioma.

Dr. Lucien Howe remarked on the readiness with which small intra-ocular growths are sometimes removed, and related a case in which a small growth projecting into the anterior chamber was cut away, with very good final result.

Removal of a Foreign Body.—Dr. William Thomson, of Philadelphia, Pa., related a case of the removal of a piece of steel embedded in the crystalline lens, the lens being removed in its capsule with the steel in it. He also exhibited a foreign body removed encapsulated in a connective-tissue band in the vitreous, and which was located as to position by means of the *x*-rays, the foreign body not being visible in any other way.

Dr. William M. Sweet, of Philadelphia, Pa., demonstrated on the blackboard the method of triangulation adopted in determining the position of the foreign body.

Dr. C. A. Oliver exhibited a series of radiographs demonstrating his method of triangulation, and objected to Exner's method, as being not so practicable with the human eye as on the model.

The society re-elected the present officers for another year.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SENILE TUBERCULOSIS—MEAT DIET IN GOUT—POSTERIOR BASIC MENINGITIS—HOSPITAL REFORM ASSOCIATION—ANTI-QUACKERY LEAGUE—WOMEN AND HOSPITALS—DEATH OF DR. JAMES ANDREW AND MR. J. W. TEALE—INFLUENZA AND DIPHTHERIA.

LONDON, April 30, 1897.

TUBERCULOSIS in the aged is a much graver disease than in the young. It may affect the joints or viscera, and in the former simulates for a time rheumatic or gouty affections. Later suppuration and disorganization clear up the diagnosis, but too late for interference. I find very few notices of the disease in the text-books, so that a paper read by Mr. Howland Marsh before the Medical Society on Monday, recording illustrative cases, must interest many readers. He had not seen recovery when the disease attacked a large joint in a patient over fifty-five. The treatment advised was rest, building up the general health, opening abscesses under rigid asepsis, and, when disorganization occurred, amputation. He also described cases of "subcutaneous ulceration," in which the tuberculosis spread in a horizontal plane, giving rise to extensive undermining of the skin by tuberculous granulation tissue. For this he advised free incisions and scraping.

Several fellows made remarks on the cases, and mentioned others more or less similar which had come under their notice.

Mr. Armstrong, of Buxton, then read a paper on red meat as an exclusive diet, with water at a temperature of 120° F., for the treatment of gout, of chronic gouty arthritis, recurrent renal calculi, migraine, and gouty dyspepsia. He related cases in which he had obtained excellent results from this regimen after other modes of treatment had failed. He attributed the bad effects commonly believed to be due to the ingestion of meat by gouty patients to the carbohydrates and sugar consumed. Fermentation and putrefaction were, he said, checked by his treatment, and although it was very disagreeable it should be carried out strictly under close supervision. Of course, therefore, it is only applicable to severe and difficult cases, but in these he had found it very successful.

Dr. Haig admitted that a meat diet now and then seemed to do good in gout, though the disease was really due to the uric acid ingested with meat. He assumed that the action was that of a stimulant, which provoked elimination of the acid.

Dr. Luff joined issue as to the statement that uric acid was ingested in meat, on the ground that its presence in this food has never been proved. His own researches go to show that uric acid is never a normal constituency of the blood or tissues.

Dr. Haig rejoined that if uric acid had not been demonstrated in meat, other bodies which he considered equivalent had, viz., the xanthin class.

Dr. Luff retorted that these bodies belonged to a different class, their properties and reactions differing widely.

Mr. Buxton Browne attributed the results to the exclusion of injurious articles, and said renal calculus may be cured by excluding sugar, alcohol, and starch.

Dr. Thorowgood thought the treatment corrected the flatulent dyspepsia which attacked gouty patients who indulged too freely in starchy foods.

The discussion was adjourned.

On Tuesday the adjourned discussion on Dr. Carr's paper on "Non-Tuberculous Posterior Basic Meningitis in Infants" took place at the Medico-Chirurgical Society meeting. The paper was noticed in my last letter. Dr. Barlow congratulated the author on his carefully analyzed cases and statistics, though he did not indorse his proposed etiology. He thought it probable that cases of alleged recovery from tuberculous meningitis were examples of this group. The fluid was cerebrospinal, not dropsical or inflammatory. Obstruction of the foramen of Magendie was by no means universal, and when present was probably due to inflammatory adhesions. He thought otitis media, so frequent in children, played a part in producing the disease. He mentioned a case in which the patient recovered after being tapped, and hoped early operations might be successful. Mr. Battle was also in favor of early operation. Mr. Raymond Johnson, who had operated in two of Dr. Carr's cases, thought if tapping was to be done it should be early, for in marked hydrocephalus the escape of the fluid could not be limited and convulsions set in. Drs. Lees, Moore, Church, and Abercrombie joined in the discussion, and Dr. Carr replied and said he had given up the idea that obstruction of the foramen of Magendie was the cause, since it was shown that the foramen was sometimes open.

The Hospital Reform Association held a successful meeting at Birmingham last week. Mr. Jordan Lloyd took the chair, and in his speech remarked that the time of a distinguished man ought not to be taken up by trivial cases nor by patients who could afford to pay for medical aid. He advocated also central control of charities, chiefly on the ground of economy, though it may be questioned whether this would be effected. A resolution was passed in favor of the recommendations of the association for the better regulation of the out-patient and casualty departments. The association is only six months old, but it has certainly made some impression. Dr. Honder, the founder, traced to its influence a distinct reform in one of the London hospitals. Now Birmingham has been moved, and her daily papers, which are of a very high order, are giving a good deal of space to the subject. The next move is to be a meeting at Liverpool or Manchester, which both need awakening on the subject. The plan of exciting discussion in various places seems to me a good one.

An Anti-Quackery League has been founded, and will find plenty of work in disseminating information about the frauds on the public committed by the great army of quacks. This league is not to be a doctors' organization, but is to represent the public, and persons of various callings are on the committee. That the public needs enlightenment is obvious from the manner in which advertisements of transparent frauds are found to pay. Some quacks have registered their business as companies of limited liability. This week "Mother Seigel's syrup" is offered to the confiding public for a cool million sterling, and the prospectus admits that £40,000 is enough for working the business, and the vender is to have the £960,000.

The women's journals are attempting to get up another case of oppression. The new grievance is that men have monopolized the management of hospitals. Women have done good on boards of guardians and would very likely be useful on hospital committees. The staff of the new hospital for women are all women; so are the secretaries. I am not sure about the committee. It would seem that women's hospitals should be the first to be blamed for any grievance, if it really exists, as to the exclusion of the sex. I know hospital managers who would be glad enough to retire in favor of women who would assist with money and brains.

Society papers are fluttering over the news that a sister of a lord has become a medical student, and hopes to obtain some day an appointment as a medi-

cal officer to an Indian rajah. A reasonable ambition perhaps, but not so remarkable in these days, when royal personages have entered the profession.

The death is reported of Dr. James Andrew, consulting physician to St. Bartholomew's Hospital, aged sixty-seven. He retired from practice some time ago, with the esteem of all his confrères and the gratitude of the many students he had trained during his long services at the hospital and school. He was censor of the College of Physicians, 1886–87; Lumleian lecturer, 1884; Harveian orator, 1890. Few men have been followed with more kindly feelings into their retirement, and many will feel his death as a personal loss.

Mr. John William Teale, of Scarborough, died on the 19th. He was an Oxford M.A. and F.R.C.S. Eng., and a magistrate of the town where he had long been a highly esteemed surgeon. He was seized with pneumonia during a holiday he was taking for salmon fishing, a sport of which he was an ardent follower.

Influenza and diphtheria are both on the increase in London. The fatal cases of the former registered in the last four weeks were 28, 34, 22, 37. The deaths from diphtheria rose last week to 40, being 10 above the average for that week in the last decade.

OUR PARIS LETTER.

(From our Special Correspondent.)

END OF A CAUSE CÉLÈBRE—CONDEMNATION FOR CRIMINAL ABORTION—DEMANDS FOR GOVERNMENTAL ACTION AGAINST IRREGULAR GYNÆCOLOGICAL CLINICS—OPHTHALMOLOGICAL CONGRESS—DEATH OF DR. MAISONNEUVE, ETC.

PARIS, May 1, 1897.

THE condemnation of Drs. Boisleux and de la Jarrige to five years each of penal servitude for performing criminal abortion on Miss Thomson, a fitter at Redfern's, whose death from infectious peritonitis was caused directly thereby, has had a very wholesome effect. The French public not only endorses the finding of the jury, but "doctors" having private and irregular gynæcological clinics of the kind in which Miss Thomson was killed, and I am told there are still such here, have been very forcibly shown the risks they run and the danger in which they stand. It is to be hoped that the chamber of deputies will now pass such draconian laws as will force all these clinics to abandon their nefarious traffic and oblige all private clinics to be legalized and placed under direct municipal or governmental control or supervision. The case, which was particularly flagrant and only one of a fatal series occurring in Dr. Boisleux's clinic, resulted in three deaths—those of the mother and fœtus and that of the seducer, who shot himself from remorse. Under the circumstances the sentence was a very light one. It has, however, been productive of much good in the way above mentioned, and is a step in the direction of causing the disappearance altogether of criminal abortion—an evil which is prevalent in all large cities.

The French understand the words "liberal profession" to mean exactly what they say and interpret them in their broadest sense, especially that of free education in general and as far as compatible with the medical budget and expenses. Witness the gratuitous courses at the École de Médecine.

The following additional free courses are announced: 1st. Technical and practical bacteriology and microbiology, by Dr. Latteux, chief of the histological laboratory at the Broca Hospital. This course has the advantage of being not only technical and theoretical but also essentially practical, and is destined to put students as well as practitioners in a position to carry out all the researches required in every-day medical practice, by individual exercise and repetition by themselves of all the experiments with the principal normal and pathological microbes. 2d. Gynæcology. Dr. Charles Fournel, laureate of the Faculty of Medicine and member of the Obstetrical and Gynæcological Society of Paris, will begin on April 27th a public and gratuitous course of medico-chirurgical gynæcology at the École Pratique. 3d. Ophthalmology. Dr. Kœnig is continuing his work as director and chief of the Ophthalmological Clinic in the Rue Monge.

It may be said with truth that Paris is the city of clinical work and research, and were I to attempt to list the clinics they would run well up into the hundreds. No wonder then that among so many good ones an occasional *louche* one should be found. "Louche," which really means ambiguous, has become a professional word with the French police and signifies with them loose, irregular, and shady—such clinics as the one alluded to at the beginning of this letter, into which innocent people are decoyed and operated upon for money solely. The more the better is the word with them, but operate anyhow: time is short and a dead woman more or less matters not; as for the fœtus, why, that does not count anyhow. Happily there are very few of these, even in so large a centre as Paris, and it is to be hoped that the tremendous outcry and stir that have been raised about the case in question will result in the prompt suppression of all such.

The French Society of Ophthalmology will hold its congress of 1897 at the Hôtel des Sociétés Barantes. The first sitting will take place on Monday, May 3d; the others, of which there are four, will be held respectively as follows: Tuesday, May 4th, at 8 o'clock in the morning, business sitting at 11 A.M.; third sitting Wednesday, May 5th, at 8 A.M.; fourth sitting at two o'clock the same afternoon; fifth and final sitting on Thursday morning, May 6th. Professor Panas, of Paris, will read a report on the "The Rôle of Autoinfection in Ocular Affections;" Dr. Fage, of Amiens, will read a paper on "Rupture of the Choroid;" Dr. Terson, of Toulouse, on the third day will present the most important report of the congress, that made in the name of the committee on the proposition formulated at the last session by Dr. Lucien Howe and adopted by the society: "Is it desirable to propose to the government to make a law for the prevention of blindness resulting from ophthalmia in the newborn and what is the best form for such a law?" Dr. Bull, of Paris, will be heard at the fourth sitting on "The Value of the Ophthalmometer from a Practical Point of View." On the fifth day Dr. Teillais, of Nantes, will make a communication on "Sarcoma of the Orbit."

The congress will listen to sixty-four reports and papers during its session, and there will also be an exposition of instruments, apparatus, dressings, and appliances used in ophthalmic surgery, optics, and electro-therapeutics. It is to be an up-to-date congress, and the large volume that its proceedings will make will be a valuable and standard book of reference in ophthalmological literature and practice.

Calcareous and sandy formations in the different parts of the body, but more especially in the appendix and intestines, occupy the professional mind just now as much if not more than other matters. Thus, at a recent meeting of the Société Médicale des Hôpitaux, Dr. Mathieu presented a sample of intestinal sand, obtained from a man affected with simple constipation and in whose case there was no muco-membranous enteritis. This sand, mixed in the fæcal matter, had been expelled, accompanied by lively pains, simulating those of appendicular colic.

One of the surgical celebrities of the second empire

has just passed away in the person of Dr. Maisonneuve, founder of the French Society of Surgery, the last meeting of which adjourned in honor of his memory as soon as the announcement of his death was made. Dr. Maisonneuve spent the last few years of his life at his native town, remote from Paris, and seemed to have been entirely forgotten. He was a brilliant and daring operator in his day, and was best known through his urethrotome and his advocacy of *écrasement linéaire*.

"EXPENSIVE SANITATION."

To the Editor of the Medical Record.

Sir: My attention was called to a letter signed "A. B. C.," entitled "Expensive Sanitation," in the issue of your paper of the 8th inst.

The writer of this letter does not intend to convey the idea that the facts there stated are based upon his own knowledge, but upon alleged information obtained from a morning newspaper.

It is untrue that it will require ten million dollars in bonds to be issued by the city for payment of damages to owners of rear tenement houses which have been condemned by order of the board of health. Condemnation proceedings are instituted pursuant to chapter 567 of the laws of 1895, as amended by chapter 37 of the laws of 1897, and re-enacted by the charter of the Greater New York, known as sections 1,315 and 1,316.

It has been the policy of the board of health since the adoption of these laws not to condemn rear tenement houses unless the facts show that the premises are unfit for human habitation and are not reasonably capable of being made fit for human habitation, and by the provisions of section 3 of the foregoing law it is provided that the compensation to the owners shall be the value of the materials of the buildings.

Seven rear buildings have thus far been taken by the board of health, at a total cost to the city of $1,078, or an average cost per building of $154.

The owners of eleven rear buildings voluntarily removed them, after proceedings were instituted under the law, and received no compensation from the city authorities.

"TRANSITORY DISTURBANCES OF CONSCIOUSNESS IN THEIR MEDICO-LEGAL ASPECTS."

To the Editor of the Medical Record.

Sir: In his able paper on "Transitory Disturbances of Consciousness in their Medico-Legal Aspects," published in your number for April 24th, Dr. Hirsch gives an importance to the simulation of unconsciousness by criminals at the time of the commission of their crimes which seems to me unwarranted. It is common, indeed, for those whose motives have been criminal, to deny such consciousness and all memory of their criminal act, just as they deny the act itself whenever there can be the least doubt of the fact. But this denial can have only the slightest value in determining the mental condition of the accused. The consciousness and memory of others are so far beyond our reach that the lowest grade of cunning is often sufficient to baffle the shrewdest expert upon this point. I cannot agree then with the learned writer, that "the psychiatrical expert should be able to give a definite answer to the question of insanity" through an inquiry into the fact of simulation.

The fact of delirium has, however, its objective tests, which appear in the words, looks, and actions. For myself, a large experience in the examination of those who have attempted to commit homicide, suicide, and other crimes has convinced me that most of these persons remember more or less perfectly the feelings and impulses which led up to their crime, and were conscious when it was committed. The primary question, then, in these cases is as to the existence of delirium. In that delirium which precedes or follows epileptic seizures, and which has strongly marked features of its own, there can be no doubt of unconsciousness and irresponsibility. But we must often go beyond the simple fact of delirium to find the tests of a medico-legal insanity. Intoxication and other causes may induce a temporary delirium, but when this has been brought on by the voluntary act of the criminal the law does not admit it as an excuse for his crime. On the other hand, when delirium is due to causes beyond the volition of the subject, the law will excuse him from responsibility for crime committed under its influence.

In the recent case of Maria Barberi it was impossible either to affirm or to deny the theory of epileptic insanity upon any scientific grounds. It is plain, indeed, that neither judge nor jury gave any weight to this theory upon her trial. But that she was delirious at the time of the homicide, and that this delirium was produced by an intense feeling of shame and despair in view of her ruin was a probable conclusion. It was due then, in fact, to the base and criminal passion of her seducer, and she could not be held responsible for the homicide which proceeded from it. If this was indeed the ground of the jury's verdict, it seems to have had a better foundation in mental science and in common sense than if it had been based on the theory of psychical epilepsy or unconscious fury.

CRIMINAL ABORTION.

To the Editor of the Medical Record.

Sir: In the issue of April 10th Dr. H. P. Beirne presents an article on criminal abortion which can be criticised to some extent. In my experience with pregnant women I find many who desire abortion, but I have yet to find the individual who is capable of producing abortion on herself. I have questioned them on the subject time and again as to their method of procedure, and their answers were so plainly absurd that I did not hesitate to place these women outside the possibility of this act. 'Tis true there are many criminal abortionists, but unless they have had much information from professional sources they are of little account in that line of business.

Abortions are spoken of as being performed with great frequency and great success among the most unenlightened on this subject, but the medical profession does not find it so, even among accidental miscarriages. The physician has to use his utmost skill in the treatment of a miscarriage. How can the unprofessional be so successful in their forced abortions? I do not believe these abortions take place so frequently, because people don't know how to produce them. This talk about mothers teaching their daughters is rank nonsense, as the mother knows nothing more than what she has heard. There is but one possible method of producing abortion open to the laity, namely, by the introduction of a sound into the uterus, and I'll defy the vast majority of women to accomplish it. Dr. Beirne speaks of a medicine to bring women around. The doctor may know of such a medicine, but I'll challenge him to the world that he can't name it or obtain it. It has never existed. The life and soul of the im-

pregnated ovum are not at the mercy of any mother. They are beyond her reach, and within the reach only of physicians and criminal abortionists, who must have received previous instruction from professional sources.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 15, 1897:

	Cases.	Deaths.
Tuberculosis	168	89
Typhoid fever	13	1
Scarlet fever	192	14
Cerebro-spinal meningitis	1	8
Measles	303	10
Diphtheria	281	37
Laryngeal diphtheria (croup)	10	10
Small-pox	2	1
Chicken-pox	25	1
Leprosy	1	0

Ray to the Rescue.—An English lady in making a cake lost her diamond ring in the dough, but did not discover the loss until the baking was complete. Rather than sacrifice her production or run the risk of having a guest swallow the ring, she sent the cake to an *x*-ray studio. The ring being located by the shadowgraph without spoiling the form of the cake, extraction was readily accomplished.

Transposition of the Viscera, with a Tricelian Heart.—Jellett (*Lancet*, March 27, 1897, p. 878) reports the case of a newborn child that he found in an asphyxiated condition, respiring feebly, with a weak and irregular heart and the face and body cyanosed. Schultze's method of artificial respiration was instituted, hot baths were given, and the lips and mouth rubbed with whiskey. Upon feeling for the heart in the usual manner, *i.e.*, by pressing the fingers upward under the ribs a little to the left of the middle line, pulsation could not be felt, owing to the presence of what was supposed to be a greatly enlarged liver. Upon palpating the abdomen on the right side, to determine the size of the liver, the fingers could be pressed upward beneath the ribs, and the pulsation of the heart was felt to the right of the middle line. All attempts at revival failed, and the child died in the course of ten minutes. Upon post-mortem examination, in addition to complete transposition of the viscera—the position of lungs, heart, liver, stomach, and spleen being reversed—the heart was found to be almost twice the normal size, and when opened it was found to possess but three cavities, two auricles which opened into a common ventricle.

Suicide by Auto-Extirpation of the Larynx.—The remarkable case is recorded by Szigeti (*Vierteljahr. f. gerichtl. Med.*, 1896, H. 4; *Wien. med. Wochenschr.*, April 10, 1897, p. 680) of a woman, forty-two years old, who committed suicide by extirpating her larynx. She was found dying on the floor of a bathing compartment, with her larynx lying in a pool of blood near by. Death took place eight or nine hours later, amid symptoms of cerebral anæmia. The woman had taken a sharp table knife in her right hand, had extended her neck strongly backward, and with numerous incisions from left to right had opened the neck between the hyoid bone and the thyroid cartilage. She probably next grasped the larynx with her left hand and cut it out. An incised wound was present upon the dorsal aspect of the third phalanx of the middle finger of the left hand. The soles of both feet were bloody, so that it is probable that the woman walked a few steps after completing her act of destruction.

Prophylaxis of the Puerperium.—Dr. Puls (*Annals of Gynæcology and Pædiatrics*, January) concludes: 1. Puerperal septicæmia is the result of contact infection. 2. Subjective antisepsis prevents infection. 3. Objective antisepsis should be practised only in cases of operative interference, but the prophylactic vaginal douche is not a safeguard against infection; the vaginal surfaces must be cleansed similarly as before a gynæcologic operation. 4. The secundines must be delivered *in toto*, since the health of the lying-in depends upon a complete evacuation of the uterine cavity and a further source of infection is wanting in the absence of placental or membranous remnants. 5. A normal lying-in period is unnecessarily tampered with by irrigating the genital tract. 6. Obstetric nurses ought never to nurse contagious diseases.

A New Diphtheria Antitoxin.—The *Archives des Sciences Biologiques*, issued by the Imperial Institute of Experimental Medicine of St. Petersburg, contains some interesting information respecting the researches carried out by Dr. Smirnow on a new method of obtaining a diphtheria antitoxin of considerable therapeutical activity. The object which Dr. Smirnow had in view was to reduce the time and the expense involved by the present method of preparing the serum, and the method which he alighted upon was the electrolysis of virulent diphtheria broth cultivations. By this means he has succeeded in obtaining an antitoxin of great power which gives excellent results even when employed in much smaller doses than those at present found necessary with the ordinary horse serum. He states that even in advanced cases of the disease the injection of from one-half to one cubic centimetre enables the animal to resist the inoculated disease without marked reaction, either general or local. It seems that the new antitoxin is itself quite innocuous, for guinea-pigs can withstand with impunity doses ten times as strong as those required for curative purposes. —*The Medical Press.*

The American Gastro-Enterological Association.—The initial meeting of this association will be held at Philadelphia, June 3d, 1897, at which the following papers are to be read: "Gastro-Intestinal Diseases as a Speciality," by A. L. Benedict, Buffalo, N. Y.; (*a*) "The Diagnosis of Gastric Carcinoma," (*b*) "The Cause of the Digestion and Absorption of Rectal Nutritive Enemas," by J. C. CONGENITAL DISLOCATION OF THE HIP-JOINT, WITH SPECIAL REFERENCE TO THE NEW NON-CUTTING OPERATION OF LORENZ. FOR REPOSITION OF SAME—PRESENTATION OF PATIENT UNDER TREATMENT.[1]

BY GEORGE R. ELLIOTT, M.D.,

INSTRUCTOR IN ORTHOPÆDIC SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE object of this paper is the consideration of the unbloody or non-cutting operation of Lorenz, of Vienna, for congenital dislocation of the hip-joint, with partial demonstration of the same and presentation of the patient under treatment. It may not be amiss to mention briefly the essential pathological findings of congenital dislocation of the hip, as we know them to-day.

1. Acetabulum. This is rudimentary, usually small, slightly concave or flat, triangular, with its base directed backward and upward. In very young children hyaline cartilage is found. Sometimes the acetabulum presents a convex contour that may be bone, or fat and residual ligamentum teres.

2. The upper end of the femur is atrophied, becoming markedly so as age advances. Since we have chiefly to do with the first years of life, I will confine what I have to say regarding the findings to early life. The head of the femur is small and flat. The neck is short, often reduced to a mere groove between the flattened head and trochanter, resembling the upper end of the humerus.

3. Ligamentum teres. Occasionally absent, always perishes eventually and usually as early as the fourth year.

4. Capsule. This usually hugs the head and neck like a close-fitting cap. Its anterior wall is tightly drawn over the anterior acetabular wall and is more or less adherent to it. The capsule frequently presents a purse-like constriction.

As a rule, the dislocation of the head is backward and upward. Occasionally it is dislocated forward and upward. Phelps has reported two such cases.

We come now to the main object of the paper and will deal at once with the operation for the unbloody reduction of the congenitally dislocated hip-joint.

Those of you familiar with the cutting operation of Hofa-Lorenz know that the object sought for in that operation is:

1. To bring to the level of the acetabulum the head of the thighbone dislocated upward. This is accomplished by extension kept up in bed several days prior to the operation and at the time of operation.

2. To enlarge the rudimentary acetabulum after free incision by a process of gouging.

3. To implant the head of the thigh bone into this enlarged socket.

4. To render this artificially formed joint in course of time mobile by a properly applied system of massage and gymnastics.

The unbloody operation is along the same line with certain modifications. Anatomical difficulties, however, so easy to remove with scalpel and gouge in hand, offer problems which are to be overcome in a manner now to be described.

The first step of the operation consists in the reduction or bringing the head of the dislocated thigh to the level of the acetabulum. The patient is anæsthetized to a degree of extreme muscular relaxation. If manual extension is insufficient, which is frequently the case, a band is passed around the perineum, protected by padding, and a soft band is put about the ankle. This latter band is attached to a screw-extension apparatus. The extension is now very carefully and evenly exerted. The operator grasps the muscles of the thigh with one hand while the other is kept on the dislocated joint. As the extension gradually goes on, the operator manipulates the thigh muscles, increasing their tension by intermittent pressure against the femur beneath, while with the hand upon the joint he appreciates the descent of the trochanter. The extension is stopped at the moment when the upper margin of the trochanter is at or just below the Nélaton line. While the extension goes on the pelvis on the diseased side is drawn down, causing some abduction of the thigh. This abduction is desirable to exert increased extension of the adductor muscles abnormally

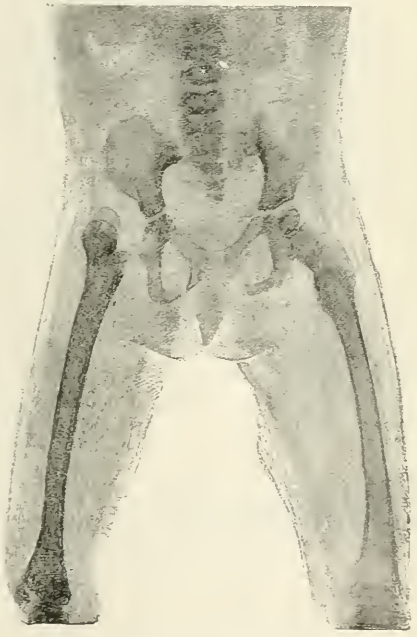

FIG. 1.—Hip-Joint of Patient prior to Operation, Showing Anatomical Peculiarities of Congenital Dislocation.

[1] Read before the New York Post-Graduate Clinical Society, April 2, 1897.

contracted. Fracture is to be avoided through care in having the extension uniformly exerted.

When we are satisfied that the head of the femur has reached the level of the acetabulum—and this is readily apparent to the touch by noting the relative position of the trochanter to the Nélaton line and to the anterior superior spine of the ilium—the extension that has taken but a few minutes is suspended, and we proceed to the second step in the operation, the wedging of the reduced head of the thighbone into the pocket of the acetabulum. This is styled reposition.

Here is the chief difficulty of the operation, due in main to the changed anatomical findings. The chief anatomical barrier is the anterior fibrous wall of the capsule hugging closely the surface of the acetabulum and rendered more taut by the extension that has just been exercised in the reduction. The acetabular

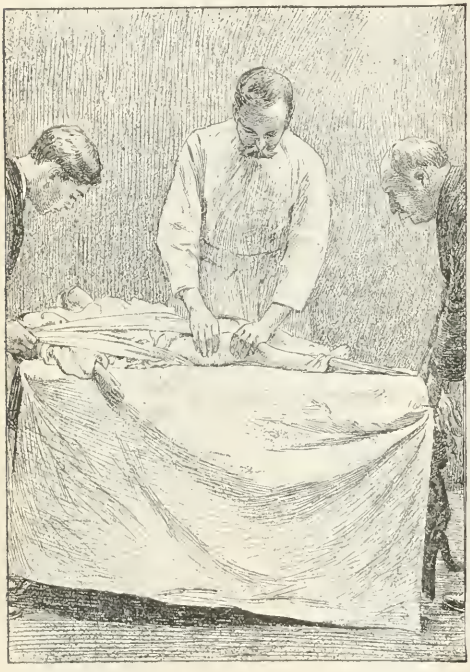

Fig. 2.—First Step, or Reduction.

space must be opened as much as possible. This is largely accomplished by flexing the leg on the thigh and the latter at right angles, which relaxes the anterior capsular wall.

The head of the femur must now be given an approximately frontal direction, thus turning it toward the hiatus of the now relaxed capsular pocket. Although the head is in the proper position to enter the acetabulum, no amount of manual force will drive it in. The operator standing on a stool seizes the thigh, flexed at a right angle to the trunk, with one hand, and, with the other grasping the head of the femur, he, by a system of extension combined with rotation and gradually increasing abduction, opens the way into the dormant-lying acetabulum pocket. When the abduction, which must be gradually exerted, has reached a considerable degree, the head of the femur, still manipulated by one hand, is felt to leap over the posterior edge of the acetabulum, and the surgeon feels at once that reposition has taken place.

Hear what the enthusiasm of Lorenz leads him to exclaim at this juncture: "This event, always expected with great tension of the mind and deep longing, is accomplished like the triumphal entrance of a princely lord through the doors of his hereditary residence from which he has been excluded for a long time, through stress of circumstances, amid the chiming of bells, the beating of drums, and firing of cannon which shakes the foundation of his castle. And yet this plaintive music of nature is for the parched ears of the operator a sound-intoxicating song of the spheres; as long, at least, as he preserves during his laborious work a receptive soul for such enjoyment." In plain Anglo-Saxon the successful reposition produces at this point a distinct noise that may be heard some little distance from the patient, but is chiefly appreciated by the operator.

Having accomplished then a real and true reposition, owing to a great disproportion between the rudimentary acetabulum and the head of the femur the reposition is not stable—a redislocation readily occurs. This takes place when you lessen the extreme abduction and the head goes back into its dislocated position. It can be reposed and dislocated at will. This I have had occasion to observe over and over again.

In the usual case, in order to retain the reposed head, it is necessary to keep the angle of abduction not far from ninety degrees. When the head is properly reposed, it can be felt anteriorly midway between the symphysis and anterior superior spine of the ilium and the hollow space so diagnostic of the difficulty is obliterated.

The third step in the operation has for its object the formation of a solid acetabulum. Only a small part of this can be done by the operator; the chief part belongs to the after-treatment. By manipulation the soft parts of the acetabular cavity may be moulded, considerable patience and strength being exercised, but the substantial changes occur gradually when the patient with properly fixed joint is allowed to go about. In order to retain the head of the bone in contact with the acetabulum and thus reawaken the process of growth so long dormant, the thigh is fixed at about an angle of ninety degrees of abduction—in favorable cases a somewhat lesser angle. The fixation is made with a plaster-of-Paris bandage carefully applied about the pelvis and extending to the knee-joint of the affected side.

The pains due to the operation subside in a day or two, and the patient is urged to walk. It is advisable to add a few inches to the shoe of the foot of the diseased side and give some support at first; but this walking about constitutes one of the most important parts of the treatment. Every step tends to drive the head of the bone deeper and deeper into the rudimentary acetabulum. Growth is reawakened, the parts are reactivated and a nearthrosis is gradually built up. Lorenz styles this part of the treatment—the loading the head of the bone with the body weight, together with the reposition, that is, the real entrance of the head of the femur into the rudimentary acetabulum—as the two chief points in the operation decidedly original with him.

It is surprising how soon these children learn to walk. If they do not learn to walk, even with support, nothing can be hoped for from the operation.

The first fixation is left on three months and then removed. If the joint is found good and the reposition stable, the patient is allowed to go about with the sole on the sound foot raised from two to four inches, so as to keep up a tendency to slight abduction in the previously dislocated member. Massage and gymnastics are advised.

As a rule, it is advisable to subject the patients to a second fixation period of three months, and here the

abduction may be markedly reduced, say, to an angle of forty-five degrees, and the sole of the healthy foot now slightly raised. In double congenital dislocation Lorenz operates upon one leg at a time, and when the stabilization of one joint is good the second operation is performed. He formerly operated upon both at one *séance*, but found walking so difficult that he abandoned it.

The operation is practically limited to young children, as a rule not to exceed seven years, preferably under four.

The little patient I present to-night is, I believe, the first reported case of this operation in this country. She is five years of age, and prior to the operation had a well-marked congenital dislocation of the right hip, presenting the usual objective symptoms. There was a three-quarter-inch shortening of the affected leg; the trochanter was markedly above the Nélaton line. A depression existed on the anterior surface of the thigh, the contour of the hip-joint was changed, the adductors were contracted, the pelvis was tilted, a compensatory scoliosis was present—in short, the classical picture of the difficulty. Some difficulty was met with in making the reposition. The adductors were so contracted that even under chloroform the thigh could not be abducted more than fifteen degrees. The extreme degree (about ninety) of abduction you now see was obtained only by exercising considerable modelling force. As the head of the femur passed over the posterior wall of the acetabulum, the sound Lorenz so enthusiastically refers to was quite marked. In performing the operation the details enumerated to you were carefully followed.

I have witnessed Professor Lorenz perform this operation in twelve cases, in all of which he succeeded in making a true reposition. I saw also the fixation splint removed from five cases that had been operated upon previously, and in four of them the joint appeared stable. In three of them, however, the second fixation was applied at a considerably reduced angle of abduction. The stabilization of the joint was so good in one case that it was not deemed necessary to apply further fixation. In one of these five cases there was considerable mobility after removal of the bandage. A second fixation splint was applied, but I believed he looked upon an ultimate good result as somewhat doubtful.

Now, a word regarding the priority of this operation. At the twenty-fifth congress of the German Association of Surgeons, held at Berlin, May, 1896, Lorenz presented four cases of congenital dislocation of the hip-joint, upon which he had operated, as he claimed, by an entirely new method. His first public allusion to this operation, I believe, was made in January of the same year before the Royal Imperial Society of Physicians at Vienna and published the following April (one year ago). Considerable discussion followed Lorenz's presentation before the German congress, and the originality of the operation was questioned, especially by Mikulicz and Schede. It was said closely to resemble the method of Paci, of Italy, described by him in 1888.

Bergmann, president of the congress, called upon Lorenz to make a demonstration the following day before that body. This was done, and it was generally agreed that a new principle in treatment had been discovered. Paci, however, in two communications to the *Berliner klinische Wochenschrift*, attempted to show the similarity of the operation to his, and attempts still further to substantiate this in communications to the *Berliner klinische Wochenschrift*, June and August, 1896. These communications have met with crushing rejoinders from Lorenz, and I do not well understand how an unbiassed mind after carefully studying the two methods can fail to see that the principles of treatment in the two operations are radically different.

In 1888 Paci described a treatment that aimed at restoration of the congenitally dislocated hip-joint. This operation is very well known. To show wherein it differs from the operation described above, it will not be out of place briefly to describe its different steps.

Paci divides his operation into four stages, which he calls tempi: 1. Flexion of leg and thigh upon the pelvis quite to the physiological limit. This, combined

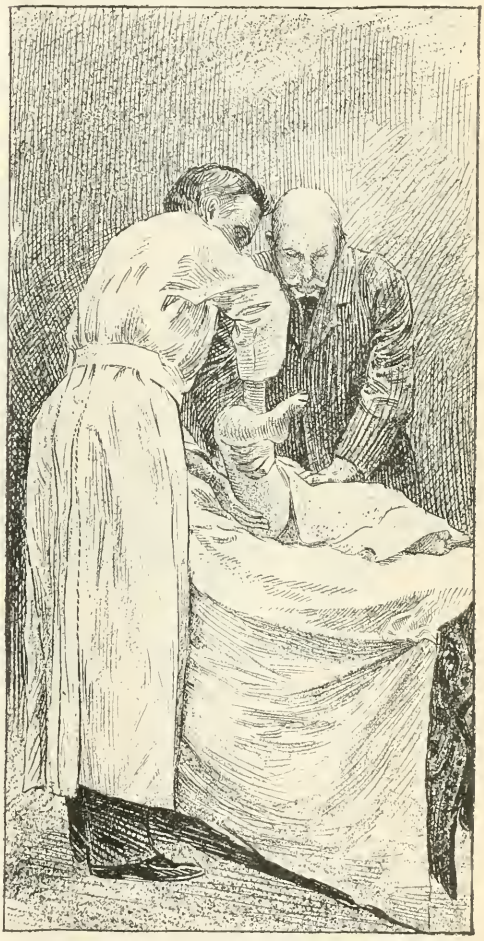

Fig. 3.—Second Step, or Reposition with Modelling of Acetabulum.

with pressure on the knee-joint, is said to bring the head of the femur out of the ext. iliac fossa to a point under the acetabulum. 2. Moderate abduction. The leg is abducted to the extent of fifteen centimetres from the lateral line of the body. 3. Outward rotation. 4. Slow extension in bed. The after-treatment consists in fixation every four weeks with slightly preserved abduction. Extension is continued three months in bed. After four months the patient walks about on crutches, and for months afterward is cautioned not to place too much weight on the disabled limb.

To use Paci's own words, he says: "The result is often excellent, because the head has occupied its natural position in the acetabulum in such a manner that we appear to have before us a true reduction. But

often the head contents itself by taking position quite in the neighborhood of the rudimentary acetabulum, or beneath the anterior iliac spine." This is as strong as he expresses himself in his reply to Lorenz, published in the *Wiener klinische Wochenschrift* for June, 1896, and with the object in view of attempting to show that Lorenz's operation was practically identical with his own.

Carefully analzying the two methods, we find but little really in common. The end product of Paci's operation is undoubtedly a nearthrosis formed in the vicinity of the rudimentary acetabulum, and not a true reposition. As has been pointed out, a reposition is absolutely impossible at the slight degree of abduction, viz., fifteen centimetres, that he makes. Any one who will make a true reposition can satisfy himself on this point. After a reposition, requiring, as it does usually, an abduction of about ninety degrees, a redislocation occurs long before the thigh reaches the fifteen centimetres limit of Paci.

This extreme degree of abduction is a *sine qua non* of a true reposition; and it is the true reposition, the actual putting the head of the femur into the rudimentary acetabulum, that Lorenz insists upon as one of the chief features of his operation. It is complete reposition or nothing. Not resulting thus, the operation is a failure. No attempt is made to establish a nearthrosis in the neighborhood. Lorenz gets the reposition and immediately loads the joint with the body weight, and usually in three months has a well-working joint. Paci, on the other hand, gets only an approximate reposition, continues his treatment over many months, and finally gets a nearthrosis in the neighborhood.

I am not prepared to deny that Paci's demonstration at the Roman congress in 1895 may not have set Lorenz thinking, but I feel quite positive that the numerous bloody operations that Lorenz has performed (two hundred and thirty up to September 25, 1896) so thoroughly familiarized him with the pathological findings that he was led to attempt a true reposition, the result being the complete treatment that he has given us. The bloody operation now so well known is surrounded by many difficulties that interfere with good results. It requires a long, careful after-treatment, that the surgeon is so prone in his busy life to neglect, and stiff joints and contractures too frequently follow. On the other hand, the treatment following the non-cutting operation is almost entirely done by the patient in walking about. While this operation is restricted rather to quite young children, yet with our rapidly increasing knowledge of diagnosis it will not be many years before the congenital difficulty in question is recognized sufficiently early by the general physician to render the operation practicable.

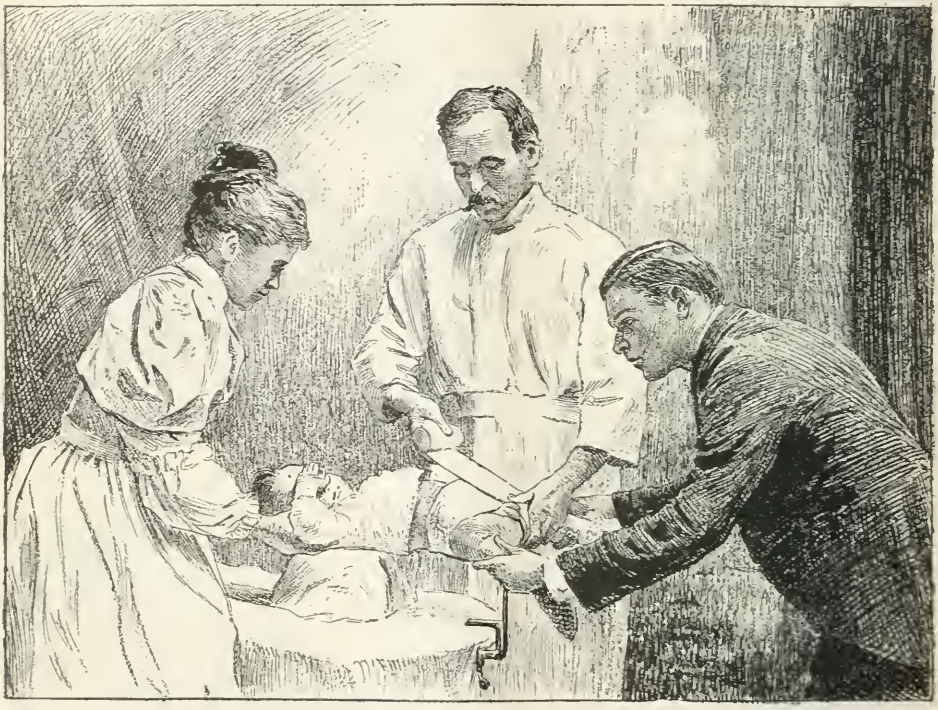

Fig. 4.—Fixation at 90° of Abduction.

This dislocation is not uncommon. Lorenz, up to September 25th of last year, in a period of about one year, had operated upon eighty-three cases. Many patients now, with our insufficient diagnostic knowledge, go travelling about from doctor to doctor, from clinic to clinic, and either a faulty diagnosis is made or the patient is told that nothing can be done.

Finally, the operation we have just considered is a real addition to surgery, and, throwing all enthusiasm aside, I feel confident that it will soon be performed with strikingly good results in all civilized parts of the world.

ATAXIA IN A CHILD.[1]

By MARY PUTNAM JACOBI, M.D.,

NEW YORK.

I HAVE purposely called the case I have the honor to present to the section this evening "a case of ataxia," because this purely symptomatic title is noncommittal in regard to the precise diagnosis of the disease, and I desire to have the diagnosis I have myself made submitted to the opinion and control of the members of this section.

The family history of the patient offers tragical peculiarities. The parents are Jewish peddlers, first cousins. I have been unable, during an acquaintance extending over eight or ten years, to elicit any evidence either of syphilitic history or of tuberculous diathesis; but my information in regard to the father may easily have been imperfect. The mother has certainly been in fair health since marriage, except during a period of suffering from laceration and ulceration of the cervix uteri. This was remedied by an operation, and she has since remained well. Three children have been born in the family, all girls, and the tragic peculiarities to which I have referred lie in the fact that both the eldest and youngest child are congenital idiots, with spastic paraplegia. The eldest, aged fourteen, is now at Syracuse; the youngest is at Randall's Island. The second child is the patient, a pretty and extremely intelligent child, who until her present illness has always been in good health. She is eleven years old. This illness began in the middle of April, 1896, with severe fever, during which, as the mother put it, the child "talked very old-fashioned-like" but was not exactly delirious. On the third day there is said to have been diplopia; the neck became very stiff; the child lay flat in the bed and could not sit up, but could move all four limbs. She screamed with the violence of the pain in her head, and also complained of shooting pains all through her body. She vomited frequently. There was no eruption. After five weeks the fever left her, and then for three weeks the child lay in bed quite motionless; could not even speak, because she had no strength to move her lips, and indicated her wants by movements of the eyes and a slight grunt. During this time there was, for a week, paralysis of the rectal sphincter and involuntary evacuations, which had not occurred before. There was no other paralysis, and sphincter control returned at the end of a week. The patient was treated at home by a physician who diagnosed a cerebro-spinal meningitis. After nine weeks' illness, the patient got out of bed, and had to learn to walk; she was extremely feeble, and her head would drop forward on her chest. In three months from the beginning of the illness, she came down stairs, and tried to help her mother in sweeping and other housework. This was in August; but before the Jewish New Year in September, she suffered a relapse, beginning with shooting pains through head and trunk. These pains recurred in paroxysms, during which the patient would go to bed until the paroxysm subsided, then get up again and go about. There was no fever at this time. The neck would become stiff, also the legs, but much less so. At this time the child was sent to a hospital in Woonsocket, Rhode Island. While there she vomited constantly. After two weeks she was sent home, and the mother alleged that the doctor suggested hysteria as a cause of the vomiting.

The child remained at home until December, when she was received into the children's ward of the New York Infirmary, December 9th. She was then pale, thin, and evidently very weak. She lay flat on her back, and any attempt to move brought on pain in the head. This was most marked if the head itself were moved. There was no hyperæsthesia of the scalp to touch or to pressure. The cervical spine was somewhat stiff, and forward flexion of the neck caused pain in the cervical spine, a point painful on pressure persisting at the level of the seventh vertebra.

There was no paralysis either of limbs or of cranial nerves. The pupils were normal in appearance, contracting to accommodation but sluggishly to light. The visual field was not examined at this date, the 9th of December, but a first examination, made on January 25th, found the field much contracted, especially in its upper quadrant. A subsequent perimetric observation, taken by myself and Dr. Alice Wakefield, while the child's pupils were still somewhat dilated from atropine, showed a much larger field. A watch could be heard not farther off than a foot from the right ear, though much farther from the left.

On the first day of examination I found thermo-anæsthesia over the right side of the body, including the face, arm, and leg, while both pain and tactile sensibility were preserved, and some degree of hyperæsthesia was noticed over the same area. The test was made by means of a test tube full of very hot water, whose temperature was readily and painfully perceived on the left side, but not noticed on the right at all. This aberration of the sensibility was noticed only on a single occasion. The hamstring muscles of both legs were moderately rigid. The knee jerks were entirely absent, but at the time the fact was attributed to the rigidity of the flexor muscles, which prevented the free movement of the legs. It was also impossible to obtain the gluteal, abdominal, or epigastric reflexes. The pharyngeal reflexes were, however, perfect. At the time of admission to the hospital, the child was suffering chiefly from marked asthenia, moderate headache, persistent nausea, and slight vomiting, which at the time had no cerebral character. Attempts to sit up in bed were followed by vertigo, which increased the distress. The bowels were constipated, but the abdomen was not at all retracted. There was no fever; the pulse was normal: no meningitic streak could be obtained on the skin. For four days after admission, the patient suffered from retention of urine and needed the catheter; then the function became normal.

The diagnosis of cerebro-spinal meningitis made during the previous summer was accepted, and it was supposed that exudations formed during the acute disease were still persisting at the base of the brain. Iodide of potassium was given with the hope of facilitating reabsorption. On the 9th of December the medication was begun with a minimum dose of five grains three times a day. On December 18th a considerable improvement was noticed in the patient's headache; vertigo, nausea, and hyperæsthesia had disappeared; there was hardly any tenderness at the cervical spine to pressure or movement; the child had left the bed and was walking about the ward. The hamstring muscles were still rigid and the knee jerks then, as has been the case ever since until to-day, were absent. The iodide was increased to thirty grains a day. The child continued to improve, suffering only from constipation and occasional slight nausea, and on January 17th was dismissed feeling fairly well.

On the 18th of January the patient was brought back by her mother, complaining of still being weak and miserable, and worse than when in the hospital. It was then noticed for the first time that her gait was not simply that of weakness from a long illness, but staggering and distinctly ataxic. The feet were placed far apart; it was not possible for the child in walking to keep to a straight line; every little while she clutched at some support. She could stand for a

[1] Read before the pediatric section of the Academy of Medicine, March 11, 1897.

couple of seconds with closed eyes and feet near together and parallel, and then invariably swayed and fell over. There was no high raising of the foot nor flopping on the heel, as in locomotor ataxia. Recumbent, no ataxia was perceptible in any of the movements of the legs.

There was no morbid symptom of the upper extremities at all. The hamstring muscles were still rigid, the knee jerks absent, and there was marked diminution of electrical sensibility and contractility in the quadriceps and anterior tibial muscles of both legs. It was necessary to advance the secondary coil to eighty millimetres to obtain contraction, and with this strong current from a battery that was in perfectly good order, the child made no complaint of pain. She claimed to feel much better after the electrization. There was some relative weakness of the right leg, for she could not stand on that alone, as she could on the left, nor readily cross the right thigh over the left, while she could easily cross the left over the right.

This paresis, however slight on the right side, may possibly have been associated with the hyperæsthesia and thermo-anæsthesia which were observed limited to the right side, on one occasion, and the lessened hearing in the right ear.

Two days later, in the horsecars, the child was seized with a violent paroxysm of projectile vomiting. After this she seemed almost collapsed, her face was drawn and pinched, her limbs were numb, her legs gave way under her, so that she could not stand. The numbness was promptly relieved by faradization, and the color returned to the child's face. She began to laugh, and said gleefully: "Oh, I feel good." On the 25th, the rigidity of the hamstring muscles was entirely gone, but the knee-jerk reflexes were still absent. Faradic contractility had greatly improved, though unequally in the two legs. On the left side contractions of the quadriceps and tibialis were obtained at twenty millimetres, on the right at thirty. On the 27th, the reaction again changed; contractions were obtained on the right side with the coil at ten millimetres, on the left side at twenty—thus the reverse of the previous proportion.

On the 29th, the child was readmitted to the infirmary, suffering from asthenia, from occasional attacks of vomiting only rarely violent, from transient vertigo, and with ataxia and reflex conditions which have been sufficiently described. The temperature was 99.4° F., the pulse 90. An ophthalmoscopic examination was made for the first time, by Dr. Alice Wakefield, who discovered an optic neuro-retinitis. A second examination was subsequently most kindly made at my request by Dr. Webster, who confirmed the observation of Dr. Wakefield in every particular. Like her he noted that the condition was not one of choked disc, with an abruptly limited prominent papilla, but a descending neuritis. "The outlines of the optic discs," he writes, "are still traceable, but veiled or blurred by exudation. The discs are slightly swollen, but probably more than half this apparent swelling is due to hypermetropia. The retinal vessels are somewhat distended and slightly tortuous, the result of pressure upon the blood-vessels by exudation into the nerve substance. The same obstruction accounts for the multiplicity of the vessels running off from the discs, the smaller ones being distended so as to be of noticeable size."

The excitement of the visit and the fatigue of the examination seemed rather to exhaust the child and bring on a recurrence of the vomiting or gastric crisis, associated with pains about the head and neck, and a sensation of a fatty substance lodged in the throat. The temperature rose to 104° F., the pulse to 128. The fever subsided in the course of thirty-six hours, and in two or three days the child again seemed pretty well.

Two days ago, however, she again took to her bed, this time with a new symptom. She complained of severe shooting pains, starting from the level of the lower dorsal spine, to course along the track of the last dorsal, ilio-hypogastric, and ilio-inguinal nerves, and to be apparently disseminated all over the abdomen and at the vulva. There was no pain in any part of the trunk on pressure, except over a limited area on the right side just below the ribs and over the last dorsal nerve. The pains occurred in brief paroxysms at intervals of from ten to thirty minutes or longer, the child suddenly screaming out, and, pressing her hands over the abdomen, complaining bitterly of "pain in her belly." The temperature rose to 102° F.; the pulse was accelerated in proportion. The paroxysms seemed to point distinctly to an irritation of the posterior root zones. These pains lasted for a day, and then on the evening of March 10th subsided spontaneously. To-day, March 11th, for the first time since the child has been under observation, the knee jerks have reappeared, being even a little exaggerated.[1] It would seem as if this return were in some way associated with the spinal irritation, otherwise indicated by the shooting pains.

By isolated grouping of different symptoms in the case of this child, several different diagnoses would be suggested. I have mentioned that the physician at the Rhode Island Hospital decided in August that the vomiting, which was then the most prominent symptom, indicated an hysterical neurosis. The active intelligence and alertness of the child, her ready susceptibility to emotional impressions, and also ideas, do, indeed, suggest hysteria much more than any organic disease of the central nervous system. The same diagnosis might also be suggested by the frequent variation in the intensity of all the symptoms: by the single observation of right hemi-thermo-anæsthesia, right hemi-paresis, and diminution of hearing; by the marked diminution of electrical sensibility observed once; by the great contraction of both visual fields observed January 25th, and the greater limitation of the visual field of the right eye, which was still found by Dr. Webster on February 28th; possibly also by the contraction of the flexor muscles of the thighs, which, after persisting for some weeks, have now disappeared. The most noteworthy variation, however, is that of the knee-jerk phenomenon, which has been negative to repeated tests from December 9th till to-day: and yet this evening, after the child has suffered for several days from severe spinal pains attended by fever, the knee jerks have reappeared.[2] On the other hand, the child, though emotional, is not in the least affected or inclined to exaggerate her illness. On the contrary, she shows a pathetic eagerness to note and emphasize the least sign of improvement in her condition, and when by herself, practises trying to walk on a straight line in order to cure, as she imagines, the unsteadiness of her gait.

Further, there are no fixed hysterical stigmata; the contraction of the visual fields first observed, was largely contradicted by two subsequent observations, and was, therefore, either a transient phenomenon, or due to inaccuracy of the observation from imperfect responses of the child when questioned during the testing. It is noteworthy, however, that even at the third test the visual field of the right eye was smaller than that of the left. The persistence of the pharyngeal reflexes counts strongly against constitutional hysteria[3] and there are various positive symptoms of organic disease.

[1] This was shown at the section meeting, when, at my request, Dr. Sachs tested the patellar tendon. The reaction has continued to be manifest ever since, though it is no longer exaggerated.

[2] They remained restored on the following days.

[3] See paper by Egger (Archiv für Psychiatrie), who, in one hundred cases of undoubted hysteria, found loss of the pharyngeal reflexes in ninety-eight.

My own conclusion is that what hysterical symptoms are present are the superficial consequences of the organic disease. The ataxia, especially marked in station with closed eyes, the presence of Romberg's symptom (sluggishness of ocular light reflex with preservation of reflex to accommodation), and especially the loss of the knee jerks, which, until to-day, has seemed the most fixed symptom of the disease—conditions occurring at an age of election and in a patient with the family history of this child—strongly suggest the possibility of Friedreich's disease in its incipient stage. The seventh and eighth years, *i.e.*, the period of the second dentition, from the eleventh to the fourteenth, the period of puberty, are the most frequent epochs for the first manifestations of this hereditary disease. This child, aged eleven and one-half, is just entering upon the second period of liability. The slightness of the present ataxia, and its strict limitation to the functions of the lower extremities, might be attributed to the incipiency of the disease, which is known to be extremely variable in its rate of progress, often pausing for years at certain stages. In *The Lancet* for 1893 is given the history of two sisters and a brother out of a family of six, in whom a peculiar irregularity of walk began to develop at puberty, followed by weakness and constantly increasing ataxia, which gradually progressed to the upper extremities, and then became associated with indistinctness of speech. There was some loss of muscular sense in the legs, but no rigidity of any muscles. The knee jerks were absent in two cases, preserved in the third. The intellectual development was preserved in all, and in the brother was said to be high. At the time of the report, the patients were aged, respectively, forty-two, forty-nine, and fifty years, and enjoyed good general health. Menzel relates, in the *Archiv für Psychiatrie* for 1891, the case of a man in whom the first symptoms began in his seventeenth year, being then limited to some uncertainty and weakness of gait and ataxic unsteadiness of the hands. The symptoms did not progress further for thirteen years. The patient died at the age of forty-six.

With a march as slow as in these cases, it would be conceivable, in a case like that here presented, that the symptoms should remain at their present status for many months longer, and yet be destined ultimately to progress into the completely developed disease. The absence of the knee jerks, though said to be observed in the majority of cases of hereditary ataxia, is not universally so. I have found records of several cases in which this phenomenon persisted, and this was the case with Menzel's patient and with one of the three English patients I have cited. Finally, as has been noted in Dora, the knee jerks have just reappeared in a somewhat exaggerated form.

Contraction of the knee flexors does sometimes occur in Friedreich's disease, but late, and associated with muscular weakness and malposition. It was an early symptom in this case, and, moreover, transient, for it has now disappeared. The decisive reasons, however, for setting aside the hypothesis of hereditary ataxia in Dora Nathan's case, are: first, the origin of the present condition in an acute febrile illness with symptoms as severe as have been described; and, second, the appearance of cerebral symptoms while as yet there is not the slightest disturbance of function in the upper extremities. The most important among these cerebral symptoms is the double neuro-retinitis; but there are also headache of varying severity, vertigo, diminished ocular reflex to light, and frequent paroxysmal vomiting. The latter might be interpreted either as encephalic or as a visceral crisis, but such interpretation would not incline the diagnosis toward Friedreich's disease, for in this visceral crises do not occur.

The form of ataxia in this case is distinctly cerebellar; but, in the assumption of cerebellar disease, the prolonged absence of the knee jerks becomes a puzzling and exceptional feature. Whatever the precise nature of the lesion, it must be, at its present stage, irritative in character—should, therefore, be expected to increase the muscular tonus habitually controlled by the cerebellum, and thus be attended by an exaggeration of myotatic irritability. In eight cases of tumors of the posterior fossa, lately analyzed by Jacobsohn in the *Archiv für Psychiatrie*, the patellar reflexes were preserved in all. In six of these cases a tumor was found involving the middle lobe of the cerebellum. On the other hand, in 1892, Henry Handford reports to *Brain* a case of cerebellar tumor of the size of a large walnut, growing from the middle lobe, in which the knee jerks were completely absent on both sides. The plantar and abdominal reflexes were present, and there was a very slight ankle clonus. The author was so much puzzled by the loss of the knee jerks in this case that, although very decided symptoms indicated an intracranial tumor, he found "great difficulty," he says, in accepting this diagnosis.

A recent discussion before the Medico-Chirurgical Society of London has tended to make prominent a view long advocated by Hughlings Jackson, though not generally accepted. According to this view, muscular tone, and the tendon reactions dependent on that, are maintained by cerebellar influence, which is, normally, more or less antagonized by the influence of the cerebrum. This influence reaches the cord circuitously, by the way of the cerebrum and the pons, to which the cerebellar influence is transmitted through the superior and middle peduncles respectively. "We may note," observed Gowers in 1888, "that the path from the sensory muscle nerves, on which the myotatic irritability immediately depends, probably goes to the cerebellum, and the centripetal impressions from the muscles influence cerebellar co-ordination. The loss of muscle reflex action in cerebellar disease is to be compared with the loss of superficial reflex action in disease of the cerebral hemisphere; each is the result of an influence exerted on the spinal reflex centres."

"When," to quote Hughlings Jackson, "the influence of the cerebrum is cut off by any lesion, the unantagonized influx of cerebellar energy becomes the cause of an increased muscular tonus, of muscular rigidities, and of exaggerated tendon reflexes. Conversely, if the paths transmitting to the cerebellum the centripetal muscle impressions be cut off, the necessary stimulus to cerebellar co-ordination is lost, and with it muscular tonus and myotatic irritability."

These views of Dr. Jackson have recently been recalled to prominence in a discussion held before the Medico-Chirurgical Society of London. Cases were cited by Bastian, Bowlby, and Buzzard, in which a total transverse lesion of the dorsal cord, due to severe traumatism, fracture of the spine, was followed by flaccid paraplegia, and total loss of knee jerks. This was attributed to loss of cerebellar influence over the cord, when its centripetral paths had been completely interrupted. Similar observations were mentioned in certain cases of Potts' disease paraplegia, by Dr. Collins in a recent discussion before the New York Neurological Society.

In Handford's case, the tumor was large enough to have disintegrated the middle lobe of the cerebellum, upon which, according to Nothnagel's law, the maintenance of equilibrium exclusively depends, since ataxia is not observed unless this special part of the cerebellum be affected, by either intrinsic or adjacent disease. Ferrier,[1] as a result of experiment rather than of clinical observation, contradicts this law, saying with Luciani that in animals the effect of extirpation of the middle

[1] Brain, 1894.

lobe is not more pronounced than that of one lateral hemisphere. As the author admits in animals a much greater independence of the spinal centres than in man, it is possible that the results of his animal experiments would not apply to human beings.

However, on this hypothesis, the maintenance of muscular tonus and of equilibrium should constitute the double portions of a single function, and thus persist or fail together.

In the case now presented, if it be really due, as seems probable, to some form of cerebellar disease, the two functions are very unequally affected. The inco-ordination is relatively slight, the loss of knee jerks was for a long time complete. Gowers, in the first edition of his great treatise, admits as an anomaly difficult to explain, the occasional loss of the knee jerks in cerebellar disease. In an essay on the functions of the cerebellum, which he published in the *Neurologische Centralblatt* for 1890, the same writer observes: "There is no reason to suppose that the action of the middle lobe of the cerebellum is transmitted downward. Both paths from the spinal cord, the inferior and the lateral peduncles, conduct upward. There is no proof that any fibre from the cerebellum passes down to the cord. . . . An irritation of nerve cells in the cerebellar hemispheres is irradiated to the thalamus opticus and corpus striatum. The middle lobe has the same structure as the hemispheres, but a different function. It is a regulating centre for those centripetral impulses which have a special relation to the motor processes upon which equilibrium depends. . . . The mortor cortex has an inhibitory action on the reflex muscular centre on which the tendon phenomenon is dependent. The cerebellum has an inhibitory action on the cells of the cerebrum. . . . The knee jerk is sometimes lost in disease of the middle lobe of the cerebellum, because, owing to this, the habitual muscular tonus is defective. Similar loss in tabes is, like the coincident ataxia, the consequence of disease or interruption of the paths traversed by the ascending muscle nerves."

Thus Gowers seems substantially to adhere to the theory of Hughlings Jackson and Bastian. Ferrier, however, as late as 1894, rejects the theory—observes that abolition of the knee jerk in cerebellar disease is the exception and not the rule, and that the cerebellum or its middle lobe may be extirpated in monkeys without abolishing myotatic irritability. He refers this to the spinal centres. Ferrier admits, however, that these have more independence in the lower animals than in man, and, in regard to his first contention, it is evident that lesions which are not completely destructive must be irritative, and therefore, by the very hypothesis, should exaggerate and not abolish the knee jerks.

This consideration does not, however, remove all the difficulties in the diagnosis of the present case. If abolition of the knee jerks implies an especially destructive lesion of the cerebellar vermis, other symptoms would, we should suppose, be especially severe. A destructive lesion means a tumor of some size. The middle lobe of the cerebellum is a favorite seat for one form of tumor frequent in children. I mean, of course, tubercle. A solitary tubercle embedded in the vermis, superior or inferior, might not for a long while exercise enough pressure to excite the extremely severe headache characteristic of intracranial and especially of cerebellar tumor. The ophthalmoscopic examination does not, however, point to tumor: not a choked disc, with prominent abruptly limited papilla, but a neuro-retinitis was found, indicating rather a creeping process initiated by a basilar meningitis. Yet such a lesion, superficial in situation and irritative in character, should be expected to cause a condition of the knee jerks exactly opposite to what here obtains.

Another explanation might be found in the coincidence of a spinal lesion, a posterior sclerosis, with intracranial disease.

In the *Archiv für Psychiatrie* for 1890, Wollenberg relates a case, diagnosed as tumor of the cerebellum, on account of titubation, ataxia of the left arm, and other symptoms characteristic of intracranial growths, but in which the total loss of the tendon reflexes was held seriously to cloud the clearness of the diagnosis. The difficulty was met by assuming the coincidence of a spinal tabes. This explanation was justified by the autopsy; a tumor was found in the left hemisphere of the cerebellum, but in addition, an extensive degeneration of the columns of Goll, of the tissue intervening between them and the columns of Burdach, and also of the posterior root zones. In the discussion of this interesting case, the author does not consider the question whether there were any causal relations between the posterior spinal sclerosis and the lesion of the cerebellum, the upper station in which so large a portion of the posterior spinal tracts terminate.

The case related by Menzel, which I have already cited, shows the coincidence of cerebellar lesion and spinal sclerosis, but introduces other perplexities. The cerebellar lesion consisted of a congenital (?) atrophy. Upon this was grafted a posterior sclerosis of the spinal cord. Ataxia began at the age of seventeen, increased very slowly for thirteen years, then more rapidly, and became complicated with the usual cerebral symptoms, until the death of the patient at the age of forty-six. In this case, the paths transmitting muscular impressions and also the organ for the maintenance of muscular tonus (on the theory of Jackson and Bastian) were both defective, and yet the patellar reflexes were preserved throughout, the disease occasionally becoming exaggerated. In my own case, the spinal pains which have occurred on several occasions, and of which the patient has just suffered a severe attack, seem to indicate that the disease, whatever its precise nature, has involved the spinal meninges, or nerve-root zones, or both. A meningeal lesion extending to the cord in the form of a slight sclerosis of the posterior columns would, through this secondary condition, determine the abolition of the knee jerks, and in a temporary exacerbation would almost inevitably set up just such shooting neural pains as those from which the child has just suffered for a short time. In the acute illness of May, and also during the relapse in August, "shooting pains all through the body" constituted a prominent symptom. The return of the knee jerks at the moment of this acute exacerbation of spinal irritation might be attributed to the influence of the latter, or else to a substantial improvement in the whole condition of the patient under the influence of the medication.

It is difficult to explain all the symptoms in the case by any one lesion. Ataxia, vertigo, vomiting, and asthenia suggest a tuberculous tumor embedded in the cerebellum, the absence of severe headache and of choked disc being explained by the small size of the tumor. The absence for several months of the patellar reflexes, though unusual in cerebellar disease, is not unprecedented, but such an explanation almost necessitates the presence of a tumor of considerable size, destroying a large part of the tissue of the middle lobe. But the previously noted conditions indicate that if a tumor really exists it must be quite small. Again, the neuro-retinitis seems to indicate a basilar meningitis of some kind: but a basilar meningitis occupying the usual locality at which it affects the optic tract, namely, the interpeduncular space, should also involve some other cranial nerves, notably the third and the fourth. None of the above diagnoses suffices to explain the spinal symp-

toms, the stiffness and pain at the cervical spine which existed in December, the attacks of shooting pains which, prominent in the original febrile illness, have recurred several times since; nor the bilateral rigidity of the flexors of the knees.

Isolated patches of meningitis, with involvement of the subjacent nervous tissue, if disseminated at several points, could, however, account for all the symptoms. Such a patch over the inferior vermis, the roof of the fourth ventricle, might suffice to explain the cerebellar symptoms, while remaining too superficial to disturb the medulla, as a tumor in this locality soon does through pressure. Similarly superficial and localized patches about the optic tracts, or chiasma anterior to the nerves of the interpeduncular space, would serve to initiate the neuro-retinitis. Other patches in the spinal meninges would account for the spinal symptoms, and even, through some degree of posterior sclerosis secondarily induced, for the loss of the knee jerks. The attack of thermo-anæsthesia also belongs here. The frequent variation in the intensity of the symptoms, which has been so striking a feature of the case, could on this hypothesis be explained by variations in the vascularity of the tissues around the chronic meningo-cerebro-spinal lesions, variations in the degree of congestion, consequent irritation. Another explanation of this variability in the symptoms has been offered, namely, that it depends upon variations in fluid effused into the ventricles under the influence of the meningitis. In regard to this explanation it is important to note that the child has never shown the least sign of stupor or even dulness, such as is habitually associated with ventricular effusion.

The nature of such cerebro-spinal meningitis remains a problem—whether it be the chronic residue of an infectious cerebro-spinal meningitis, whose acute stage was traversed ten months ago; whether it be tuberculous, whether syphilitic, or whether the meningitis serosa of Beninghaus. No positive signs exist elsewhere of either syphilitic or tuberculous diathesis, and the case lacks many characteristic features of cerebro-spinal syphilis, though possessing some. The paradoxical ocular reflex resembles that observed in syphilis, but the absence of paralysis in either cranial or spinal nerves differs greatly from syphilis. The prolongation of the affection, and the almost steady improvement which has now been observed for some weeks, are opposed to any form of tuberculous disease, except possibly a solitary cerebellar tubercle, and that does not suffice to explain all the symptoms. There remains the hypothesis of residual disease from an ordinary infectious cerebro-spinal meningitis. This was the diagnosis made on first assuming charge of the case. I have felt inclined to change it on several occasions, as new phases of the disease were unfolded, but at its present stage this seems to be, on the whole, the most probable diagnosis.

At the present time the child receives twenty grains of iodide of potassium and one-twentieth grain of biniodide of mercury three times a day, and is continuing to improve.

Note.—By April 10th, just a month from the date of the above paper, the child, though delicate, seemed almost well. There was no ataxia on locomotion, and even the static ataxia with closed eyes had almost entirely disappeared. A month later, May 10th, the patient seemed quite well, and an ophthalmoscopic examination showed only some œdema of the discs.

Rebellious Neuralgia of the right arm was wholly cured, and without motor or sensory trace of the operation two years after, by intradural resection of the eighth posterior cervical root upon the right side.—CHIPAULT, *Gaz. Méd. de Paris*, February 13th.

ASTHENOPIA AS A FORERUNNER OF NEURASTHENIA.

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL; PROFESSOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

It has long been known that the inability to use the eyes on near objects, without discomfort, is one of the early symptoms of locomotor ataxia. This form of asthenopia is easily recognized, if attention has once been turned to it. It depends upon irregularities in the action of the external muscles of the eye, and these in turn are dependent upon the general muscular weakness, which is one of the early symptoms of the disease. I desire carefully to distinguish what I am about to say from a discussion of the asthenopia, or, better said, the weakness of the external muscles of the eye, characteristic of grave disease of the spinal cord. I mean a well-defined asthenopia, entirely different from the paresis of locomotor ataxia—one that has all the subjective symptoms of true asthenopia, but which lacks one essential part of this condition.

The patients who are unable to use their eyes upon fine and near work, such as reading, writing, sewing, and the like, without ocular discomfort, are, in large proportion, found to have a positive error in the refraction, such as a considerable degree of hypermetropia or astigmatism, or both. On correction of this, the asthenopia is almost invariably relieved. But in the cases I am now classifying, there is no considerable error of refraction; none, at least, that of itself produces asthenopia. The greater part of the human race which is not myopic is hypermetropic. It cannot be said that a low degree of hypermetropia is, of itself, a sufficient cause of asthenopia. Just so with corneal astigmatism. Unless it reaches a diopter with the rule, or a quarter of a diopter against the rule, it does not, of itself, produce asthenopia. In addition to hypermetropia and astigmatism, presbyopia, with a considerable degree of astigmatism occurring in conjunction with it, is very often a source of true asthenopia in early middle life.

But there is a large class of people with asthenopia who consult an oculist who have, as to their refraction, a normal eye—at any rate, an eye which has no intrinsic conditions which may cause weak sight.

The cases of which I am about to write must not be confounded with those seen by every ophthalmic practitioner, in which, although there is need for glasses, and they are properly fitted, the patients are still not able to work, without asthenopia. In these instances, asthenopia occurs simply because the subjects of it are using their eyes beyond the capacity of the eyes themselves, or of their nervous or muscular system, or both. This is true asthenopia complicated with a neurotic or debilitated constitution. While writing this article I received a letter from a presbyopic patient, who has suffered from neurasthenia for some years, and who is adequately provided with glasses, but who cannot use her eyes as fully as she desires, in poring over volumes pertaining to a subject in which she is greatly interested, from morning till night, to the neglect of all proper open-air life. She asks for an eye wash that will enable her to do what she wishes to accomplish, or else she desires her glasses changed. With such cases as these we are all perfectly familiar. I am writing of people who clearly do not need any glasses whatever, and who yet cannot use their eyes.

Given a normal refraction in the two eyes, there can be no such thing as want of muscular equilibrium, except in cases of paresis. The irregular action of the muscles in locomotor ataxia is not to be classified with the so-called "muscular insufficiencies." It is a weakness of all the muscles, and varies from day to

day. It is a very different thing from the weakness of the interni seen in myopia, which is almost an invariable accompaniment of a high degree of that error of refraction.

When a patient comes to me having normal vision, a low degree of hypermetropia—that is to say, hypermetropia of from one to three diopters, and either no astigmatism at all, or half a diopter with the rule, I conclude that there must be something besides the eye which is at fault in the production of the asthenopia. Repeatedly I have found this condition of things to be the premonition of neurasthenia, or general nervous breakdown. To give such patients glasses is at the best to give them a placebo. The result of such a prescription is sometimes disastrous, since it veils the true condition and encourages them to continue to think of their eyes as the cause of all their troubles. We should be inflexible in our exact conformity to the principles laid down so clearly by the results of ophthalmoscopic and ophthalmometric investigation, and not prescribe glasses for those people in whose cases there are no scientific indications for their use. There is an idea prevalent in the mind of some general practitioners, and I fear also in that of some ophthalmologists, that there is virtue in a convex spherical glass of a low degree—in resting the eyes for distant vision, although the vision is perfect without it, and is at the best made a little less distinct with it. In my judgment no one is ever the better for glasses unless he or she sees better with them, or is much more comfortable with them. In the latter case, when the vision is not improved, there is usually facultative hypermetropia, or a low degree of astigmatism, and the patient will see as well at a distance with the glasses as without them. Even then, when the vision for the distance is perfect, I do not urge or advise such patients to wear glasses, except for the near. Careful observation on this point is of importance in the diagnosis, and in the conditions that I am writing about, for if an expert believes that glasses will be of service to a person when there are no positive indications in the eyeball itself for their use, he will often endeavor to do the impossible—that is, try to relieve a jaded nervous system by putting useless and troublesome lenses before the eyes.

In the early stages of neurasthenia the eyes are sometimes indexes of how much the general system is overworked. When the examinations result negatively, or we find that there is only myopia, which very seldom is the cause of true asthenopia—although it may be of inflammatory conditions—which prevent the eyes from being used with comfort, then we should very carefully abstain from ordering a glass, but endeavor, by the aid of a neurologist or general physician to find out what really is the trouble with such a patient. A careful search into the habits and environment of daily life will often determine this. I could multiply the instances, chiefly occurring in young men and young women, for whom the whole gamut of glasses is run in vain by those who believe strongly in the curative value of convex, cylindric, and prismatic lenses for constitutional disease, even when no error of refraction exists, until the breakdown from neurasthenia, or, in the case of women, sometimes from uterine or ovarian disease, makes the matter plain to every one except to him who is possessed with the idea that the human economy revolves around the muscular action of the eye.

Malaria also produces asthenopia, and this fact, it seems to me, is also often overlooked. In New York City it is always necessary in obscure cases of asthenopia to secure a history as to the previous or present existence of malaria. I have cured many cases of asthenopia with Warburg's tincture. In view of the fact that various maladies are often erroneously ascribed to malaria, it may be well for me to say that I do not admit the diagnosis of malaria unless there is a positive history of intermittent or remittent malarial fever. In three recent cases in which the asthenopic symptoms were relieved by antimalarial treatment, two were from notoriously infected places on Long Island, and the other from Staten Island. In the latter case excavations for a building adjacent to the residence were the cause of the outbreak. I hold that if malarial fever has once occurred in a subject, subsequent diseases are either modified by the reappearance of the malarial parasite or uncomplicated malarial disease may again arise. I am thus particular on the subject, because the general exaggeration in regard to the frequency of malarial disease sometimes leads the medical observer to forget that it may crop out again if it has once actually existed.

The point I make in what I have been saying is that whenever in a case of asthenopia the refractive conditions do not clearly justify from an optical standpoint the prescription of a pair of glasses, they should not be advised, but a thorough investigation of the whole train of symptoms should be undertaken. An incidental advantage in such a course is that the expert in ophthalmology will demonstrate to the general profession that there are rules for the prescription of glasses, and show that we do not, like an optician with a customer, change from one to the other at every new ocular symptom, or upon every whim of a nervous patient. The ophthalmologist who does this is forever floundering in a bog.

The ophthalmologist may find it interesting in this connection to recall the definitions of neurasthenia, as given by the standard writers. That of Dana[1] seems to me especially clear and comprehensive. "Neurasthenia is a morbid condition of the nervous system of which the underlying characteristics are weakness and excessive irritability. . . . Neurasthenia," he continues, "occurs most often between the ages of eighteen and thirty." Every ophthalmic observer who will refresh his memory by turning to his case books for his unsatisfactory cases of asthenopia will, I think, find that a majority of them belongs between these years, and that some of them traced the first signs of their nervous breakdown to inability to use the eyes continually.

THE TREATMENT OF LARYNGEAL TUBERCULOSIS WITH CUPRIC INTERSTITIAL CATAPHORESIS, WITH REPORT OF CASES—THE ADVANTAGES OF DIRECT LARYNGOSCOPY IN THIS METHOD.[2]

By W. SCHEPPEGRELL, A.M., M.D.,
NEW ORLEANS, LA.,
VICE-PRESIDENT OF THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY, ETC.

One of the gravest diseases that demands the attention of the laryngologist is tuberculosis of the larynx. The gravity of this affection lies not only in the fact that the disease itself is intrinsically of a most serious nature, but also that it is usually a complication of pulmonary tuberculosis; the patient has, therefore, little of the vital resistance necessary to battle against the encroachment of the tuberculous disease in the larynx, this condition being aggravated by the fact that the parts are continually reinfected by the tuberculous expectorations from the lungs.

Primary laryngeal tuberculosis is exceedingly rare; in fact, many authors have even disputed its existence. Statistics, however, prove that, while it is of infrequent occurrence, it sometimes exists without disease of the

[1] Text-Book of Nervous Diseases, p. 446. New York, 1892.

[2] Read before the meeting of the Southern section of the American Laryngological, Rhinological, and Otological Society, New Orleans, March 3, 1897.

lungs that can be detected by the most scrutinizing methods of examination. *Prima facie*, it is not impossible that the tuberculous disease in the system may develop primarily in the tissues of the larynx as well as in the tissues of the lungs, although the latter, for many reasons, are the usual location for the tuberculous infection.

The treatment of this grave affection has long claimed the attention of laryngologists, especially since the means of laryngoscopic examinations have been perfected; but in the majority of cases the prognosis was so grave that but little hope of a cure has been entertained in the majority of cases. The methods of treatment, both medical and operative, are large in number, and this very fact would seem to indicate the lack of confidence in any individual method.

Heryng, of Warsaw, has advocated the treatment of tuberculous laryngitis by curettage and the application of lactic acid, and the results which he published, while the percentage of cures was small, were still more favorable than those obtained by any method previously tried. The objections to this method are that it is difficult to apply in many cases, and the reaction which follows, but more especially that the surgical removal of the diseased areas exposes the unprotected tissues to constant reinfection from the tuberculous sputum—for, as already stated, primary tuberculosis of the larynx is an extremely rare disease. Heryng does not recommend curettage for all cases, and he advises electrolysis in tuberculous laryngitis when there are hard neoplastic infiltrations of the ventricular band, especially when their extirpation with the curette is liable to be followed by a dangerous hemorrhage. He also advises electrolysis in tuberculous chorditis with or without the formation of tuberculous ulcers.

The galvano-cautery has also been recommended in this disease, and Srebrny,[1] who has treated eleven cases of tuberculous laryngitis with the galvano-cautery, reports the following results: In four cases the result was satisfactory for from one to three months, the further course of the disease being unknown. Four cases ended fatally after six and ten months. The fifth and tenth cases belonged to the most severe form of tuberculosis of the larynx and the lungs. In the first three cases there was a recurrence of the disease in the larynx. Of five cases, in the first the cure was still present two and one-half years after the operation: in the second, two years; in the third, fifteen months; in the fourth, nine months; and in the fifth, twenty months. Srebrny states that the pain after the operation is slight, as also the reaction.

In comparing the surgical and galvano-cautery treatments in this condition, Srebrny believes that the second is equally as efficacious as the first. He reaches this conclusion from the following premises: The number of operations required for the electro-cautery treatment is not greater than that required by the surgical method; the pain after the galvano-cautery applications is not marked in any case, while in two cases in which Heryng's curette was used, and in one in which Krauze's double curette was applied, the pain was quite violent. Srebrny has not seen œdema follow this application, as noted by Heryng. In the galvano-cautery treatment there is no possibility of hemorrhage when it is properly applied, while in the surgical method this takes place quite frequently—a very important point in a patient already suffering from a debilitating disease. Srebrny, however, does not advocate the electro-cautery in infiltrations of the aryepiglottic ligaments, on account of the possibility of œdema consecutive to the application. The results obtained by Srebrny are more satisfactory than those that have heretofore been obtained, but these results have not yet been corroborated by the experience of other operators.

[1] Medycyna, Nos. 2–5, 1893.

The application of the electro-cautery to the larynx requires great manipulative skill, and some of the most prominent writers have advised against its application in this region. While this is not my individual opinion, as I have frequently had satisfactory results from its use in the larynx, still I fully appreciate the difficulty attending its application.

In seeking a treatment for laryngeal tuberculosis, my desire has been to select a method which would be conservative, not especially difficult to carry out, and, if possible, applicable in all cases of this disease; it should not be painful, should be followed by little or no reaction, should be devoid of hemorrhage, and should not expose the parts to reinfection from the tuberculous expectorations.

The application of electricity for the passage of medicaments into the tissues, or cataphoresis, has received a great deal of attention in the past four or five years, and it has been practically and scientifically demonstrated that certain medicines may be carried into the tissues by the action of the galvanic current. This is due to the affinity of the poles for certain sub-

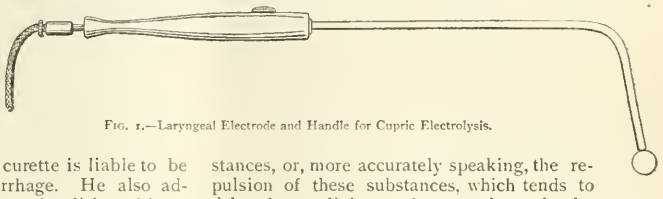

Fig. 1.—Laryngeal Electrode and Handle for Cupric Electrolysis.

stances, or, more accurately speaking, the repulsion of these substances, which tends to drive the medicine to the opposite pole, just as the positively electrified substance will repel the negatively electrified pith ball. This method has already been used for some years for the treatment of goitre in the cataphoric application of iodine, and, while the results in this treatment have not been very satisfactory, I believe this to be due not so much to the inefficiency of the iodine as to the fact that the method has not been scientifically applied.

In the treatment of laryngeal tuberculosis with cataphoresis, we have a method of saturating the diseased tissues with such medicaments as will neutralize the infectious character of the disease, and which will, at the same time, stimulate the tissues to a healthy reaction.

In my investigations with the treatment of laryngeal tuberculosis by cataphoresis, I have tried a variety of substances, especially creosote, guaiacol, iodine, chloride of zinc, and the oxychloride of copper. Creosote I abandoned after a few trials, as it proved to be too irritating to the tissues and caused too much pain and reaction after the application. Iodine I found useful, but not so efficacious as the oxychloride of copper; and guaiacol, which is really creosote deprived of its irritating properties, I found very useful and especially applicable in cases in which there was considerable pain, as its application was usually followed by marked diminution of the pain, and this effect frequently lasted twenty-four hours after the application. I therefore still make use of guaiacol when the relief of pain is the principal object. Cocaine may also be used in this connection, but its effects are too transient and the systemic effects are not well tolerated by the tuberculous patient.

In the oxychloride of copper we have a salt possessing marked germicidal properties, while exerting at the same time a stimulating effect on the pathological tissues, which is very superior to any other medica-

ment which I have used in this treatment. Its microbicidal properties are not so strong as those of the chloride of zinc, but the latter I found to be too corrosive and irritating to be recommended in this disease, although I have found it of special value in the application of cataphoresis to malignant neoplasms in this and other regions.

The method of cataphoresis is simply a development of the principle of electrolysis. When two platinum needles are passed into water and the galvanic circuit is closed, bubbles of gas will be evolved at each of the needles, the water having been decomposed, and oxygen is given off at the positive pole and hydrogen at the negative. If instead of platinum needles we use

Fig. 2.—Extra Spherical Points.

iron, the nascent oxygen which is evolved at the positive pole will at once combine with the iron, forming oxide of iron, and this process will continue until all the metal in the positive needle is changed to the oxide. If copper is used, a similar result will take place, the cupric oxide taking the place of the pure copper metal.

If these needles are passed into animal tissues, the change is somewhat more complex, as we have not only the electrolysis of the water, but also of the salts and other materials forming the tissues. The decomposition will then result, in addition to the oxygen and hydrogen, in acids and alkalies, the alkalies developing with hydrogen at the negative and the acids with oxygen at the positive pole. When copper needles are used for this purpose and connected with the positive pole, the combination of the copper and acids (principally hydrochloric) will result in the formation of the oxychloride of copper. This salt, formed at the positive pole, is repelled by this pole and is driven into the tissues in its passage toward the opposite pole. Not only will this cataphoric action take place when copper needles are passed into the tissues, but also when these or other forms of electrodes are pressed against the moistened skin or mucous membrane.

The cataphoric application of oxychloride of copper has already been used in ozæna, and the results in this obstinate disease have been unusually satisfactory. In the application of this method to laryngeal tuberculosis, I found it difficult and impracticable to use the needles, not only because the movement of the larynx might cause the loosening of the needles and laceration of the tissues, but also because the punctures made by the needles opened the portals for further entry of the pathogenic microbes. I therefore selected spherical electrodes of pure copper, one-eighth to one-fourth inch in diameter, applied to the diseased areas by means of an insulated handle, and have found these efficient for the cataphoric process, and when properly applied not giving rise to pain, irritation, or reaction after the application. It is of great importance that only pure copper should be used in this method; commercial copper contains zinc in its composition, and I found this to be especially irritating in this treatment. Pure copper obtained by electrolysis is to be preferred.

The galvanic current only can be used in this method, as the faradic and alternating currents possess no cataphoric properties. Weak currents should be used at all times, and I have rarely found more than five milliamperes necessary, and have frequently used much less. A rheostat should always be used, so that the current may be admitted and reduced without pain. The copper electrode must be connected with the positive pole, and the negative pole connected with a large dispersing electrode applied to the nape of the neck.

The throat should first be sprayed with a five-per-cent. solution of cocaine or eucaine, although I have found in several of my cases that after a few applications have been made the anæsthetic was no longer necessary. The applications should be made every second day, as a rule, although the physician must be governed by the strength of the patient and other circumstances in the number and interval of the applications. These applications should be continued until the parts resume their normal condition, or until the conditions no longer justify the exertion of the patient necessary for the application.

I have found the use of direct laryngoscopy or autoscopy, as described by Kirstein, of special value in this treatment. This method, in which the laryngeal mirror is dispensed with and the tongue pressed downward and forward by means of a special depressor, and the head and body of the patient are placed in such a position that the eye of the examiner is in a line with the tracheo-laryngeal axis, is a very useful addition to the methods of our specialty. Unfortunately it is not applicable in all cases, and the irritability of the throat of most tuberculous patients makes it still less so in this class of patients. The pathological processes of laryngeal tuberculosis are usually in the posterior part of the larynx, which are the most easily seen and reached by this method, so that it very much facilitates the cataphoric method of treating this disease.

When direct laryngoscopy is used, the electrode, instead of being bent in the usual angle for the larynx, is straight with a slight downward flexion only at the end of the electrode. The applications are then made directly without the aid of the laryngeal mirror.

When the copper electrodes are applied to the tissues, the decomposition of the copper takes place, giving rise to the oxychloride of copper, which passes into the tissues toward the dispersing electrode. It is important when the applications are made that the electrode be slightly rotated or moved about, so as to avoid the adhesion of the electrodes to the tissues, which would give rise to an abrasion which it is desirable to avoid. When an adhesion has taken place, the circuit should be slowly broken with the rheostat, the current reversed by means of a polarity changer, and a light current passed in the opposite direction for a few minutes. The electrode may then be easily removed without laceration of the tissues.

The advantages which I have found in the method of applying cupric electrolysis in the treatment of laryngeal tuberculosis are as follows:

1. There is no real destruction of the tissues, and there are no lacerations of the surfaces which might form a point of entrance for new pathogenic germs for reinfection, as is the case with the method of curettage, and, to a certain extent, also with the galvano-cautery and simple electrolysis. The cure is effected by the

Fig. 3.—Electrode for Direct Laryngoscopy.

healthy reaction of the tissues in the same manner in which we often see specific lesions heal when the system is under the influence of mercurials.

2. In the cases which I have treated by this method there has been absolutely no reaction or hemorrhage following the application—a point of great importance with tuberculous patients.

3. This method does not demand the high degree of manipulative skill required for curettage, or for the manipulation of the electro-cautery in the larynx, and is especially simple when direct laryngoscopy can be used.

4. This method is applicable in all cases of laryngeal tuberculosis.

In concluding this communication, I will give the clinical history of three cases which I have treated by this method with satisfactory results. I have attempted this treatment in a number of other cases, but discontinued it either because the pulmonary disease was so far advanced that the efforts of the patient in undergoing the treatment were not advisable, or on account of too great irritability of the throat of the patient.

In the first case the patient suffered from tuberculous laryngitis complicating tuberculosis of the lung. There was marked infiltration of the arytenoid region, with incipient ulceration of the interarytenoid commissure. In this case the cataphoric treatment was at once instituted, and after seven applications at intervals of three days the case had improved so much that the patient was permitted to go to the mountains for the benefit of the condition of his lungs. The infiltration had very much diminished, especially over the left arytenoid, where only a small amount was still visible. After six weeks' absence the patient returned, with the tuberculous disease of the lungs much aggravated, but the laryngeal condition was but slightly changed, in that the infiltration was somewhat more noticeable, and there were no ulcerations visible in any part. The patient subsequently succumbed to tuberculosis of the lungs, but the treatment had relieved him of all the pain and irritation attending the progress of the laryngeal complication.

In the second case, also complicated by severe pulmonary tuberculosis, the tuberculous lesions were more decided in character, the ulcerations having extended over a considerable portion of the right ventricular band, and both vocal cords being involved. In this case the granulations were reduced, the ulcerations healed, and the infiltration was somewhat diminished, when the application had to be discontinued on account of the weakness of the patient, who subsequently succumbed to tuberculosis of the lungs.

The third patient had suffered for seven months from tuberculous laryngitis, but tuberculosis of the lung was either entirely absent or it could not be detected by the most careful physical examination. The sputum showed the tubercle bacilli, which were found only after repeated examinations. The patient weighed one hundred and ten pounds, was so weak that he could walk only when supported, suffered from constant irritation of the throat which gave rise to a hacking cough, and deglutition was so painful that he could swallow only with the greatest difficulty. There was no history of any specific infection, nor were there any physical evidences of such a condition. The arytenoid region was much infiltrated, with extensive ulceration of the interarytenoid fold, which extended to the left over the ventricular band. The epiglottis was tumefied with an ulceration of the left anterior portion. The anæmia, infiltration, and ulceration presented a typical image of laryngeal tuberculosis. The patient could speak only in whispers, and the pain in deglutition was so severe that he subsisted only on liquids, and even these he could now swallow only with difficulty. The patient had been treated by several physicians without success, one of whom had used antiphthisin, but with no apparent benefit. The cataphoric treatment was at once commenced, at first being applied every third day and afterward twice weekly. Improvement was noted after the third application, and after the ninth the ulcerations had healed so far that the patient could swallow semisolid food with but little pain. After the eleventh application the ulcerations had entirely healed, so that the patient could now take solid food without pain or difficulty, and he at once improved in strength and in appearance. The applications were continued twice weekly, and the infiltration gradually receded, and eight weeks later had entirely disappeared. The voice, which at first had been entirely lost, gradually improved, and at the end of the treatment was restored, only a slight huskiness persisting. His weight had advanced to one hundred and thirty-six pounds, and he was able to resume his regular business occupation. I saw this patient six months after the treatment, and his larynx showed no return of the laryngeal disease and his health was excellent.

THE CLINICAL VALUE OF GLYCOSURIA AS A SYMPTOM OF DIABETES MELLITUS.[1]

By L. C. WADSWORTH, M.D.,

NEWPORT, KY.

When asked by the committee to prepare a paper for this evening, I was somewhat at a loss to find a topic that would be of interest to you. I am sorry to say that my clinical experience with the disease I have selected, so far as the number of cases is concerned, has been limited. Hence much that I can say will be but a repetition of what has been already said by writers on the subject. The fact, however, that it is well for us to bear in mind that the margin between what is known and what is necessary to be known for the good of the patient is often a pretty wide one, tempts me to present the history of a case which probably belongs in this margin.

My observation of this case extends over a period of about six years. It is that of a man, twenty-five years of age, who discovered by accident while making some experiments in a chemical laboratory that his urine had a specific gravity of 1.040 and showed the characteristic reaction for sugar by all the tests. The consultation of an eminent physician, author, and professor of theory and practice of medicine in one of our leading colleges, resulted in a diagnosis of diabetes mellitus, and the usual treatment and prognosis. The diagnosis was made wholly upon the presence of sugar in the urine, there being no other symptom present. The fact that the case was out of the ordinary led me to search for the cause. It was found that the patient was the eldest child in a family of eleven children, of whom all were living, well, and apparently healthy, and had had no diseases except the ordinary diseases of childhood. The examination of specimens of urine from each showed a specific gravity ranging from 1.026 to 1.035, some having a slight sugar reaction, and others a typical sugar reaction. The urine of the father and mother was found to be normal, and both were in good general health. The family history on both paternal and maternal side showed an unusual proportion to have died at advanced age, and in every instance in which death had occurred it was found to have had no relation to the topic under discussion. The father died at the age of fifty-four years of enterocolitis, superinduced by an attack of grippe, after an illness of five months. The patient spoken of above excretes about thirty-two ounces in twenty-four hours, and shows a specific gravity of about 1.040. This has been as high as 1.042, and has been reduced to 1.026 by an absolute milk diet for ten days.

The quantitative tests show the urine to contain about ten per cent. of sugar, or forty-eight grains to the ounce. The patient seems to be well and healthy in every other way, except for an eczema recurring during the winter months on parts exposed to the weather, which has now about disappeared and does not seem to have any bearing upon the topic at issue. The case, as I have said, has been under observation for about six years, and I believe that it is possible for this condition to have existed for a much longer

[1] Read at a meeting of the Northern Kentucky Medical Society, February 5, 1897.

period. Repeated examinations of the urine under various treatments and diets has always shown the presence of sugar, though it can be greatly reduced in amount by the exclusion of carbohydrates, treatment having little or no effect.

Diabetes mellitus is usually recognized by the passage of a large quantity of urine containing an abnormal amount of grape sugar or glucose, usually of a high specific gravity, excessive thirst, perverted appetite, progressive emaciation, and muscular weakness. The disease runs a chronic course, and in the majority of cases terminates fatally in two or three years.

The terms glycosuria and glucosuria are used by some authors to denote diabetes mellitus. I think, however, their proper use should imply merely an abnormal amount of sugar in the urine, which may be temporary or permanent, or may recur at frequent intervals, and they characterize therefore only a symptom of diabetes and not the disease itself. The cause of the disease is still very obscure, and so far as it concerns us in the practice of medicine I may safely venture the assertion that its cause is unknown. It is consequently sometimes classed among diseases of the kidney, on account of the abnormal urine; sometimes among diseases of the liver; among diseases of the digestive system and alimentary canal; or among constitutional diseases.

In the mortality statistics of the United States census of 1880 it is classed among general diseases, along with rheumatism, cancer, and consumption. The disease was recognized by the ancients, and the books tell us that Celsus, in the first century, was probably the first clearly to describe the disease. Galen was the first, 131, to describe it under the name of diabetes. In 1674 Willis first associated the presence of sugar in the urine, which he discovered by the sweetish taste. Subsequent observers succeeded in separating the sugar, and in 1787 Rollo began the dietetic treatment of the disease by withholding vegetable food. In 1823 Gmelin found that sugar was formed by the digestion of carbohydrates. In 1835 Ambrosani demonstrated sugar in the blood. Under normal circumstances the blood always contains a slight amount of sugar, but this ingredient is not excreted by the kidney in any appreciable quantity; if it exceeds a certain limit, however, then sugar will be excreted in the urine, and we have what is known as glycosuria. The amount of sugar in the urine is comparatively slight and it soon disappears again. Its presence under these conditions does not imply any persistent abnormal condition. Excluding the possibility of diabetes mellitus in a given case, a glycosuria may be due to poisoning from various substances, among which I might mention hydrocyanic acid, mercury, amyl nitrite, curare, carbonic-acid gas, and morphine. Von Merhning has recently discovered a glucoside in the bark of the roots of cherry and apple trees, a substance which if given to animals produces sugar in the urine. Temporary glycosuria is frequently met with in acute infectious diseases—scarlet fever, diphtheria, malarial poisoning, typhoid fever, typhus fever, cholera, malignant pustule; and a far more frequent cause is disturbance of the nervous system. Thus, it may result from severe concussion of the brain, fracture of the skull, cerebro-spinal meningitis, cerebral hemorrhage, and in epileptic fits. It is especially apt to occur when there is a disease of the medulla.

This calls to mind the close connection between this clinical fact and the famous discovery of Claude Bernard, who found by experiment that when certain injuries are inflicted upon the floor of the fourth ventricle glycosuria inevitably follows. It has been claimed by some that diseases of the stomach and liver may cause glycosuria. It is, however, an interesting fact that extensive disease of the liver, as seen in phosphorus poisoning or in cirrhosis, causes no glycosuria, even when the patient's diet contains large amounts of sugar. Atrophy of the pancreas seems to have a definite relation to diabetes, as it has been found by some authors that we can produce severe diabetes in dogs by the extirpation of the pancreas. Ligature of the duct to the gland does not produce this condition. There must, therefore, be some special function of the pancreas not yet known, and when this function ceases to be performed the consumption of sugar in the animal economy is deranged.

It is difficult to determine whether all cases of diabetes are identical. In most of the typical cases this question may be answered affirmatively with little hesitation; but, considering the case that I have reported to you to-night, I must with reluctancy say that in some there is ample room for doubt; although as we shall see, the cardinal symptom, glycosuria, is and has been present in abundant quantity ever since its discovery.

In many cases of diabetes, and some of them most severe, no cause whatever can be made out. The disease seems to develop itself in persons previously perfectly healthy. Diabetes occurs everywhere, but certain countries and districts seem to be particularly liable to it; for example, India, Ceylon, and Italy, and some parts of Germany. Jews are very liable to the disease. Most cases occur in persons between thirty-five and fifty years of age. Next in liability to the disease come younger individuals, those under thirty-five years and over twenty years of age. After the fiftieth year diabetes is not very exceptional; in children under ten years it is very exceptional, although we do sometimes find such cases. Males are much more often attacked than females. With few exceptions the symptoms of diabetes come on slowly and gradually. Sometimes the symptoms are merely general and indefinite, such as languor, emaciation, weakness, and deficient endurance. Sometimes we have mild nervous disturbances, including headache, mental depression, wakefulness, neuralgia; and in still other cases gastro-intestinal disorders, including nausea, eructations, and irregularity of the bowels. In most cases the skin is remarkably dry and rough. Some authors claim to have found sugar in the perspiration. We often see a rapid loss of hair and a shedding of the nails. In a great many cases there is a great tendency to furunculosis. At last the patient's attention is called to the altered character of the urine, and particularly to its increased amount. He also notices that he is very thirsty, and that in spite of his enormous appetite he is constantly growing weaker.

I believe that according to our latest teaching, and one that is now followed by physicians, a knowledge of the abnormal condition of the urine must be established, especially the increased amount of sugar, before a positive diagnosis of diabetes mellitus can be made; and I shall therefore proceed to describe these changes as laid down in the recognized text-books on the practice of medicine. Usually the first thing that attracts attention is the increased amount of urine passed. This may vary in quantity from three quarts to three gallons. In some cases the polyuria will almost cease from time to time. In color the urine is a light yellow, proportionate in intensity to the amount. Ordinarily it is clear and without sediment; but after it has stood for some time it may become cloudy, as a result usually of the abundant development of fermentation spores. The odor may be somewhat aromatic. The taste is distinctly sweetish. The reaction is acid, and may be increased on standing, because of the lactic acid and alcoholic-fermentation process which the sugar undergoes. The specific gravity is almost invariably increased on account of the sugar present. If we find a pale urine with a specific gravity of over

1.025, we can feel almost certain that there is sugar present. The specific gravity may range from 1.025 to 1.060. In exceptional instances it is found as low as 1.020—but this is in cases in which the patient is very much debilitated and usually just before death. The diagnosis requires that sugar be found in the urine. The sugar found in the urine, and in the blood as well, is grape sugar. The amount secreted varies considerably, there being from a few grains to a pound in twenty-four hours. The amount is affected greatly by diet, mode of life, and treatment. The greatest amount ever known to be produced in twenty-four hours was two and one-fifth pounds. The percentage ranges from mere traces to ten per cent., and will be more often found to be about two to four per cent.

Of the many tests by which sugar may be detected in the urine, I will mention only four: The two copper tests (Trommer's and Fehling's), the fermentation test, and the volumetric or Whitney's test. The copper tests are based upon the deoxidizing or reducing power which grape sugar possesses for these metallic oxides, which in the presence of alkalies are converted into the lower state of oxidation or are reduced to metals. The tests for sugar should always be preceded by tests for albumin, which if present should be removed by coagulation and filtration. In making Trommer's test I wish to call attention to the fact that various organic substances besides sugar have a tendency to reduce cupric oxide at a temperature of 212° F. It is well to set aside a tube, without heating it, for from six to twenty-four hours. If sugar be present the formation of cuprous hydrate will take place at an ordinary temperature, while in other organic matters this does not usually occur.

It is also well to remember that a change of color does not indicate sugar, and that a precipitate of earthy phosphates must not be mistaken for cuprous oxide, and that other substances may deoxidize cupric oxide at a temperature of 212° F.

My favorite test preparation is Fehling's, and I overcome the disadvantage of its not keeping by having separate bottles for the cupric and tartrate solutions: I make the mixture at the time of using the test, and always boil the solution before adding the suspected urine.

The fermentation test I have used, but find disadvantages in the length of time required for its performance, the unreliability of the ferment, and the fact that small quantities of sugar evolve so little carbon dioxide that a doubt may be felt as to the presence of sugar.

The volumetric or Whitney's test is a solution of ammonium cupric sulphate, of which one drachm is decolorized by one-thirtieth grain of glucose. The solution to the amount of one drachm is placed in a test tube and heated to the boiling-point. The urine is now added, drop by drop. If no sugar is present no change will occur; but if it is, the blue color will begin to fade and finally the liquid will become perfectly colorless. By a carefully arranged table a correct quantitative estimation of sugar can be made. On account of the simplicity, accuracy, and brief period of time required in making this test, I regard it as one of our most valuable ones.

I think for all practical purposes two of the tests I have named, viz., Fehling's and Whitney's, are about all that is necessary to be used in ordinary cases.

Diabetic urine sometimes contains other varieties of sugar, which, however, are only in small amounts and are of no practical value. The amount of urea is usually increased, while, on the contrary, uric acid is decreased. The amount of phosphoric and sulphuric acids corresponds to the amount of urea; or, in other words, to the decomposition of albuminoids. Occasionally the amount of phosphates is large, and may replace the sugar in the urine. The amount of chloride of sodium excreted depends, as in health, merely upon the amount ingested.

Hallervorden discovered that in many cases the amount of ammonia is much increased, and in spite of this the urine has an acid reaction. It is therefore evident that diabetic urine, since it contains a large amount of ammonia and yet has an acid reaction, must have among its constituents some unusual acid. Hence the conclusions of recent investigations, that this acid was oxybutyric acid, which by its action formed acetone, and this substance, accumulating in the blood, produced the grave nervous derangement termed diabetic coma. Since the consensus of opinion is that sugar in the urine is the most prominent symptom in diabetes mellitus, the question of its origin plays an important rôle.

We have the assurance of one fact, viz., that the secretion of sugar depends in large part upon the amount of sugar ingested in the way of starchy foods. It can be clearly demonstrated that the amount of sugar will increase or diminish in proportion to the amount of starchy food consumed. If a diabetic patient abstains totally for a sufficient length of time from starchy foods, sugar in the urine in a great many instances will disappear altogether. This, however, will reappear when starchy foods are again ingested. Therefore it seems that the system of diabetic patients is almost incapable of oxidizing sugar into carbonic-dioxide gas and water; but, on the other hand, Kulz has proved by numerous experiments that oxidation of sugar does take place to a certain extent, and he has also found that many varieties of fruit sugars are decomposed in diabetic patients, and that their ingestion does not lead to an increase in the amount of sugar in the urine. The disturbances in metamorphosis affect other substances besides carbohydrates. The oxidation of albuminoids does not take place, but their destruction is increased. I have already stated that the amount of urea in diabetic urine is increased. Several experimenters have shown, by means of carefully conducted investigations, that this amount of increase of urea is not merely relative but is absolute. The system of a diabetic patient destroys a larger amount of albumin than does the system of a healthy person—the quality, quantity, and other conditions being the same in both cases. This, however, may not be true in some of the milder cases, but is a well-established fact in severe cases.

It is also certain that in severe cases a part of the albumin is transformed into sugar, escapes oxidation, and is excreted in the urine. This can be proven by the fact that in some cases of diabetes sugar continues to be present in the urine, although the diet is exclusively nitrogenous. Accordingly some have divided all cases of diabetes mellitus into two classes: a milder form, in which sugar ceases to be excreted when starchy foods are excluded from diet, and a severer form, in which sugar persists upon an exclusive meat diet. There are certain external influences which have a tendency to modify the excretion of sugar in diabetes. We find muscular activity wastes mainly non-nitrogenous substances, and accordingly we find in diabetes that an increase of muscular exertion, other things being equal, diminishes the amount of sugar excreted. Acute febrile diseases may cause a great diminution in the amount of sugar, but in a large proportion of cases this does not occur. Probably the altered diet plays an important part in this connection, and again the special modification of tissue metamorphosis caused by the high temperature or by the disease itself may exert some influence upon this condition.

The mysterious phenomena of diabetes mellitus present a problem the solution of which has been sought most industriously post mortem, in order that the cause might be discovered on pathological grounds,

but no satisfactory results have been attained in this way. If we exclude the organic diseases, such as tuberculosis and nephritis, which, while they are only complications, yet are usually common occurrences, the pathological changes in diabetes are trifling.

Bernard's discovery, that an injury inflicted in a certain spot on the floor of the fourth ventricle produces glycosuria in animals, has directed the attention of investigators to the condition of the nervous system in the disease. In some instances tumors, sclerosis, or similar troubles have been found in the medulla and cerebellum; but in these cases the diabetes was evidently not idiopathic. In idiopathic cases the central nervous system presents no striking macroscopic changes. By means of the microscope investigators have found lesions of the medulla in frequent instances. The minute blood-vessels are widely dilated; there are small capillary hemorrhages, some of a more recent and others of a more remote date; and occasionally the microscopic foci of myelitis. The nervous elements proper—the nerve fibres—show no changes. The liver has been naturally the object of careful examinations, because of its well-known function in the manufacture of glycogen, but thus far has not enlightened our knowledge and does not seem to have any pathological relation to the disease. No thorough investigation of the chemical composition of the blood has been made. One important characteristic of diabetes, however, is the gradually increased proportion of sugar in the blood, there being usually between one-fifth and one-half of one per cent., while in health it rarely contains over one tenth of one per cent. The lymph may contain sugar, while the saliva, perspiration, bile, and gastric juice rarely do.

I have endeavored to give you a summary of the facts pertaining to the clinical significance of the presence of sugar in the urine as a symptom of diabetes, as we are taught. I trust that I shall be excused from detailing the theories that have been advanced to explain the phenomenon of glycosuria. Basing my conclusions upon the case I have reported and four other cases which came under my observation, three of which were only temporary, I think it should be clearly understood that the presence of sugar in the urine, regardless of the amount, is not in itself sufficient to warrant a diagnosis of diabetes mellitus. I admit that glycosuria is the chief cardinal symptom that must always be present, and yet I believe there must be other equally important pathological conditions present in the kidney before the diagnosis can be established; what these are I will not attempt to say, for with our present knowledge any statement in regard to them would be only a guess. In view of the frequency of polyuria, I think it worthy of a great deal more significance than is ordinarily attached to it, for the reason that it clearly shows there are other pathological conditions present in the kidney than those which produce the abnormal secretion of sugar. Furthermore, in support of the view I have taken, I wish to call attention to the frequency of complications, viz., nephritis, tuberculosis, syphilis, and alcoholic excesses, which must in themselves be sufficient to bring about a weakened condition of the kidney and assist in paving the way to diabetes mellitus.

Soft-Rubber Goods rapidly deteriorate by the destruction of the material of which they are made. This rotting process is supposed to be due to the action of the atmosphere and moisture. We cannot keep them in a vacuum, but my Esmarch bandage, now fully eighteen years old, is still unimpaired; the result probably of always keeping it in a small, tightly closed tin can, where it has been but little exposed to atmospheric changes. PARCELLS.

Progress of Medical Science.

Epidemic Cerebro-Spinal Meningitis Due to Meningococcus Intracellularis.—Stoeltzner (*Berliner klinische Wochenschrift*, April 19, 1897, p. 333) has reported a further case of cerebro-spinal meningitis in which the meningococcus intracellularis was isolated from the spinal fluid obtained by lumbar puncture. A child, two and a half years old, was seized with symptoms that rendered the diagnosis of cerebro-spinal meningitis probable. During the progress of the attack lumbar puncture was practised, evacuating turbid fluid, in which were found pus corpuscles and meningococci intracellulares.

The Treatment of Diphtheria with the Antitoxin.—According to the report of Dr. Zuppinger, as quoted by the Vienna correspondent of *The Lancet* (April 3, 1897, p. 993), there were treated with diphtheria antitoxin in the Crown Prince Rudolf Hospital for Children, during the year 1896, 168 children, 2 of whom remained under observation at the end of the year. Of the whole number, 136 (82 per cent.) recovered, and 30 (18 per cent.) died. Eight of the children were admitted in a hopeless condition and died within twenty-four hours: 1 suffered also from tuberculous cachexia, and 1 died from pneumonia following scarlet fever. If these cases were deducted, the mortality would be reduced to 12 per cent. From 1894 to 1895 the death rate for diphtheria in this hospital fell 16 per cent., and from 1895 to 1896 it fell a further 7 per cent.

Malarial Hæmaturia.—As the result of a statistical study, a committee of the Tri-State Medical Association of Mississippi, Arkansas, and Tennessee (*Memphis Medical Monthly*, April, 1897, p. 157) finds that so-called malarial hæmaturia is a disease of the prime of life, those attacked ranging from three to sixty years of age, twenty-four being the average. No occupation seems to be exempt, the patients representing every class found in the parts of the country from which the reports were received, and in due proportion. The colored race is not entirely exempt; among fifty-seven cases, five were in colored persons. Forty-one cases occurred in males and sixteen in females. All of the cases occurred between July and March, the largest number, seventeen, occurring in October; the next, twelve, in August; the next, ten, in September; then five in November, four in December and February, three in January, one in July and March. Three of the patients were intemperate, forty-four were credited with good habits, and as to ten no statement was made concerning the mode of life. It was not found that the drinking-water was responsible for the disorder. Fifty-one cases were reported as occurring in persons who had been subject to malarial attacks for a greater or lesser length of time. In all of these the fever was of the intermittent type. Of the fifty-seven cases the onset of the hæmaturia was marked by a chill in thirty-nine, in nine by fever, and in nine no data on this point were furnished. Nausea and vomiting were present in all but three cases. The urine was reported to be of a pokeberry-juice color in twenty cases, black in twenty-five, wine color in seven, chocolate color in three, and pokeberry-juice changing to chocolate in two. Jaundice was appreciable in fifty-four cases. In thirty-six cases quinine had been certainly given before the attack; in only one case had quinine not been given. Forty-two of the cases were treated on an eliminative plan, without the use of quinine, with thirty recoveries and four deaths, the latter as a result of complications. In thirteen cases quinine was the basis of treatment, with eight recoveries and five deaths.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 29, 1897.

THE DISPENSARY BILL.

THE strong feeling of the profession of this city manifested in the unqualified indorsement of the present dispensary bill was strikingly demonstrated at the recent meeting of the Medical Society of the County, when the committee appointed to confer with the governor made its report, and when a discussion on the propriety of the continuance of the work of the committee took the regular order of business. It is quite evident after so much ventilation of the dispensary question that medical men are practically unanimous in their condemnation of the present abominable abuse and thoroughly earnest in advocating its remedy. The fact that the governor positively declined to sign the document will strike every one acquainted with the points at issue with becoming surprise. As it is not a measure that involves any political issue, there is no seeming reason for trimming to any one-sided expediency. If his excellency is reported correctly as saying that the proposed law might interfere with the rights of citizens to give and take charity in any form, he clearly misconceives the real purposes of the act. On the contrary, the provisions of the bill, aimed at the numerous and universally admitted outrages of medical charity so openly and persistently practised in most if not all of the dispensaries, guarantee the best and most ready service to the really deserving by preventing every possible diversion in wrong directions of free medical service. The bill is in the interest of the deserving poor from the beginning to the end, and makes it possible, by restricting necessary benefits to them, to remove all doubts as to the practical aims of the proposed scheme.

In the framing of the measure every effort was made to reconcile all the avowed differences between the boards of management and the medical staffs of the different institutions by referring all matters in dispute to an impartial tribunal, the State board of medical charities. There was no reason to fear that absolute justice would not be done to all parties concerned, or that any power vested in the board would not be used with becoming discretion. Accustomed to adjudicate on all matters pertaining to the proper dispensation of public charities, it was eminently competent to balance relative claims for preference and adjust reasonable differences of opinion between managers and medical attendants. No one who was in earnest in the attempts to correct the abuses offered any tangible argument against such a compromise. With the minority, however, which was in favor of continuing the present system, the sole object was to defeat every measure, good or bad. It was hardly becoming, then, for the chief executive of a great State to dodge his true responsibility in the matter. His assumption that the enactment of such a law might interfere with the equal rights of citizens, rich and poor, who should be at liberty to take all the good they could get, was ridiculously absurd, savored only of buncombe statecraft, and was an open encouragement for the worst form of subtle pauperism. Instead of supporting proper charity, he in reality abetted its most dangerous and most pronounced abuse. The medical profession, however, will not soon forget this insult to its laudable intention of correcting one of the most flagrant evils of the times, and will not weary in its persistent efforts still to right the wrong to which it has been subjected. It is not yet done with the discussion in spite of the attitude of the governor, and we are glad to learn that the County Society continues its committee and still flies its flag.

FEES FOR TIME AND TROUBLE.

THERE are so many ways by which the professional man can be cheated of his just due for services that it becomes him to be constantly on his guard against losses. He is so often imposed upon that his clients are never backward with an excuse to dodge their legitimate obligations by every means known to the tricky lines of what is called sharp business practice. The letter of Dr. Mundé in another column calls attention to an experience which is by no means new to any man in active practice, and the result which obtained in this particular instance is not an unusual one. In times of accident and of emergency the summons for immediate medical assistance always appeals to the physician in the neighborhood, but, as in the case before us, the readiness to pay for the same is not so well pronounced. In Dr. Mundé's case the patient was dead when he arrived, although he came immediately, at much sacrifice of valuable time and to the temporary neglect of other patients in waiting. When the bill is presented, the husband of the deceased resorts to the meanest of all tricks, by contending in court that the doctor was not summoned by him. On this technicality the judge gives the defendant a non-suit. It is plain to be seen, if this ruling is to be considered as a precedent, that it will not be easy in future to indulge in hurried calls for medical aid, when the parties asking for such service are not known to the parties summoned. By the very nature of the service required, the physician never hesitates to respond at once, and the least that can be done afterward is to pay him for his time and trouble in making the visit.

Even if it be found when he arrives at the house that his services are not required, it does not in any sense relieve the patient or his family from paying for

time and the sacrifice of professional business to which the hasty and imperative call may subject the ever-willing helper. Ethically, legally, and professionally, the request to see a patient implies on the part of the one who makes it an obligation to pay for service rendered or attempted. In an emergency call with a reasonably ready response, the mere fact that the patient is dead before the arrival of the doctor does not in any way cancel the pecuniary liabilities of the situation. It matters not how many physicians are summoned, all should be paid. It is certainly not their fault when they are called too late.

EYE AND EAR DEFECTS IN SCHOLARS.

The gratifying results of the sanitary inspection of the public schools by the health board has encouraged the latter to enlarge its sphere of usefulness in the direction of the ophthalmological examination of the scholars. The object is to accommodate visual defects by properly seating the pupils in the classrooms and by the proper distribution and direction of light in mitigating eyestrain. Commissioner Fowler very consistently advocates the measure, in which he is seconded by the president of the health board. There is no doubt of its necessity. Many of the schoolrooms are improperly lighted, and the pupils are placed without regard to any supposed visual defect and must necessarily be denied the usual opportunities for proper education through the various methods of ocular demonstration. It is to be hoped that the board of education will act in harmony with the health authorities in mitigating an evil to which attention has been often drawn, and thus place every scholar on an equal footing as to the advantages to be derived from the otherwise most excellent public-school system. While considering this part of the subject, another of equal importance will suggest itself—that of examination of the many defects of hearing to which school children are notoriously subjected. The placing of such pupils as may be hard of hearing within easy range of the teacher's voice may demonstrate in a very satisfactory way the difference between real and apparent stupidity. Certainly both are very reasonable means to very desirable ends.

COLLEGE ATHLETICS.

It is an encouraging sign of the times that one president of a college in the West has the temerity to inveigh against the present fad of college athletics, not that exercise judiciously taken is not conducive to the health of the student, but that the prevalent games are altogether unnecessary to that end and are distinctly brutal in their tendencies. While admitting that there is a strong temptation in the view of the public applause at such exhibitions to excel in rough-and-tumble struggles for the ball, to strain wind and muscle in the boat race, and to test endurance to the utmost in running-matches, there is a decent medium in such endeavors which invites serious consideration. The accidents and deaths from football alone outweigh all the good that can be claimed for the so-called sport as a safe and healthful one. The self-reliance and hustle which come with the discipline of opposition is replaced by the determination to win at all hazards. In the excitement of the moment all self-control appears to be lost in the fierce determination to worst the antagonist. The reputation of the college appears to rest more on the quantity of muscle than of brains There are more hurrahs for the begrimed football champion than there is applause for the relatively obscure student who honestly wins the prize for Greek or mathematics. In such a respect the colleges are certainly falling off from their former standard as institutions of pure learning. The education is at the wrong end—skill with the feet is taking the place of work with the brain. We are aware that it is claimed that the athletes are generally the best students, but, even granting the assumption, it is just as true that they are such in spite of their muscle.

There is no doubt also that the colleges, in view of notoriety gained by the public exhibitions of football, rowing-matches, and the like, covertly wink at the performances of the strong boys, at the same time pretending to frown upon the usual demonstrations of the inevitable brutality. Hence it is gratifying to know that one college through its president is bold enough to denounce the whole thing, even at the risk of his institution suffering therefrom in public estimation.

News of the Week.

The New York University-Bellevue Hospital Medical College has certainly a great name, but whether fame and happiness will come with it we cannot foretell. If current report is true, the union of the two colleges was brought about in a way that does not augur well for the future *The Post-Graduate* says, concerning the methods used to effect the consolidation of the schools, that it is "informed that the whole negotiations up to the consummation by the regents of the University of the State were carried on by representatives of the Bellevue College and the council of the university, while the faculty of the medical school were kept in the dark until the last moment. At any rate, the professor of practice in the university has resigned, and there is an air of discontent pervading the medical circles of the south side of East Twenty-sixth Street. The Bellevue College faculty are now credited with being masters of the situation, having fastened their name on the combined college, and provided for their future at a time when such a provision was generally supposed to be imperative." We trust our esteemed contemporary has so far forgiven if not forgotten the past that there is no chuckle deep down below these lines.

The Late Dr. Ros.—The medical board of the Woman's Hospital records with deep sorrow the death of Dr. Leoncio Ros, one of the senior assistant house surgeons, whose career has been suddenly ended by an accident which destroyed his life while in the performance of the duties incident to his position. Dr.

Ros served the hospital with great faithfulness and most conscientiously. He had earned the respect and confidence of his associates. His attractive personal qualities and his devotion to his profession already augured well for a brilliant future. We desire to extend to the members of Dr. Ros' family our sympathy in this sad bereavement. It is ordered that a copy of this minute be sent to his family, and also that this minute be published in the New York MEDICAL RECORD and the *New York Medical Journal*. May 18, 1897. (Signed) T. Gaillard Thomas, M.D.; Thomas Addis Emmet, M.D.; Henry D. Nicoll, M.D.; Clement Cleveland, M.D.; Bache Emmet, M.D.; Horace Tracy Hanks, M.D., secretary of the medical board.

Errata.—Dr. A. B. Bonar writes: "Will you kindly make the following corrections of typographical errors? 'Hyperæsthesia' should read 'hypæsthesia' in line five, second column, page 722; also in line nine from the bottom of the first column, and in line five from the top of the second column of page 723. As hypæsthesia is exactly the opposite of hyperæsthesia in meaning, these typographical errors change the meaning of the sentences greatly. Also on page 724 in the fourth line from the last of Case V., 'are' should be 'is.' This is, however, unimportant."

Greene County (N. Y.) Medical Society.—The annual meeting of this society was held at Cairo, Tuesday, May 11th. The retiring president, Dr. E. H. Merriam, of Coxsackie, delivered his address "On the Natural Course of Disease." The following officers were elected: *President*, Dr. F. R. Searles, of Catskill; *Vice-President*, Dr. H. E. Lomax, of New Baltimore; *Treasurer*, Dr. C. E. Willard, of Catskill; *Secretary*, Dr. W. C. Wright, of Leeds. Dr. C. H. Chubb, of Palenville, was elected delegate to the American Medical Association.

New York's Loyalty to the American Medical Association.—If the managers of the American Medical Association doubt, as they sometimes appear to do, the deep and absorbing interest taken in the approaching semi-centennial meeting by New York physicians and journals, we would respectfully refer them to the Montreal correspondent of *The Lancet*. This unusually well informed, we might almost say inspired individual says, regarding the meeting of the British Medical Association, that "the committee on invitations has been rather surprised at the number of possible American visitors to the meeting, and a note of warning has been uttered that this is not a pan-medical congress. Some New York journals, fearing the effect of the Montreal meeting on the Philadelphia meeting of the American Medical Association, have flatly stated that they hope no American physicians will attend the British Medical Association unless as the invited representatives of some society or association." We trust that now certain captious critics, who accused the MEDICAL RECORD of anglophobia, will recognize the true motive which impelled us to warn our readers against going to Montreal unless they were invited.

The American Medico-Psychological Association has just concluded in Baltimore its fifty-third session after a very successful meeting. A number of interesting papers were read and much business was transacted, the most important of which was the report by Dr. Edward N. Brush, superintendent of the Sheppard Asylum, on a new law in regard to the commitment of the insane. The chief features of the law are those requiring petitions for the commitment of insane persons to be made to a judge of a court of record, who shall thereupon appoint two competent physicians, possessing certain qualifications set forth in the bill, to examine the patient. If they return a verdict of insanity, this must be approved by the court, which shall then issue the commitment. Friends and relatives of the patient, however, in urgent cases, may send him to an institution pending these proceedings, under a certificate of examination dated not more than twenty days prior to the application for admission, and this certificate must be approved, in order to retain the patient in the institution, within five days by the judge of the circuit court of the county or of the criminal court of the city before which the petition is pending. This somewhat resembles the law in New York. The officers of the association who were elected were: *President*, Dr. R. M. Bucke, Ontario, Canada; *Vice-President*, Dr. Henry M. Hurd, superintendent of the Johns Hopkins Hospital; *Secretary and Treasurer*, Dr. C. P. Burr, Flint, Mich.; *Auditors*, Dr. P. L. Murphy, North Carolina; and Dr. S. B. Lyon, New York, and *Councillors* for the term of three years, Dr. J. T. Searcy, Alabama; Dr. J. W. Burgess, Montreal, Canada; Dr. F. C. Hoyt, Clarinda, Ia.; and Dr. H. C. Eyman, Ohio. The election of a board of editors for the *Journal of Insanity* resulted in the choice of Dr. Henry M. Hurd, of the Johns Hopkins Hospital as president of the board and editor-in-chief of the journal, and as his associates: Dr. G. Alder Blumer, State Hospital, Utica, N. Y.; Dr. E. N. Brush, Sheppard Asylum, Baltimore; and Dr. J. M. Mosher, Albany, N. Y. The association will meet in St. Louis, Mo., in May, 1898.

Medical Society of the State of Pennsylvania.—The forty-seventh annual session of the Medical Society of the State of Pennsylvania was held at Pittsburg, on May 18th, 19th, and 20th. Rev. J. Crocker White, D.D., delivered the opening prayer. Dr. D. T. Davis, chairman of the committee of arrangements, delivered the address of welcome. Dr. William B. Atkinson made the secretary's report, and Dr. G. B. Dunmire that of the treasurer. Dr. G. Gable, of York, presented the report of the committee on legislation. The report of the committee on pharmacy was presented. Dr. J. Chalmers Da Costa delivered the address in surgery. Dr. J. Chris. Lange read a paper entitled "Asphyxiation by Carbonic-Acid Gas as the Death Penalty." Dr. S. MacCuen Smith discussed "Chronic Suppurative Inflammation of the Middle Ear." Dr. Charles W. Dulles read a paper entitled "Comforting Facts about Consumption," and also one upon the subject of hydrophobia. Dr. A. P. Brubaker delivered the address in hygiene. Dr. T.

J. Elterich read a paper on the "Treatment of Laryngeal Diphtheria with Antitoxin and Intubation." Dr. Percival J. Eaton presented a communication entitled "The Daily Inspection of the Public Schools." Dr. Wharton Sinkler read a paper on "Epilepsy." Dr. D. H. Detweiler read a paper dealing with the subject of "Malpractice Suits and the Remedy." Rev. F. S. Neveling, M.D., read a paper on "The Treatment of Typhoid Fever." Dr. G. Hudson Makuen read a paper on the "Treatment of Speech Defects." Dr. W. W. Keen read a paper entitled "Resection of a Tumor of the Liver by Elastic Constriction Outside of the Abdominal Cavity." Dr. E. O. Kane read a paper entitled "Why the Tobacco Habit is Peculiarly Reprehensible in and Detrimental to Physicians." Dr. L. J. Lautenbach presented a communication entitled "Necessity for Active—not Passive—Ear Treatment in Ear Disease." Dr. T. C. Gable made "Some Remarks on Appendicitis, with Reports of Operations." Dr. W. T. English read a paper on "The Element of Fear in Hæmoptysis," and Dr. J. M. Douthett one on "Climate in Consumption." Dr. Adolph Koenig, of Pittsburg, was awarded the contract for publishing a monthly journal, the *Pennsylvania Medical Journal*, which shall be the official organ of the society, and at the end of the year shall become the property of the society if it so desires. The following officers were elected for the ensuing year: *President*, Dr. W. Murray Weidman, of Reading; *First Vice-President*, Dr. W. B. Atkinson, of Philadelphia; *Second Vice-President*, Dr. J. W. Grayson, of Washington County; *Third Vice-President*, Dr. B. W. Detweiler, of Lycoming County; *Fourth Vice-President*, Dr. R. Bittenger, of York; *Secretary*, Dr. C. L. Stevens, of Athens; *Treasurer*, Dr. G. B. Dunmire, of Philadelphia. The next meeting will be held at Lancaster, in May, 1898.

College of Physicians of Philadelphia.—A stated meeting of the College of Physicians of Philadelphia was held on May 5th, Dr. R. A. Cleeman presiding. Dr. John H. W. Rhein read a conjoint paper, by Dr. S. Weir Mitchell and himself, entitled "A Clinical Re-examination of the Motor Symptoms of Chorea," in which it was pointed out that in some cases the movements occur or are the more pronounced during rest, in others during activity; that the movements are sometimes intensified by intention efforts, and at other times diminished under the same condition; and that sometimes the movements can be controlled by an effort of the will, while at others they are aggravated by the same influence.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending May 22, 1897. May 20th.—Surgeon H. G. Beyer ordered to the Naval Museum of Hygiene for temporary duty in connection with the preparation of new microscopical outfits for ships and hospitals.

Small-Pox in New York.—Some time ago there was a lull in the reports of new cases of small-pox, and it was thought the city's slight visitation was over; but recently fresh cases have appeared. Three cases were discovered on Monday last, and removed to North Brother Island. Since the 1st of March forty-six cases have been reported in the city.

A Case of Physical Endurance.—The author of the article with this title, which appeared in the issue of May 8th, was Dr. Francis Crosson and not Cresson, as printed.

The American Medical Association at Denver.—Dr. J. W. Graham, of Denver, writes that the medical profession of that city and of Colorado, after careful consideration, has decided to extend to the American Medical Association, at its coming meeting in Philadelphia, a most cordial invitation to meet in Denver in 1898. They have sufficient funds pledged to guarantee handsome entertainments, and the railroads are in sympathy with the movement and have promised low rates. Arrangements will be made to enable delegates and their families to visit parts of the Rocky Mountains free of charge, and at nominal excursion rates to visit Colorado Springs, the medicinal springs at Glenwood, and all other points of interest.

Yellow Fever from Colon.—The surgeon of the steamer *Finance*, which arrived at New York from the Isthmus on May 21st, reported that a passenger had died of yellow fever during the voyage, and had been buried at sea. The passengers and crew were held for examination. The same vessel brought a case of yellow fever on her last trip, which ended April 22d.

The Maine Medical Association will hold its forty-fifth annual meeting at Portland on June 2d, 3d, and 4th. The president of the association is Dr. D. A. Robinson, of Bangor; the recording secretary, Dr. Charles D. Smith, of Portland; and the corresponding secretary, Dr. G. M. Elliott, of Brunswick.

The National Confederation of State Medical Examining and Licensing Boards.—The seventh annual meeting of this association will be held in Philadelphia on Monday, May 31st, under the presidency of Dr. William Warren Potter, of Buffalo. Members and ex-members of State medical examining boards, physicians, and educators who are interested in the cause of higher medical education, are cordially invited to attend.

Obituary Notes.—Dr. J. W. Rosebrugh, of Hamilton, Ontario, died at his home in that city on May 6th. He was sixty-nine years old. He graduated in medicine from the University of New York in 1853, and from the University of Victoria Medical College in 1855. His entire professional life was passed in Hamilton, where he gained early the reputation of a skilful surgeon. He was an active worker in medical societies, and was president of the Ontario Medical Association in 1887.—Dr. Benjamin Eddy Cotting died in Boston, on May 21st, at the age of eighty-four. He graduated in medicine in 1837. Since 1843 he was curator of the Lowell Institute, succeeding Dr. Jeffries Wyman in that office. He was vice-president of the Massachusetts Medical Society in 1852–54, and its president in 1874–76.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

(Continued from page 752.)

Third Day—Thursday, May 6th.

THE first part of this session was in charge of the American Orthopædic Association. The subject selected was

Congenital Dislocation of the Hip.—DR. E. H. BRADFORD, of Boston, opened the discussion and illustrated his remarks with a large number of lantern views. He said that in cases of congenital dislocation of the hip we knew now that there was always an acetabulum. The only condition with which it might be confounded was coxa vara, but in the latter the gait was not at all the characteristic gait of congenital dislocation. The best line of incision in the operative treatment of congenital dislocation was the one described by Lorenz. It passed from the anterior superior spine of the ilium obliquely downward along the outer edge of the tensor vaginæ femoris, and along the anterior edge of the gluteus medius. After exposing the head of the femur and the acetabulum, the latter was curetted out sufficiently to allow of the replacement of the femur. The capsular attachment along the lesser trochanter and spiral ridge should be entirely freed, so that the finger can be passed around the head, neck, and lesser trochanter. It was not necessary to free the attachment of the muscles to the great trochanter. A point overlooked by the surgeon was that the attachment of the capsule to the lesser trochanter and lower down might form an obstacle to the reduction of the dislocation. A new method of treatment was one in which no incision was made. The child should be placed in a frame and subjected to a preliminary stretching for a few days. Nothing was gained by ordinary traction downward, but gradual abduction should be made at the same time that traction was made on the limb, the child lying in the horizontal position on a frame. This stretched the shortened capsular attachment, one of the chief obstacles to the reduction of the dislocation. This having been done, the child should be placed under an anæsthetic and the affected limb should be stretched at right angles to the body. The speaker said that he had found that this could be done conveniently by means of the Thomas splint, with a windlass attachment. The next step is to flex and abduct the limb, and put it up in a plaster-of-Paris spica in order to relax the muscles. No discomfort was experienced by the patient after these procedures. As soon as possible the child should be gotten up and encouraged to walk on crutches. After a week or two the child should walk without crutches. Massage was given in order to strengthen the trochanteric muscles, and the child was instructed to walk with the leg slightly abducted. In conclusion, the speaker said that in children from two to five years, or possibly seven years old, congenital dislocation of the hip was a curable condition. From seven to fifteen years of age the treatment should be by incision. Cases older than that might be considered as beyond treatment.

DR. V. P. GIBNEY, of New York, continued the discussion. He said that he had seen six or eight cases of congenital dislocation every year, but only in recent years had he made any effort to treat them. At one time he felt that he had gotten one or two good results from the mechanical method of treatment advocated by Dr. Buckminster Brown, of Boston. It was well to remember that the limp would persist, no matter how successful the operation might be. He did not know of a single subject, in this country at least, who had been operated upon by the Hoffa or Lorenz method who did not limp, notwithstanding the fact that the head of the bone was in place, and there was every appearance, aside from this, that a cure had been effected. He could not, therefore, take the very cheerful view of these cases that Dr. Bradford had done. He had encountered several cases in which there had been a distressing chronic suppurative arthritis of the hip. He did not feel at present warranted in urging upon the profession either the operation of Hoffa or of Lorenz as a cure for these cases. The preliminary stretching was of great importance. At present Lorenz was urging a new operation, which he called the "bloodless method" of reducing congenital dislocations of the hip. Already Lorenz had operated in fifty or sixty cases in this manner, and he claimed that by the patient walking early on the limb the acetabulum would be deepened.

DR. HARRY M. SHERMAN, of San Francisco, said that he had personally observed Lorenz operate in these cases by the incision method. Lorenz incises the capsule with a sharp-pointed knife and then with a large knife shaped like a tenotome, passed into the capsule, he divides it very thoroughly. With the finger as a guide, the acetabulum is next curetted to the desired depth. During this part of the operation, by means of aseptic towels and a simple traction apparatus, great tension is maintained upon the limb. Having inserted the head of the femur in the acetabulum, a skin suture is introduced and a strand of iodoform gauze is carried deeply into the wound. The leg is then placed in the extended position and very much abducted, and both extremities are then put up in plaster-of-Paris, and kept firmly apart by a wooden crosspiece. The patient is kept in this retention appliance for six weeks, after which the child is allowed to get up and walk. There is usually free motion in the hip at first, but little by little this becomes less, and flexion and abduction develop in cases that do not receive proper after-treatment. Lorenz combats this deformity by the systematic use of gymnastics and massage. Dr. Sherman said that his own experience had led him to believe that it was possible without this tiresome six months of massage and exercises to get a good result. Occasionally a paralysis of the sciatic nerve would be observed in these operative cases, as a result of the stretching to which the nerve had been subjected. The early result—that is, within six months after the operation—was certainly very satisfactory in Lorenz's cases. With increasing experience and improved technique, Dr. Sherman said, he believed the result would be satisfactory.

The Classification of Acute General Peritonitis; the Prognosis and Treatment of the Different Varieties.—The remainder of the session was in charge of the American Surgical Association.

DR. NICHOLAS SENN, of Chicago, opened the discussion with a paper on "The Classification of Acute Peritonitis." He presented several different classifications based on different points of view, thus:

I. Anatomical Classification: (*a*) Ectoperitonitis; (*b*) endoperitonitis; (*c*) parietal peritonitis; (*d*) visceral peritonitis; (*e*) pelvic peritonitis; (*f*) diaphragmatic peritonitis.

II. Etiological Classification: (*a*) Traumatic peritonitis; (*b*) idiopathic peritonitis; (*c*) perforative peritonitis; (*d*) metastatic peritonitis; (*e*) puerperal

peritonitis; (*f*) peritonitis infantum (including fœtal and intra-uterine peritonitis and peritonitis neonatorum).

III. Pathological Classification: (*a*) Diffuse septic peritonitis; (*b*) putrid peritonitis; (*c*) hemorrhagic peritonitis; (*d*) suppurative peritonitis; (*e*) serous peritonitis; (*f*) fibrino-plastic peritonitis.

IV. Bacteriological Classification: (*a*) Streptococcus infection; (*b*) staphylococcus infection; (*c*) pneumococcus infection; (*d*) bacillus coli communis infection; (*e*) gonococcus infection; (*f*) tuberculous infection.

V. Clinical Classification: (*a*) Ectoperitonitis; (*b*) diffuse septic peritonitis; (*c*) perforative peritonitis; (*d*) circumscribed peritonitis; (*e*) hæmatogenous peritonitis; (*f*) visceral peritonitis; (*g*) pelvic peritonitis; (*h*) puerperal peritonitis; and (*i*) subdiaphragmatic peritonitis.

By ectoperitonitis, the speaker said, is meant an inflammation of the attached side of the peritoneum, as distinguished from inflammation of the serous surface. The process is characterized by a tendency to limitation, although it might become quite diffuse in the retroperitoneal space. Parietal peritonitis is most frequently met with as an extension of an infection from one of the abdominal or pelvic viscera. The nomenclature of visceral peritonitis is lengthy, *e.g.*, perigastritis, perienteritis, perityphlitis, perihepatitis, perisplenitis, and perisalpingitis.

As peritonitis is always the result of infection with pathogenic microbes, an etiological classification must take into consideration the different avenues through which the microbes gain entrance into the peritoneal cavity. Idiopathic peritonitis is such a rare affection that its existence is doubted by many. By far the most frequent cause of acute peritonitis is perforation of an ulcer of any part of the gastro-intestinal canal, or of an abdominal or pelvic abscess. Metastatic peritonitis is seldom seen except as a lesion of pyæmia. In puerperal peritonitis the infection may extend from the endometrium through the Fallopian tubes, or may follow the lymph channels or the thrombosed uterine veins. Intra-uterine peritonitis most frequently kills the fœtus between the seventh and ninth month of gestation. Peritonitis neonatorum is most frequent in connection with puerperal fever.

The pathological classification was based almost entirely on the gross and microscopical appearances of the inflammatory exudation and transudation. The term "diffuse septic peritonitis" should be limited to those cases in which, as a rule, death occurs before any gross pathological changes have had time to form. The inflammatory product in putrid peritonitis is a brownish fœtid fluid. In acute peritonitis the transudate is occasionally hemorrhagic, owing to the tearing of vascular adhesions, or in connection with scorbutus or typhoid fever the inflammatory product is in the form of brown patches. Suppurative peritonitis is always more or less circumscribed.

The microbe most commonly found in septic peritonitis is the streptococcus pyogenes. When the infection is due to the staphylococcus there is greater tendency to localization of the inflammation. Occasionally the pneumonia diplococcus is the bacteriological cause of acute suppurative peritonitis. Infection with the colon bacillus usually causes suppurative and fibrino-plastic peritonitis. The gonococcus produces a plastic peritonitis or localized suppuration. In tuberculous peritonitis suppuration takes place only when the tuberculous product becomes the seat of a secondary mixed infection with pus microbes.

Peritonitis having its source in an infected state of the blood should be called hæmatogenous or metastatic peritonitis. It has been observed in connection with nephritis, pyæmia, rheumatic arthritis, and the acute exanthemata. Pelvic peritonitis is seldom met with in men, being usually the result of the extension of an infective process to the peritoneum from the female pelvic organs.

Dr. Robert Abbe, of New York, continued the discussion by reading a paper on "The Prognosis and Treatment of the Different Varieties of Peritonitis." He said that the surgeon did not fear post-operative peritonitis in those cases in which during the operation the bowel or the gall bladder or the urinary bladder might be injured, provided the complication was properly and immediately treated. But such was not the case when a septic peritonitis had been established prior to operation. It was now universally admitted that in every case the inflammation of the peritoneum was brought about by some septic microorganism. So far, no definite relationship had been established between any particular variety of peritonitis and any special micro-organism. It had been shown experimentally that the peritoneum would absorb from the twentieth to the thirtieth of the body weight of the animal in an hour, or the whole body weight in twenty-four hours. Injections of carmine enabled the experimenter to trace the course of the current from the peritoneum into the mediastinum. It must be remembered that there was a difference in the grade of the toxæmia, although every case was toxic. In many regions of the peritoneum inflammation not only began as a localized process but remained so, owing to the formation of protective adhesions. The peritonitis, however, was rarely so confined when it started in the middle portion of the abdominal cavity. The most desperate forms of infective peritonitis which the surgeon was called upon to treat were those resulting from perforation of the viscera, notably in connection with appendicitis. Perforation of the stomach, for instance, with discharge of the gastric juice and digestive fluids into the peritoneum, did not usually give rise to immediate evidence of inflammation, as was the case in perforative appendicitis. Dr. Robert F. Weir had collected ninety-seven cases of operation for perforating gastric ulcer, with twenty-two recoveries. At the present time an equally encouraging prognosis could be given regarding gunshot injuries of the abdomen. If the operation were done within twelve hours, experience had shown that half of the subjects recovered; if postponed somewhat longer, only one-quarter of the subjects recovered. In rupture of the urinary bladder the mortality had been reduced from ninety to fifty per cent. In peritonitis due to perforation of a typhoid ulcer, recent statistics showed twenty-six per cent. of recoveries after such a perforation had given rise to a general peritonitis; whereas as late as 1891 no recoveries had been recorded except in a few cases, in which nature had saved life by the slow process of establishing a fistula. The most important class of all was that of perforative appendicitis, treated first by the general practitioner with hopeless expectancy, and not turned over to the operating surgeon perhaps for from three to five days. More light was needed on those cases in which there was peritonitis, recognized by the naked-eye appearances, not limited by adhesions, and coming from a distinctly diseased appendix that had discharged septic fluid into the general peritoneal cavity.

Dr. Andrew J. McCosh, of New York, in continuing the discussion, said that the chief criticism he had to make on the classification presented by Dr. Senn was that it was unnecessarily elaborate for the purposes of the clinician. Regarding the pathological division, for example, he did not think it was possible clinically to distinguish between diffuse septic putrid, and suppurative peritonitis. These forms in termingled so that it was impossible to determine where one began and the other ended. The bacteriological

division seemed to him the most satisfactory, because the most definite and logical.

Regarding the prognosis, he believed that the duration of the septic process had the greatest influence on the outcome of the disease. He was inclined to lay a good deal of stress upon the peculiar resisting power of individual patients, and particularly on the age as an element in the prognosis. Nearly all of his patients who had recovered had been under the age of thirty-five years.

Turning to the consideration of the treatment of peritonitis, the speaker said that it must be difficult in practice to divide the cases, as some had done, into two classes, viz., those requiring sponging and those demanding thorough irrigation. In the most virulent forms of peritonitis the gross appearances were often but little marked; hence it would seem safer to regard every case as of the gravest form, and treat it accordingly. In all cases in which the surgeon was sure that the peritonitis was unlimited, the wisest plan was to resort to thorough irrigation. It was not necessary to remove entirely the septic matter, as the peritoneum had the capacity of destroying a certain amount. This fact had been abundantly demonstrated, both by experiments on animals and in actual surgical practice. In his opinion irrigation, if properly carried out, was more thorough than mere sponging, and the scrubbing process must certainly cause some damage to the peritoneal endothelium, thus lessening its power of resistance against infection, and encouraging the migration of colon bacilli through the walls of the intestine into the peritoneal cavity. Dr. McCosh said that formerly he had been inclined to doubt the propriety of removing the intestines from the abdominal cavity, both on account of the attendant shock and the difficulty of returning them, but in the past year or two he had become convinced of the value of this procedure. It was his custom to turn the patient on the side and rapidly draw out all the intestinal coils into hot towels, held by assistants. The coils were then thoroughly but gently cleansed by pouring over and through them large quantities of hot sterile salt solution, at the same time that the rubber hose from a three-gallon irrigating jar was pouring a stream into all the corners and crevices inside the abdominal cavity. It was essential that the water should have a temperature of not less than 110° F. or more than 115° F. Some would object to such a high temperature, but in his hands it had been shown that a temperature of 112° F. was not only not harmful but was decidedly beneficial as a heart stimulant. It was also important to leave a considerable quantity of the salt solution in the peritoneal cavity, as this stimulated the circulation, and by encouraging intestinal drainage favored the flow of the septic current into the intestine instead of out of the intestine into the peritoneal cavity. Of course much difficulty would be experienced at times in returning the intestine to the abdominal cavity; occasionally it might even be necessary to allow the gas to escape through a small incision in the intestinal wall, and afterward close this incision with a Lembert suture.

Regarding the question of using opium or cathartics, Dr. McCosh said that he had been surprised to find in certain recent articles an inclination to the use of full doses of opium and a tendency against the use of cathartics. His own experience was directly opposed to this view, and he felt that the safety of the patient depended largely upon his ability to prevent intestinal paralysis and promote intestinal peristalsis. The injection of sulphate of magnesium into the rectum in patients who could not retain cathartics administered by mouth seemed to him almost valueless. For some years past he had adopted the practice of injecting certain cathartics into the small intestine, at as high a point as possible, and from some surprising recoveries in cases which, according to former experience, had seemed hopeless, he had become convinced of the great value of this treatment. It was now his custom systematically to employ in almost all his abdominal operations an intra-intestinal injection of one or two ounces of sulphate of magnesium. A saturated solution of this salt was employed and was injected through a medium-sized aspirating needle attached to an antitoxin syringe. In forty-three cases operated upon up to 1895, the mortality was about eighty-six per cent. Between January, 1896, and March, 1897, he had operated upon eight cases of diffuse septic peritonitis. One subject died within twenty-four hours, another at the end of five weeks from septic lung complications, and six recovered. With one exception, the peritonitis had apparently begun more than twenty-four hours prior to the operation, and most of the cases showed an advanced stage of septic inflammation. In six of these cases the cause was a gangrenous appendix, unlimited by adhesions; in one it was a perforating gangrenous ulcer; and in one rupture of a fœtid ovarian abscess. In order still further to assist the movement of the bowel, it was his habit to administer one dose of ten grains of calomel, immediately after operation. If chloroform had been used as the anæsthetic, this would often be retained, for some time at least. Regarding drainage, the speaker said that it was his practice to use several strips of gauze, projecting in different directions among the intestinal coils. He had also found strips of rubber tissue and strips of pure silk sponge useful for drainage. The advantage of the latter material was that it was more easily removed than the gauze. Rubber drainage tubes were more likely to be obstructed than glass tubes. He usually allowed the edges of the abdominal wound to gape for an inch or more. Regarding the wisdom of removing fibrinous patches when found on the wall of the intestine, he was still in doubt. If they were removed, a raw surface would be left which might favor the entrance of septic matter; if they were allowed to remain shut up among the intestinal coils, they might in time form abscesses.

To sum up the treatment of general septic peritonitis, he would say that success depended upon early operation, thorough irrigation, efficient drainage, and restoration of intestinal peristalsis.

Dr. George R. Fowler, of Brooklyn, discussed the subject of "Septic Peritonitis Considered from the Clinical Standpoint." He called attention to the value of such clinical terms as diffuse peritonitis, diffuse septic peritonitis, perforative peritonitis, circumscribed peritonitis, and hæmatogenous peritonitis. These terms, he said, carried with them the clinical condition involved in their occurrence, and conveyed at once the idea of the possibility of successful remedial measures, and the necessity for their immediate application if the patient was to obtain the best results from surgical intervention. The term pelvic peritonitis he referred to as meaning peritonitis arising from the female genitalia, and suggesting at once a separate clinical picture to the experienced practitioner.

Concerning prognosis of bacterial invasion of the peritoneum, much was said, especially as regards the protective and defensive power of the peritoneum. The occurrence of peritonitis without the actual presence of bacteria was spoken of. This occurred if their toxins reached the serosa, which they might do by penetrating the visceral walls without the presence of any actual lesion. Attention was called to the germicidal power of the serous effusion of the peritoneal cavity. Regarding modes of entrance, the least dangerous was that in connection with a wound of the abdominal wall. In estimating prognosis, source and

virulence of infection, mode of entrance, concomitant circumstances, hemorrhage and serous exudation, and last, but not least, the localization of the infection on the one hand, and its generalization on the other, must all be taken into account.

As regards treatment, the treatment of localized peritonitis was alluded to, the main discussion being in regard to that of diffuse septic peritonitis. During the past ten years, the speaker said, a number of cases of diffuse septic peritonitis had been operated upon successfully, and the matter had reached a stage where the surgeon's margin in escaping responsibility in not operating was becoming narrower and narrower. While there might be occasional cases in which the patient's doom was sealed from the very commencement, yet in view of the knowledge derived from the bacteriological laboratory and experimentation upon animals, it was difficult to conceive of such a case. If the Lembert suture could close the perforation as soon as made, or the gauze drain carry away the septic products as soon as formed, other things being equal, the gravity of the prognosis could be considerably lessened. Much was said about streptococcus antitoxin in the treatment of diffuse septic peritonitis. Several cases treated by the streptococcus antitoxin were reported by Dr. Fowler, but the efficacy of the serum seemed still doubtful. His own case as reported led him to express doubt as to the influence which the serum exercised over the symptoms. Furthermore, as the antitoxin of one class of bacteria was powerless against another, and as the streptococcus, while the most powerful, was not the only virulent class present, it became evident that the antitoxin treatment must be further elaborated. Opinion as regards the antitoxin treatment of diffuse septic peritonitis must be considered as yet *sub judice*.

AMERICAN GYNÆCOLOGICAL SOCIETY.

Second Day—May 5th.

Suggestions Concerning Ventral Hernia Resulting from Abdominal Section, and Its Treatment.—Dr. Andrew F. Currier, of New York, read this paper. The hernia did not always take place from the same cause. It might be due to imperfect apposition of homologous structures, an insufficient number of sutures, or too large a number of sutures, premature removal of sutures, insufficient protection of the abdominal walls after the patient left the bed, undue strain on the tissues involved in the wound, or defective vitality of the tissues. Hernia did not imply defective operative technique. Hernia could be expected to occur in no small proportion of women working at such menial occupations as laundering and scrubbing. Certain constitutional conditions also rendered the tissues vulnerable and favored hernia. The author divided operative hernia into three varieties: simple, multiple, and massive. In the multiple variety there were several pockets. This was also true of some cases of the massive variety. In the simple variety the patient's discomfort was often so small that she objected to an operation. Nevertheless Dr. Currier thought operative interference was indicated in all instances, for the inevitable tendency of operative hernia was to increase, and the patient was in constant danger.

Dr. Currier used the following method for suturing the wound left on operating for the cure of hernia: A strand of coarse wormgut, twelve inches or more in length, is inserted at its ends into two strong curved needles, sufficiently long to penetrate all the tissues of the abdomen. Both needles are introduced into the abdomen just beyond the upper angle of the wound, about half an inch apart, from without inward. The sides of the wound are then brought into apposition by successive stitches of continuous suture, including peritoneum, fascia, and muscle, from below upward, and then from above downward, changing the needle to the opposite side with each successive stitch, precisely as one would lace a shoe. If two sutures are used, *i.e.*, one for each half of the wound, the ends of each must penetrate all the tissues, including the skin, and emerge near the middle point of the wound. After these ends have been tied each to its appropriate fellow, the gaping skin is to be closed by continuous or interrupted suture. A minor practical point consists in protecting the skin at the beginning and ending of each suture by a thin strip of gauze, which is passed under each loop. The wound is sealed with iodoformed collodion, or not. The dressings are changed at the end of two weeks and the superficial sutures removed; the deep sutures remain two weeks longer. The patient is kept in bed until a few days after removal of the sutures.

The discussion on the paper related chiefly to prevention of hernia by the manner of closing the wound after laparotomy. It was participated in by Drs. R. B. Murray, of Memphis, Lapthorn Smith, J. Taber Johnson, C. P. Noble, A. P. Dudley, and the author. Homologous tissues required to be brought into apposition, and sutures to remain a time to prevent stretching of new cementing material.

The President's Address.—The president, Dr. James B. Chadwick, chose for the subject of his address "An Historical Sketch of Abdominal Surgery." He said he proposed to sketch briefly the steps by which abdominal surgery had been so marvellously extended during the lifetime of one man (Sir Spencer Wells), laying special stress upon what might otherwise be inadequately remembered—his influence on the progress of this branch of surgery. Abdominal surgery in general was the outcome of ovariotomy, so that in its early days the history of the former was included in the history of the latter. Here the president gave a brief account of the first ovariotomy, done by Ephraim McDowell on Mrs. Crawford, 1809. Dr. McDowell's professional education had been supplemented by two years' study at Edinburgh, and he had undoubtedly been inspired by the prediction of his preceptor, John Bell, that ovarian tumors might some day be successfully removed. Mr. Sizars, having read the report of McDowell's case, attempted laparotomy in 1825 three times, but unsuccessfully, and the operation was not repeated in Scotland for twenty years. Before his death, 1830, McDowell operated thirteen times with at least eight recoveries. Others had also operated in this country. In Europe the operation had met with little favor. In Germany it was first performed by Chrysmar, 1819, and from that time until 1850 only twenty-three operations were done there, with seven recoveries. In France the first operation was by Woyerkosky, 1844. From Atlee's table, 1851, it was learned that up to 1847 only about one hundred and fifty ovariotomies had been performed. There was a notable increase in the number of the operations during the ten years following Morton's discovery of etherization, 1846. After referring to the discussion, 1850, at a meeting of the Royal Medical and Surgical Society, when the consensus of opinion was strongly condemnatory of ovariotomy, and a similar condemnation before the Academy of Medicine, Paris, the author came to the period of the revival of ovariotomy, as it was called in the title of one of Spencer Wells' papers. Wells' first attempt, incomplete, was in 1857, and his first complete attempt in 1858, after which date he operated several times yearly up to 1861; then his experience increased rapidly. The secret of Wells' success did not consist in any special procedure, but by attention to a multiplicity of details. By having witnesses and publishing unsuccessful as

well as successful cases, he silenced criticisms passed upon previous operators. In 1865 he published a book giving a clinical report of his first one hundred and fourteen ovariotomies, and in 1872 tables of five hundred cases. Mention was made of the friendly relations between Keith and Wells. Dr. Chadwick first saw Wells operate in 1873, assisted him in some cases, and was his only assistant at one operation when he came down on a tumor. He told the doctor, whose case it was and who had differed from him in the diagnosis, that he was right, the tumor was not ovarian but the spleen. After a moment's consideration he said he would nevertheless take it out. Unfortunately the woman died on the fourth day. The influence of Wells' work was not long in being felt on the continent. Meanwhile in America operators had been as active as in Europe, but their influence upon the rest of the world was not so great, probably for the reason that to a great extent the operators were country surgeons who were not so ready with the pen as with the scalpel. A notable exception was Dr. W. L. Atlee, who bore the brunt of the contest to overcome the prejudices against the operation. He was ably seconded by Dr. Peaslee, who did his first operation in 1850. Spencer Wells operated over twelve hundred times, reducing his mortality with every successive one hundred cases. At this point Dr. Chadwick dwelt somewhat upon the discoveries of Pasteur and their application to surgery by Lister. All honor, he said, to Lord Lister for introducing the most important modifications of surgical methods since the world began. We found ourselves at the end of the nineteenth century with less reason to dread the opening of the abdominal cavity than our immediate predecessor had to dread even minor operations upon the body and limbs. The benefit of this advance to the individual and the race was manifest, but he would beg surgeons to pause a moment and consider if the operative mania had not gone too far. We had been told abundantly of the brilliant operations done; there had been spread out before us long series of cases in which the uterine appendages had been removed or the uterus itself extirpated; but had we learned what the future fate of these women had been? No one could deny that for the race it was an unmixed evil to have a large percentage of its women, still in childbearing age, rendered suddenly sterile beyond recall. No one could deny that it was an opprobrium on the healing art that we must remove organs, even though unessential to life, because we could not cure them. Was not our suddenly acquired ability to do these operations leading us too far and too fast in sacrificing organs and functions that might be preserved with benefit to the race and without detriment to the individual? It had been his lot daily to see women who had been operated upon by the more venturesome of his colleagues, and to find that results were by no means so uniformly successful in relieving symptoms as the operators were wont to report. In this connection mention was made of the work of Polk and others, in which only diseased portions of the ovaries were removed.

Dr. T. Addis Emmet said he recollected the first consultation called in the Woman's Hospital in New York, summer of 1855, when Dr. Sims proposed to open the abdomen of a young girl and remove what he thought was a fibroid tumor attached by a pedicle. In his insinuating, enthusiastic manner he had about convinced the board to go with him, when Dr. Stevens got up and said he was very much interested in Dr. Sims' remarks about fibroid tumors: this might be one. He did not know whether he had ever heard of a fibroid tumor before, but, whatever it was, he was as a matter of humanity opposed to the proposition to open the abdomen; for if Dr. Sims were successful it would not be long before every young man in the land would be ripping open the belly of every young woman to see whether she had a tumor or not. Dr. Sims did not operate, and the abdomen was not opened again in the hospital until 1860. In 1861 Dr. Emmet became surgeon to the hospital and was unable to get Parker, Post, Buck, or any eminent men to be present at a proposed operation or to sanction it. He thought Buck would throw him out of his office in his feeling that Emmet wanted him to sanction murder.

Dr. H. T. Hanks said he had the pleasure of meeting Mr. Wells when he was in New York, and, Mr. Wells having stated that he had performed eleven hundred and ninety-nine ovariotomies, Dr. Hanks invited him to do the twelve-hundredth operation on one of his patients at the Woman's Hospital. The invitation was accepted and the operation carried out.

Primary Tuberculosis of the Breast Complicating Pregnancy.—Dr. Edward P. Davis, of Philadelphia, read the history of the case and made some remarks on the rare condition, primary tuberculosis of the breast. The pathologist verified the diagnosis, finding tubercle bacilli: there was no breaking down of the tuberculous structures. Operation was postponed until after labor, to avoid danger of excessive hemorrhage. The entire breast was then removed. The patient made a good recovery. The axillary glands were not involved; there was little doubt that infection took place in the nipple, and was probably due to contact of a tuberculous mouth with the nipple, for the woman had been addicted to immoral practices. One interesting point was that the bacilli had not penetrated the placenta or infected the fœtus.

Dr. H. T. Hanks had amputated the breast in a pregnant woman for degeneration of the breast, supposed to be cancerous, with some sepsis. The pathologist found it to be tuberculous mastitis. The patient died of sepsis on the seventh day.

Perityphlitis and Appendicitis in Their Relations to Obstetrics and Gynæcology.—Dr. Paul F. Mundé, of New York, read the paper in abstract. Until recently nearly all cases of appendicitis had been reported as occurring in the male sex, a fact due probably to the preponderating influence of surgery of the uterus and appendages in the female. Since he had published a case complicating pregnancy about four years ago, a number of cases had been reported. Prior to 1894 he had himself recognized only five cases. In his paper he treated of questions related to pathology, diagnosis, and treatment. Complication with pregnancy should have little or no influence on the treatment; the latter should be medical or surgical according to the indications, as in appendicitis in the male. The mortality of appendical abscess in pregnancy had been, according to the statistics of Abrams, high, but no doubt the results in future would be much better. Appendicitis might be mistaken for several other conditions in women, more especially for disease of the uterine appendages and for pelvic abscess, and *vice versa*; or the conditions might coexist. But this fact need not influence one against surgical treatment. In doubtful cases he would choose a lateral instead of a median incision. Personally he had not been able to palpate the healthy appendix.

Dr. W. E. Ford, of New York, had opened an appendical abscess in a girl of sixteen. A few days later she became septic; he found a supravaginal abscess, evacuated the pus, and she recovered. In another case he was asked by two surgeons, one of skill, to see a case of supposed appendicitis in a girl of sixteen, but on arriving the pus collection was prominent above the vagina. Two quarts of pus were evacuated through the vagina; about a yard of iodoform gauze was introduced into the cavity. The patient did well for three days, then developed suddenly maniacal delirium, and died within twelve hours, from what they

believed was iodoform poisoning. There was no sepsis.

Dr. Lapthorn Smith, of Montreal, thought appendicitis was fairly frequent in women. He found evidences of recent or old appendicitis in abdominal operations about three times a year.

Dr. Dudley, of Chicago, described two cases of appendicitis in women, illustrating two routes of infection. In one the appendicitis was evidently secondary to tubal inflammation; in the other tubal infection was secondary to the appendicitis.

Dr. H. T. Hanks, of New York, had seen three or four cases of simple or complicating appendicitis since January, 1897. He made the point that it was wise to exclude appendicitis before operating through the vagina for supposed disease of the uterine adnexa.

Dr. Baker, of Boston, had operated in two or three cases and found adhesions between the appendix and right Fallopian tube which led him to think that previous abscess of the appendix had after formation of adhesions discharged through the Fallopian tube. He agreed with Dr. Hanks that in doubtful cases the abdominal route should always be chosen.

The Treatment of Syphilitic Women in Pregnancy and Parturition.—Dr. R. A. Murray, of New York, read a paper on this subject. He wished to emphasize these points: 1. That syphilis was the great cause of abortion; 2, that comparatively little space was devoted to this subject in recent works; 3, to prevent this frightful mortality attention should be directed to points in diagnosis and treatment. Dr. Murray quoted recent authority on syphilitic changes in the endometrium, placenta, fœtal bones, etc. Passing then to diagnosis, he said this was clear enough in a woman who had had many miscarriages, but under other circumstances it might require considerable tact to bring forth an admission of infection on the part of the husband, or to discover in the mother symptoms in the form of old scars, enlarged glands, sore throat, etc. In treatment Dr. Murray had obtained by far the best results from mercurial inunctions, and with these, begun by the third month of pregnancy, he had succeeded in carrying from forty to fifty per cent. of his patients through to labor at term. The infant could be medicated through mercurial treatment of the mother or by inunctions to its surface. The syphilitic child ought never to be nursed by any woman except the mother.

Dr. E. P. Davis said it was surprising how often certain indications of syphilis existed in the genital tract, including an endometritis, when other evidences could not be brought out. No examination was complete which did not include inspection of the vulva and vagina. He believed the predominant feature which made syphilis dangerous during pregnancy was anæmia. In proportion as means were taken to combat this during antisyphilitic treatment would the interests of mother and child be conserved.

Some Pathognomonic Physical Signs of Chronic Gonorrhœal Infection in Women, and their Value in the Diagnosis of Pelvic Disease.—Dr. A. P. Dudley, of New York, read an abstract of his paper. It was seldom the physician, especially the gynæcologist, saw gonorrhœa in the acute stage in women, as the patients, except prostitutes, rarely consulted him until chronic symptoms developed. The pathognomonic physical signs were a continuation of the changes begun by the acute stage, and were manifest in urethral caruncle, enlarged vulva and vaginal glands, replacement of normal epithelium through the action of the gonococci by squamous epithelium, etc. Of what value were these diagnostic facts? Their chief value was in giving a clew as to treatment and prognosis. 1. The changes in the urethra would account for urinary symptoms and pain often referred to a very different cause. 2. Vaginal abscesses, so caused, would not be simply opened but excised. 3. He would tell some patients this was the cause of their apparent senile vaginitis. 4. If he found leucorrhœa he would not tell the patient she would get well after simple curettage. 5. He would not tell a patient complaining of dysmenorrhœa that it was simply neuralgic or due to congestion. He would inquire well into the condition of the appendages, etc. 6. In structural changes in the endometrium it would tell him what cases would probably be cured by curettage, and that gonorrhœal cases would not be at once cured by this treatment alone. 7. With diagnosis of gonorrhœa based on such physical signs, he would not undertake conservative surgery on pus tubes. 8. The effect of the gonococcus upon the ovary would lead him to be careful about leaving the ovary in operations. 9. In such cases he would not be liable to do an Alexander operation for displacement. 10. The influence of gonorrhœa in causing sterility. In all cases with the physical signs of chronic gonorrhœa present in the genital tract, with lack of other evidence, the husband should be questioned closely.

Third Day—Thursday, May 6th.

When to Amputate in Preference to the Usual Operation for Lacerations of the Cervix Uteri.—Dr. Thomas Addis Emmet, of New York, read this paper. It had been thirty-five years since he had first practised what was known as Emmet's operation for the repair of the cervix uteri. The necessity no longer existed, in this country at least, for the author of it to stand on the defensive. The judgment stood that in appropriate cases better results could be obtained through its agency than by any other operation. It was only in those cases which were exceptions to the rule and could not be cured by preliminary local applications and Emmet's operation that he advocated amputation by the method described in his book and again in his paper to-day. Some women had not the time or the means to undergo the long preliminary treatment required for softening the cervix, etc., in the simpler operation. In others the cicatricial and diseased tissue extended so deeply into the cervix that even prolonged local and general measures (not operative) would not put the cervix in condition so that the lips could be brought together after all diseased portions had been removed. It must not be inferred, however, that he was not as strong an advocate as ever of a conservative course, that of saving the cervix whenever possible. The uterus was drawn gently to the vaginal outlet, held there steadily by an assistant: the arteries thus stretched were narrowed, and the hemorrhage was much diminished. It was important, too, as the excavation went on for the assistant to draw successively upon the tissues to be cut, as in this way the hemorrhage, which otherwise would be excessive, would be slight. The cervix was taken out cone shape. One should not go out as far as seemed safe, otherwise there would be too great retraction and possible injury of the peritoneum or bladder. As the operation proceeded, the bottom of the cavity must be kept at the vaginal outlet. To obviate closure of the uterine canal by contraction of the tissues, and leaving a cicatrizing surface upon the uterine stump, he drew vaginal tissue over the stump from opposite sides and secured it permanently upon its surface. The cervical canal was left fully open. A silver suture was passed from the required point out on the vagina inward through the stump, stopping short of the central opening; a similar one on the opposite side; others, one or more, in opposite surfaces of the vagina on both sides of the cervical stump, and all were properly tightened after the uterus was first replaced in a nor-

mal position. The sutures were removed about the twentieth day. No operation gave better results in cases suitable to it.

Dr. Emmet's paper was discussed by Drs. Hanks, Goffe (who objected to the term amputation of the cervix), A. P. Dudley (who believed there was real amputation and therefore approved of the term), Bache Emmet, E. C. Dudley, and Mundé. Dr. Emmet replied. He said Schroeder's operation had been spoken of. The same method had been used by him long years ago. It was an American procedure which had gone abroad and got a name.

Result of Two Hundred Operations for the Cure of Retrodisplacements of the Uterus.—Dr. A. Lapthorn Smith, of Montreal, read one of a series of papers on operative treatment of retrodisplacements of the uterus. His paper was supplemental to one which he had read at the meeting two years ago, giving the results of ventral fixation in twenty-eight cases and of Alexander's operation in twenty-one cases. Since then the former number had been increased to ninety-three, the latter to fifty-three. With few exceptions all of these cases had ended successfully, both in the immediate and in the remote result, so far as the latter was known. Most operators, he said, believed, as he did, that ventral fixation ought to be performed only when for some reason the abdomen had to be opened. Alexander's operation was to be chosen in simple retrodisplacement without adhesions. The objections to ventral fixation were chiefly three: 1. Danger of the bowel becoming caught between the abdominal wall and the fixed uterus. This had seldom occurred. 2. Such dangers as existed after any abdominal section, of adhesions, etc. 3. The danger of subsequent ventral hernia. Dr. Smith thought this danger was no greater than that of inguinal hernia after Alexander's operation, and should not influence one in choosing between the two operations. Regarding the difficulties of the two operations, the author now took the ground that the one could be performed as easily as the other, provided adhesions did not complicate the procedure. Two years ago he had thought Alexander's operation was much more difficult, but since then he had hit upon a method of finding the round ligaments which invariably brought them quickly into view. The tip of the index finger was pressed upon the spine of the pubis, an incision was made over this outward and diverging 35° to 50° from Poupart's ligament, down through skin and superficial and deep fascia, but no farther. The last part of the incision should be made with the handle of the scalpel to avoid going farther. The pearly glistening fibres of the external oblique would then be seen, with the intercolumnar fibres running across them. Some fat would bulge up between the pillars. The secret of success now lay in putting aside everything with a cutting edge, not cutting through this fat, but keeping it intact; the tip of the index finger covering the ring, a pair of Péan's forceps was pushed into the canal and opened. This could be done even with the eyes shut. The forceps in the canal caught the only structures in it, the round ligament and nerve, and they were drawn out. The peritoneum was stripped from the ligament and the operation completed. The advantages of this method were: 1, an inch incision was sufficient; 2, there was no need of dividing the fibres of the intercolumnar fascia, which was the sole support of the external inguinal ring; 3, the round ligament could be quickly found, as the normal position of the structures of the ring was not disturbed; 4, the ligaments could invariably be found. He no longer believed that they were ever absent. Inguinal hernia had not developed in any of his cases, nor was there any reason why it should. In the cases of ventral fixation there had been no interference with subsequent pregnancy, but this seldom existed, since usually the disease calling for laparotomy had demanded removal of the appendages.

Intra-Abdominal Shortening of the Round Ligaments for Posterior Displacements of the Uterus.—Dr. M. D. Mann, of Buffalo, said his object in reading this paper was to call anew attention to an operation which he had described in 1895. He had first performed it in 1893. The patient was placed in the Trendelenburg posture, the abdomen was opened, adhesions were broken up, the uterus was replaced, and a large flat sponge was put over the intestines. The uterus was pulled up as near the abdominal wound as possible, the round ligament of one side was made tense by pulling the uterus to the opposite side, and was seized with two long-handled hæmostatic forceps, the points of seizure dividing the ligament as nearly as possible into three equal portions. A needle was passed, threaded with silkworm gut or silk, through the loop nearest the abdominal wall, then under the point where the round ligament was inserted into the uterus, a considerable quantity of uterine tissue being included in the suture. The hæmostat being removed, the loop of ligament was tied to the uterus. The second stitch was passed through the ligament just as it left the abdominal wall, and then through the loop at that portion of the ligament nearest the uterus. The ligature was tied and cut as before. In this manner the ligament was doubled on itself twice, and three thicknesses of round ligament were stretched between the sides of the pelvis and the wall of the uterus. The same thing was done on the other side. Dr. Mann had performed this operation fifty-eight times, and had not met with a single failure, so far as he had been able to follow his patients. Before devising this method he had made use of that of Wylie, Polk, or others, and had met with relapses. As to ventral fixation, he thought it was contraindicated whenever there was possibility of future pregnancy.

Preliminary Report on a New Method of Vaginal Fixation.—Dr. Edward Reynolds, of Boston, read the paper. He suggested the method after having tried it in only three cases, in order that the question whether it would prove successful when tested by a large experience might be settled more quickly. It was based on the fact that the uterus was not held normally in a fixed position; that while its position was uniform in most women, yet it was readily movable and was held laxly by its supports. These, however, were sufficient under ordinary circumstances to restore the original position. It was generally admitted that the normal function of the round ligaments was probably limited to restraining backward excursions of the uterus to the extremes of the normal limits, and that they did not hold the fundus permanently forward. The following was the proposed operation: An incision was made similar to the anterior incision in vaginal hysterectomy, but shorter, barely extending beyond the lateral aspect of the cervix. It was carried through the mucous and submucous tissues until the cleavage plane between the bladder and uterus was found. The bladder was then separated from the uterus up to the level of the internal os—previously ascertained by the sound. The uterus was now replaced; the point at which the bladder separated from the anterior vaginal wall was carefully ascertained by introduction of the sound into the bladder; a cervix needle, threaded with a silk carrier, was made to enter the vaginal wall at a point a little in front of the separation between the bladder and vaginal wall, and was carried obliquely through the tissues, to emerge on the cut surface just below the junction with the bladder. A silver-wire suture was threaded upon the carrier and drawn through the anterior vaginal wall. The same suture was then made to pass through the cervix at the

level of the internal os and brought out through the anterior vaginal wall at a similar point on the opposite side. A second suture was placed as near the first as possible, care being taken that the uterus was still well forward. These sutures were twisted and turned down. Coarse wire should be used. The cut edges of the mucous membrane were then stitched together with fine catgut. The only question with the operation was whether it would prove efficient. It certainly ought not to interfere with pregnancy, for it concerned only the cervix.

Shortening the Round Ligaments through the Anterior Vaginal Fornix for Posterior Displacements of the Uterus.—Dr. J. Riddle Goffe, of New York, described the method by which he had shortened the round ligaments for posterior displacements through the anterior fornix of the vagina, instead of opening the abdomen as Dr. Mann, Dr. Dudley, and others had done. In some preliminary remarks he pointed out some objections to other operations, more especially to anterior vaginal fixation of the uterus, as in Mackenrodt's operation, for in this the effects upon pregnancy had been disastrous. Dr. Goffe operated as follows: The uterus was drawn to the vulva, a cross section was made in the vagina at its junction with the cervix, the bladder was dissected off until he reached the peritoneal reflexion of that viscus on to the uterus; the central points of the cross incision were picked up with two artery clamps, and between these, with the anterior vaginal walls drawn tight, he commenced a longitudinal incision which extended forward to the neck of the bladder. Then the bladder was dissected from the vaginal wall on both sides, with the handle of the scalpel forward toward the urethra, backward and downward toward the cross-incision, until the bladder was separated one inch or one and one-half inches on both sides. Then the peritoneum was broken through at the point where it connected the uterus and bladder, the finger was hooked over the fundus of the uterus, all adhesions were broken up, and with the finger the uterine appendages were brought down and inspected, and conservative work was done on them if necessary. With a dull instrument he made an incision from one to two inches in length through the peritoneum which covered the round ligament, dissected the ligament out from its bed, drew it down as far as he thought was necessary to suspend the uterus—one inch to two and one-half inches—doubled it upon itself, and stitched it so with two or three sutures. This was done with both round ligaments. The uterus was replaced and a little gauze packed between the bladder and uterus; the longitudinal incision in the vagina was closed. Dr. Goffe had operated in this manner eight times, all since last October. The result had been entirely satisfactory except in one instance. In the one case he failed to dissect up one round ligament, and the result was sagging of the uterus on that side. A criticism which Dr. Lusk had made when he witnessed the operation was that it seemed to involve too much trauma. Dr. Goffe thought this point should be judged by the result. The women had all made good recoveries from the operation. It was, of course, too early to judge of the lasting result.

Dr. Paul F. Mundé expressed pleasure at opening the discussion, because he had been first to do Alexander's operation in this country. He had performed it more than one hundred and twenty times, and with great satisfaction. It had held out against all rival operations.

Dr. McMonagle, of San Francisco, practised uterine suspension to the abdominal walls as done by Kelly. It was quite different from ventral fixation. Regarding vaginal fixation, it was still being done by some surgeons in San Francisco. Some of the women had afterward come to him, complaining of pain similar to that referred to by Dr. Goffe as having developed in one of his patients, and which he and others had spoken of as occurring after Alexander's operation.

Dr. A. P. Dudley preferred intra-abdominal shortening of the round ligaments, which he now did after the method of Mann, preferring this to his own method, which he had formerly practised. He did not think favorably of doing this through the vagina, as described by Dr. Goffe. It was "taking the longest distance to go the shortest way round."

Dr. C. P. Noble referred to a paper which he had read on the surgical treatment of posterior displacements of the uterus, about two years ago, and in which he pointed out a difference between fixation of the uterus and suspension of it according to Kelly's method, there being objections to the former which did not apply to the latter. The oftener he did Alexander's operation, the better he was satisfied with it.

Dr. H. J. Garrigues spoke of some points in Alexander's operation with which he was pleased. As to the scars, they were covered by the hair of the pubes.

Pelvic Blood Collections and Their Treatment by Vaginal Incision.—Dr. E. E. Montgomery, of Philadelphia, read a paper on this general subject. Blood collections in the pelvis had long been recognized. The most frequent cause was rupture of an ectopic gestation. Other causes were escape of fœtal sac through the abdominal orifice of the tube; rupture of hemorrhoidal vessels, tearing of tube or pelvic adhesions by massage, examination of patient, or other traumatic lesions; rupture or perforation of the uterus; rupture or injury of an ovarian growth; twisting of the pedicle of an ovarian or broad ligament cyst; malignant disease of the ovary or tube; internal hemorrhage during menstruation, or following an abortion or miscarriage; slipping of a ligature, or slipping back of an artery after an operation. The symptoms would depend largely upon the situation of the hemorrhage. Intraperitoneal hemorrhage was far the most serious. It was usually attended with shock, blanched face, etc. The patient might die within a few minutes. After the blood collection had remained a time, septic phenomena might develop. If not, nature would cause its absorption and leave no remains, or it might stay and its presence be attended by secondary manifestations. In case of suppuration, discharge might take place into the vagina, rectum, or in some other direction. It was best that it should be into the vagina. The treatment would depend upon whether the collection was recent and continuing, or whether it had been present for some time. If it was recent and the patient had recovered from shock, certainly it would be unwise to open and remove the clot, on account of the danger of renewing the hemorrhage. If hemorrhage was going on, the patient's condition should be improved if possible and steps taken to stop the hemorrhage at once. In general, operative treatment was better than the expectant plan, in view of the possibility of infection, etc. Allowing for cases of active hemorrhage and ectopic pregnancy, the author advocated treatment by vaginal incision. Simple small puncture or aspiration was condemned.

Sociological Aspects of Gonorrhœa.—Dr. E. W. Cushing, of Boston, read a paper relating to the effects of gonorrhœa upon society at large. In view of the serious and far-reaching consequences of gonorrhœal infection, acting on the numerous innocent victims who happened to be our patients, causing in the young married woman endless suffering, sterility, and even death, he felt that it was the duty of this society to take all justifiable means to diffuse among the people a knowledge of such dread results. Ignorance of

the consequences of gonorrhœa had influenced the destiny of nations. Carried from older nations to new, it had not only caused untold suffering but had been one agent in decimating the population. This was made clear by mere mention of the progress of gonorrhœal infection through vagina, uterus, tubes, and ovaries, and of its multitudinous manifestations in other directions.

When it came to questions of prevention we found ourselves in the presence of the social evil, which was not only as old as history but as old as humanity. So far as concerned this and countless succeeding generations, we must accept human nature as a fixed quantity which could not be changed. Man had always been swayed by the sexual impulse, and woman had responded. The author later came to the question of the prevention of spread of gonorrhœa. He regarded the regulation of prostitution as a failure. It tended to spread venereal diseases by giving a false sense of security. It would be a tremendous instrument of blackmail on the part of the police and place the small proportion of prostitutes who should register quite at their mercy, while the greater number who did most to distribute gonorrhœa throughout the community would not register at all. Moreover, such a method in order to be effectual would require the sequestration of the men as well as of the women.

But a great deal could be done by the medical profession, whose office it was to instruct and enlighten the community as well as to cure disease. Thus public opinion would be formed, which was the only reliable foundation for the enforcement of law. A number of legislative bills had been presented, looking to the prevention of venereal diseases in a variety of ways, all of which struck the author as more or less absurd and impractical. When the public came to understand that gonorrhœa was a thing to dread as much as small-pox, the fight of prevention would be aided immensely. Let us, not only as a solid profession, but as individuals and family physicians, spread abroad information on this important subject by conversation with clergymen, jurists, teachers, and others. When parents came to be informed, they would not allow their daughters to marry men about town. Further, patients having gonorrhœa must be made to take the matter seriously, and undergo a rigid course of treatment, and not marry until all danger of infection had disappeared. Finally, the author mentioned the medico-legal aspect of the question.

Dr. H. J. Garrigues said that, while young men ought to control their sexual passion, yet he advised those who were too weak to do this to protect themselves and their future wife against infection by the use of a condom when they visited houses of ill fame.

Dr. Woods Hutchinson, of Buffalo, said he had some months ago devoted a good deal of study to this and other questions in their relation to the evolution of society. It had been found that while gonorrhœa was baneful to the individual, yet in its influence upon the development of society it acted, as did certain other evils, to cut off a part of the worst elements in the community. It was fortunate for society that both the men and the women about town usually became incapable of procreation, and even that the life of the prostitute was of short duration The cause of early death was largely alcohol.

Dr. Ashton, of Philadelphia, spoke in line with the views expressed by Dr. Cushing, and strongly against regulation of prostitution in the manner attempted in Berlin and some other European cities. It served only to spread venereal disease and immorality.

Dr. A. P. Dudley, the discussion of whose paper was included with that of Dr. Cushing's, repeated and emphasized the eleven points brought out in his paper relating to diagnosis and treatment of gonorrhœa.

Officers.—Dr. Paul F. Mundé, of New York, *President;* Dr. J. Riddle Goffe, of New York, was re-elected *Secretary*, and Dr. J. M. Baldy, of Philadelphia, *Treasurer.*

The next meeting will be held in Boston, the fourth Tuesday in May, 1898.

AMERICAN PÆDIATRIC SOCIETY.

Second Day—Wednesday, May 5th.

Adherent Pericardium in Children.—Dr. William Osler, of Baltimore, read a paper on this subject. Adherent pericardium occurs without cardiac hypertrophy as well as with. The adhesions to the diaphragm are not extreme, as a rule. It should be our routine habit to examine children's hearts with special reference to this disease. Three points are to be noted: 1, bulging; 2, systolic retraction above or below the apex; 3, Broadbent's sign. This valuable sign is a systolic retraction in the line of the diaphragm behind and to the left. It is most marked in the tenth and eleventh interspaces. It is due to wide adhesions of the ventricle and diaphragm. The vessels of the neck may be seen to retract. Physical signs: Palpation is of no value; percussion gives wide dulness. Stokes-Williams fixation of the upper limit of the heart may be present. Auscultation is of no value. One of his patients had a blubbering presystolic murmur with no valvular lesion. One had a thrill. Another important point is the association of recurring ascites with adherent pericardium.

The following case gives a summary of symptoms: When six years old the subject had rheumatism; at twelve years, anasarca. He had mitral regurgitation, cardiac hypertrophy, bulging præcordium, an apex murmur, and ascites. For the latter he was tapped one hundred and twenty-five times.

Empyema Operated upon during 1896 in the Children's Service of Mount Sinai Hospital.—Dr. B. Scharlau, of New York, said that during the year 1896 there were 56 cases at the hospital in which resection of one or more ribs was practised. The subjects numbered 36 females and 20 males. The ages ranged from fifteen weeks to thirteen years. The effusion was on the right side in 25 cases, and in 30 on the left side. A child of two years, had effusion on both sides, and recovered. Twenty-two had or gave a history of having had pneumonia. During the first half of the year 16 of the 32 died. Of all the subjects 36 recovered, 18 died, and 2 left the hospital improved. The death rate was 33 per cent. The causes of death were: 2, shock on the third day; 1, diphtheria; 2, measles; 8, pneumonia; 1, diarrhœa; 1, exhaustion.

It is claimed against the operation that fistula results. If there be dead bone and high granulations, they should be removed and the healing process started anew. If the lungs fail to expand, it is because of the feebleness of the child; it is not the fault of the operation.

Dr. Chapin said that the simpler operation usually suffices, especially if the diagnosis be made early. With an incision alone, recovery takes place in a few weeks.

Dr. L. E. Holt regretted that the time of continuance of the discharge was not given. Incisions heal quicker than exsections; therefore why subject the child to the more serious operation?

Dr. W. P. Northrup described a case of double empyema that was extremely bad. Having given a whiff of ether, he plunged a knife into the side—lanced it, as it were. In fifteen days the tube was out and the wound had healed. For some reason the boy fell into the hands of a surgeon for treatment of the other side.

He removed a rib, after which the wound discharged for three months.

Dr. Osler thought the boy was fortunate in losing only one rib. The real point to be determined is: What is the cause? An empyema due to pneumococci needs only to be tapped, while that due to streptococci must be laid wide open.

Dr. H. Koplik said it was well to remember that these were hospital cases. In private practice the results would be far better. It certainly makes a difference whether a wound is to close in eight days or eight weeks. The varieties of infection are four: first, tuberculous; second, pneumonic; third, streptococci; and lastly, metapneumonic. The streptococcus is the worst, as the both lungs are likely to be affected. The extensive wound may become infected and cause death. If the child is below one year of age, cure by siphonage should be attempted. In an older or strong child a rib might be exsected. The doctor said he had seen wounds of exsection close in eight and twelve days. A tuberculous case will not recover even though many ribs are resected. One should select the operation best for the particular case in hand. Results in private practice are good, if diagnosis and operation are made early.

Sarcoma of the Skin in the Newborn.—Dr. A. Jacobi read a paper with this title. He said, in part, that primary sarcoma of the skin is rare in adults, though it occurs between thirty and fifty years of age. Genuine sarcoma is a connective-tissue growth that increases rapidly. There is no recovery from it. Congenital cases are mentioned in literature, but the description usually shows the affection to have been subcutaneous rather than in the skin. Dr. Jacobi then analyzed the recorded cases, and found but one a true case. In 1884 he was the first to distinguish these growths from cancer, and has since so taught. The second case he now added to the list, with the following history:

Age, four months. A normal labor and normal breast-fed baby. When he was one month old a pink spot appeared on the scrotum. When three months old the spot was nodulated and bright red in color. It measured one and one-half by two centimetres. It was cut out easily and healed kindly. A small spot on the penis was cauterized and healed. Lupus was excluded, because there were no swollen glands. The microscope showed the tumor to be composed of fusiform and giant sarcoma cells. It is probable that the aberration of growth occurred at the fourth month of embryonic life.

Dr. W. L. Carr narrated a case in which he had removed a round-celled sarcoma of skin and subcutaneous tissue. He could not say in which it originated.

Abscess of the Brain in Infancy.—Dr. L. E. Holt read a paper with this title, reporting four cases.

Case I.—Child, six weeks old, the youngest recorded as having abscess of the brain. Four days before death it was found to have a fluctuating swelling of the thigh, due to a rupture of the quadriceps muscle. The temperature was 99.5° F. There was neither coma nor convulsion. On autopsy the brain was found firm and the surface normal, except pus and fibrin locally in the pia mater. An abscess holding two ounces of pus was found in the parietal lobe, which measured seven by five centimetres. Streptococci were found in the liver and abscess. Staphylococci were found in the auditory canal. The ears had been pierced and contained filthy thread. Possibly the infection entered here.

Case II.—Child, three months old; ill three days. It had irregular respiration, retracted abdomen, depressed fontanelle, irregular pulse, opisthotonos, nystagmus, and strabismus. The temperature was 102° F. The pupils were normal. The abscess was found in the right parietal lobe, and the pus filled all the ventricles. Pneumococci and bacilli coli communi were found.

Case III.—Child, five months old; had sudden vomiting, crying, opisthotonos, boatbelly; pulse, 200; temperature, 98° to 104° F.; and sluggish pupils. The abscess was of the size of a hazelnut, and under the cerebellum. Diplococci were found everywhere.

Case IV.—Child, nine months old, with history of four weeks' illness. The fontanelle bulged, but there was neither paralysis nor stupor. Abscess in right lateral lobe of cerebellum. Lumbar puncture revealed no tubercle bacilli. Staphylococci and pneumococci were found. This subject had vomiting, but no retraction of the abdomen. The *tache cérébrale* was present, and a flushing as of scarlet fever. Many diagnoses had been made other than abscess.

There are now recorded twenty cases of brain abscess in children under four years of age. The causes have been trauma, ten; otitis, nine. The average duration is five weeks. Convulsions often occur at the end.

Pneumonia.—Dr. F. Gordon Morrill read a paper embodying the results of an analysis of one hundred cases of pneumonia. He preferred the term "frank pneumonia" for the fibrinous variety. The cases had been seen in the Boston Hospital; the ages ranged from fourteen months to eleven years. Twelve gave a history of contagion. Seventy per cent. had vomiting, sixty per cent. had headache. Chills occurred in five cases. The consolidation was at the back in forty per cent. of cases. Effusion happened once. Five cases had temperatures as high as 106° F. Morning remissions were common. One had reinfection after five days' normal temperature. The lungs were usually clear in nine days. Mortality, six per cent. Treatment: All had brandy, and half of them had digitalis or strychnine. Opium was used at times. The cold pack is better for pneumonia than for typhoid fever.

Hereditary Tendencies in Pædiatric Practice.—Dr. F. M. Crandall read a paper with this title. He said that heredity and degeneration are two totally different phenomena, but are frequently confused by writers. The one produces a condition similar to that of the progenitor; the other a condition dissimilar. Degeneration may be inherited or acquired. The term is sometimes applied to conditions due to entirely different causes. There are elements of good heredity which are as potent as those of bad heredity, and frequently counteract tendencies to disease which would otherwise appear in the offspring. The tendency to a given disease shown strongly by both parents is not an infrequent cause of degeneracy. The strong tendency on the part of nature to adhere to a type in each species is a potent factor in preventing the repetition of extremes and in maintaining the common average. There is no evidence to prove that the number of degenerates is now greater than it has been in the past.

Lithæmia in Children.—Dr. B. K. Rachford said that there are many symptoms in lithæmic poisoning, and many names. Leucomain poisoning he liked best. Lithæmia is known by its symptoms rather than by its pathology. It is in reality an auto-intoxication, due to an excess of uric acid, xanthin, etc. Newborn infants eliminate much uric acid, and it may cause infarcts in the kidney and small calculi in the urethra. This is the cause of so much crying and evident suffering in many young infants. They have a reddish deposit in the diapers. The hot bath relieves this condition. Excess of oxalates may be the same, and cause nocturnal incontinence. The gastro-enteric symptoms are important, as the following case will illustrate:

Male, seven months old, of gouty parents. Since birth he has had sharp attacks, accompanied by rapid breathing without physical signs: temperature, 102° F.; sickening breath and oily stools. Calomel in one-twentieth-grain doses relieves the attack. His brother is similarly affected, but has headache instead of vomiting. It is megrim.

Some of the cases begin with convulsions. There is constant intestinal fermentation, and the toxin arising so affects the nervous centres as to produce rapid breathing. The precocious tuberculous child is short lived. Not so the precocious lithæmic. He will grow and have eczema, epileptoid seizures, and megrim.

Dr. Jacobi said that infants vomited easily because the stomach is straight. In childhood and youth it becomes more horizontal. These ages have headache instead. Temperature changes as intestinal conditions do. The doctor has often seen toxic nephritis cause many symptoms, especially convulsions.

Dr. Rotch had seen many uric-acid cases in nursed babies. It was due to too high a percentage of proteids. This can be reduced by having the mother exercise more, as exercise reduces proteids.

Dr. Crandall suggested that during growth of children we should from time to time see to their dietary and exercise, with a view to limiting the lithæmic state and its consequences.

Dr. Rachford, in closing the discussion, said that uric acid is insoluble, but may mechanically do harm, as in a joint. The types of lithæmia change from gastric to cerebral, epilepsy to megrim, etc. It is well demonstrated that the formation of uric acid is by nitrogenous metabolism.

Exophthalmic Goitre Apparently Cured by the Use of Thyroid Extract.—Dr. C. J. Kerley reported such a case in a girl, thirteen years old. She was poorly developed. Her father had epilepsy in his youth. A sister died at nineteen years from phthisis. Two uncles were of feeble mind. A year before the girl had received a blow in the neck while at play. A large painful swelling resulted, but went away. Another took its place, which was not painful on pressure. The girl became languid and her eyes protruded. The lids would not close. There was no loss of power in the extremities. The pulse ranged from 120 to 140, was small and soft. The carotids throbbed. Desiccated thyroid was given three times a day, five grains at a dose. On the twenty-ninth day she could walk alone and close the eyelids. As she was dizzy, the thyroid was reduced to two grains. After five months' treatment she could dress herself. The eyes are still large, but she is practically well.

Dr. Koplik, in the absence of Dr. Huber, read the history of the latter's "Case of Goitre Treated by Thyroid Extract." The goitre was three and one-half by two and one-half inches in diameter, and cystic. The child's memory was failing. After four weeks' use the extract was stopped and the three bromides were substituted. Dr. Koplik then cited several experiments of his own with thyroid, one being in a lipomatous child, nine years old. There were blindness, tremors, deficient mind, normal but dry skin. The hair and nails did not grow. Thyroid extract had no effect except to make the child worse. Hydræmic anæmias are greatly improved under thyroid, if iron also be given. Rachitic conditions are also helped by thyroid and iron. Thyroid improves the spirits and clears the skin.

Third Day—Thursday, May 6th.

Retro-Œsophageal Abscess.—Dr. J. P. Crozer Griffith reported a case of this kind in a child, twenty-one months old. For four weeks it had a metallic cough, with croupy attacks. The child was pale and had labored respiration, the auxiliary muscles being called into action. Expiration was prolonged, as in tumor of the trachea. There was no chest dulness. There were coarse râles throughout and occasionally there was spasm of the larynx. Diagnoses of asthma and of stenosis of the larynx were suggested. There was no evidence of enlarged bronchial glands. The boy was said to have swallowed a piece of celery. Tracheotomy was done, but no relief afforded. He was steamed by the croup kettle, but the fever ran high, broncho-pneumonia developed, and death resulted. Three small bunches of fatty crystals were found under a bronchus. The abscess was in front of the first thoracic vertebra, which was eroded. This condition may be common, but few cases are recorded. In pædiatric literature they are scarcely mentioned. There are no characteristic symptoms. Dyspnœa is usual; dysphagia not so, because the œsophagus is movable. Caries of the vertebra is recorded seven times, and in two cases it was absent. It is an infant's disease, only two being recorded in adults.

Retained Intubation Tubes.—Dr. Joseph O'Dwyer read a paper on this subject. He gave several causes for the obstruction: Paralysis or traumatism: a tube too large for the patient or clumsily introduced: a last cause, subglottic infiltration. He exhibited two larynges, one normal and the other showing the subglottic infiltration. Breathing can be carried on through very small openings: therefore small tubes should be used. In the trachea there is plenty of room for any tube. Infiltrated tissue is apt to slough. If after removal of the tube dyspnœa returns slowly, it is an indication of infiltration. If it returns rapidly, œdema is the cause. Granulation tissue may form above the bands, caused by roughened tubes. Tubes should be changed after four or five days, to be cleaned of rough deposits. Adductor paralysis may occur, but it should be remembered that this is a symptom not uncommon in diphtheria treated without the tube and one should be slow to ascribe it to the tube. If the tube is producing too much pressure, a smaller one than the age register would indicate should be employed. Strictures have formed in the larynx too much pressed upon by tubes. If the tube be occasionally reintroduced, healing will be gradual and no stricture follow. An interesting case was that of a boy who lived five years with a stricture from subglottic infiltration. He had another attack of croup, for which tracheotomy was done. Through the wound the stricture was divulsed. Recovery was complete. He could have been well before, but operation had been refused. The European habit of so soon resorting to tracheotomy if the tube does not cure, Dr. O'Dwyer does not understand. It is easy to find the tube that is suited to the case. For infiltration cases he has constructed tubes with a built-up head and retaining swell. One should use a tube to suit the size of the child, no matter what the age may be.

Dr. Northrup said that few physicians see retained tubes, but all will appreciate the new tube with built-up head and retaining swell. Often the only chance for life is in the modified tube.

Dr. Jennings related the case of a child who had been tracheotomized six weeks before entering the hospital. In seven days the tube was removed. The child was well twenty-four hours, when suddenly tracheotomy had to be done again, and the tube remained ten days more. This was repeated three weeks later. The boy learned to remove the tube himself every morning, and the house physician would replace it toward night when he became croupy again. Abductor paresis may be common when real paralysis is not.

Dr. O'Dwyer, in closing, said he had seen twenty cases in which stricture had been developed cured by introducing a tube often.

Diphtheria of the Eye.—Dr. T. M. Rotch gave the history of such a case. The child was three years old, and presented palpebral conjunctivitis. There was membrane on each eye, cultures from which showed Klebs-Loeffler bacilli. Five cubic centimetres of antitoxin were administered, and the membrane melted gradually away. In twenty hours it began to form anew. Two and one-half cubic centimetres were then given, and repeated every sixteen hours until recovery was complete. Cold and red-iodide ointment had been used with no result. It is the Klebs-Loeffler bacilli that destroy the cornea in these cases; therefore one should give antitoxin freely and prevent it. Its early use will save the cornea. Streptococci were found in this child's throat. The urine did not contain albumin.

Dr. Standish said that diphtheritic conjunctivitis has been described in Germany, but has not seemed to be frequent here. It is very grave, as necrosis of the globe and loss of sight result from it. He used to doubt the diagnosis if a subject recovered. Two years ago the Lying-in Infirmary established a bacteriological laboratory, and since that time many cases have been found and proven by the germs. Clinically the cases are diphtheritic, and so they are bacteriologically. Therefore the physician should give antitoxin and save life and sight. The conjunctiva is a good culture surface and catches most infections.

Dr. Rotch, in closing, said we must give enough antitoxin to stop the diphtheritic process, even if the physiological effects or poisoning of antitoxin be produced. We can treat that afterward.

Rapid Diagnosis (Bacteriological) of Diphtheria.—Dr. Henry Koplik presented an apparatus for this purpose. It consists of an ordinary water oven, which may be kept hot by a lamp on a tripod. The outfit would not cost more than two dollars. The temperature should be maintained at 38° C. The smears from the throat are to be applied to Loeffler's peptonized blood serum. It is to be treated for two and one-half or three hours, when the growth may be removed by a platinum needle and stained on a cover glass by Loeffler's blue. Loeffler bacilli will grow in a temperature of from 20° to 39.5° C., but the low point requires a long time. An excess of heat, on the other hand, is bad, as it favors the streptococci, which may outgrow and cover the Klebs-Loeffler bacilli. The method is simple. An expert laboratory bacteriologist is not required.

Prenatal Infection Causing Diseases which Develop during the First Month of Life.—Dr. Edward P. Davis read a short paper on this subject. He said we often see toxic symptoms in infants for which we can assign no cause unless prenatal infection. He had caused cultures to be made from the placenta and blood of the mothers, from fæces, etc. These showed that pyogenic organisms exist in the fæces of infants as yet unnursed, and the same in the breast of the mother before the baby has nursed. We know an anæmic mother may have an infant with normal blood. The placenta was usually sterile. Maternal toxins may be transmitted to the child during pregnancy. The proper treatment for the child is lavage with normal salt solution.

Acetanilid Poisoning in a Newborn Infant.—Dr. Irving M. Snow read an account of such a case. The child was healthy and born by a natural labor. On the seventh day the navel wound was dusted with crystals of acetanilid. Two days later the child became livid, apathetic, very blue, as in asphyxia. The pulse was very rapid; respiration, 60; temperature, 99° F. The lungs were clear and heart valves normal. The mind seemed clear and the pupils normal. Digitalis and oxygen were given, but the rally was slow. Jaundice came on later. The stools and urine were normal. The loss of weight was fourteen per cent. in two days. Eight cases are now reported, in one of which the patient died when four days old. The frequency with which acetanilid is used by surgeons must make us watchful. It is unsafe for infants.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. L. Emmet Holt; *First Vice-President*, Dr. Henry Koplik: *Second Vice-President*, Dr. Charles G. Jennings; *Secretary*, Dr. Samuel S. Adams; *Recorder*, Dr. Floyd M. Crandall; *Treasurer*, Dr. F. A. Packard; *Member of Council*, Dr. Charles P. Putnam.

The following members were elected: Dr. J. H. McCollom, Boston; Dr. J. P. West, Bellaire: Dr. Churchill, Chicago; Dr. E. E. Graham, Philadelphia: Dr. Harold Williams, Boston.

The subject of infantile scorbutus was selected for collective investigation, the report to be made at the next meeting. The following committee was appointed: Drs. W. D. Booker, J. P. Crozer Griffith, C. G. Jennings, A. Caillé, J. Lovett Morse.

Cincinnati was selected as the next place of meeting, the exact date not being decided upon.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE COLLEGE OF PHYSICIANS ON MEDICAL AID SOCIETIES—NEW FELLOWS—A LADY CANDIDATE FOR VETERINARY QUALIFICATIONS — OYSTER FISHERIES —DUCHESS OF TECK—LISTER AT THE LITERARY-FUND DINNER—THE LATE DR. VANDYKE CARTER—BALNEOLOGY AND CLIMATOLOGY.

London, May 7, 1897

The Royal College of Physicians has at last stated its pious opinion on the medical-aid question, in reply to a memorial presented some months ago asking for guidance. The college views with disapprobation the action of societies which make a profit out of the services of its medical officers, and also the conduct of practitioners taking office on such conditions; but the college would be exceeding its powers in forbidding its fellows, members, or licentiates to meet in consultation qualified practitioners who are acting in conformity with their legal rights. Evidently the memorialists can obtain little advice or guidance from the antiquated corporation to which they submitted their case. The local Medical Society, however, had previously pronounced it unbecoming and unprofessional for any member to lend his name to such an association, and acting within their legal rights all professional men can decline to acknowledge the existence of those who continue to act in a manner condemned by the vast majority.

The college next proceeded to elect eleven members to the fellowship. It seems that the officials could not make up the customary dozen, and yet I could easily give them a dozen names of men who have been passed over time after time, and whose election would be a credit to the college. Probably they are too proud to appear to seek what ought to be an honor, but which under present circumstances cannot be so considered. It is the old story that "kissing goes by favor," and retiring or modest persons are of course left out.

The woman question has had a new development. A lady, having qualified herself for examination by the Royal College of Veterinary Surgeons of Edinburgh, applied to be examined. Objection was taken to admitting her, as there was no precedent for granting a

qualification in veterinary medicine and surgery to a woman. But the college is only about forty-four years old, and this is said to be too short a time to establish usage. It is reported that the point will be submitted to the Scotch law courts.

The city fathers desire to be appointed the authority for inspecting the Kent and Essex oyster fisheries. Their port-of-London sanitary committee has done excellent work, and the government might do well to agree to the proposal, for the corporation is the market authority, and the London market is the natural destination of the product of fisheries in question.

The newspapers this morning announce that the Duchess of Teck a week ago underwent an operation for strangulated umbilical hernia. This is on the authority of advance slips from the *British Medical Journal*, and the names of the doctors are duly given. Of course the editorial cloak covers the sin of advertising the journal, which is so bitter in the case of slighter offences by individuals. It is satisfactory to learn that the patient, a favorite with the public, is doing well.

Lord Lister presided at the dinner of the Royal Literary Fund, and was supported by quite a number of prominent medical men.

Dr. Vandyke Carter died on Tuesday, aged sixty-five. You may perhaps remember him best for his important researches on parasitic diseases, but he had served a full career in the Indian medical service and attained the rank of deputy surgeon-general and honorary surgeon to the Queen.

The Balneological and Climatological Society is making progress. Sir D. Powell made an address at a recent meeting, in which he gave utterance to some home truths on sending patients away before accurate diagnosis was determined, and on the mischief done by taking up new methods indiscriminately, instancing the Schott treatment, now brought into some discredit for this reason, although no doubt of value in a very small number of most carefully selected cases. Wise words, Sir Douglas!

OUR BERLIN LETTER.

(From our Special Correspondent.)

THE TWENTY-SIXTH CONGRESS OF GERMAN SURGEONS, HELD IN BERLIN.

BERLIN, May 10, 1897.

FOR the twenty-sixth time the surgeons of Germany assembled in congress during Easter week. The presiding officer was Professor Bruns, of Tübingen, and in his opening address he recalled to mind the numerous deaths of members during the past year, dwelling especially upon the loss of Sir Thomas Spencer Wells, who was one of the few honorary members of the society. The present congress was marked less by reports of dazzling, epoch-making discoveries than by a quiet and earnest study of surgical advancements and investigations. The entire proceedings may be arranged under three principal headings:

1. The surgical treatment of ulcer of the stomach.
2. The use and value of the Roentgen rays in surgery.
3. The operative treatment of hypertrophy of the prostate.

The papers upon the first theme were read by the well-known authors and authorities, v. Leube and Mikulicz; the former treating the subject from the internal medical and the latter from the surgical point of view. By this plan it was best shown how the internalist and the surgeon could co-operate in the treatment of this condition.

V. Leube spoke about as follows: As a rule, the plan of treatment embracing absolute rest in bed, a carefully restricted diet, together with the application externally of hot bran poultices, is sufficient to cure the condition. Under these procedures seventy-five per cent. of patients were permanently healed, twenty-one per cent. improved, and four per cent. were unimproved or died. He regards the following as indicating a surgical procedure: 1. Very serious hemorrhage. 2. Secondary adhesions or abscesses, which are not infrequent after the healing of an ulcer. 3. All cases which resist internal medical measures, and in which the patient is threatened with death from marasmus.

Mikulicz compared the dangers of the operation with those of the disease itself. The results from the operation would be much more favorable and the dangers far less if the patients were operated upon earlier—not in a miserable condition of starvation, or half-dead from repeated hemorrhages, or, in a case of perforation, until pyæmia had intervened. Mikulicz regards the danger of an open ulcer of the stomach as not less serious than that of an operation for its cure, and that an operative procedure is indicated when no relief can be given the patient through other measures.

The reading of the papers of v. Leube and Mikulicz was followed by a discussion in which Körte, Rosenheim, Braun, and others joined. Körte reviewed the surgical treatment of diffuse peritonitis. Apparently hopeless cases of diffuse peritonitis are frequently greatly benefited by the evacuation of the foul fluid in the peritoneal cavity and subsequent irrigation with sterilized water, all of which is to be done through the smallest possible opening. The system is not by this procedure ridden of the disease, but by thus disposing of so much infectious matter the peritoneum is so aided in its combat with the germs and their products that it triumphs.

Professor Marwedel (Heidelberg) followed with remarks upon the "Value of the Murphy Button in Stomach and Intestinal Operations"—a subject which is of especial interest to Americans, the genial discoverer of this ingenious surgical device being a native of their land. Marwedel described in detail the application and uses of the button, a subject too well known to need repetition here. He recommended its use, although he has seen trouble resulting from it. Owing to its peculiar construction, intestinal obstruction may result, and can cause and has repeatedly brought about the death of the patient. On the other hand, the great advantages of the button as compared with the intestinal suturing are so vast, and the entire procedure is so new, and capable of improvement at all events, that it appears advantageous to employ it still experimentally.

Franke (Braunschweig) recommended the carrying out of gastro-intestinal operations in two separate sittings. The patients are as a rule very weak and poorly nourished, and cannot stand a severe operation. Franke had, for example, in cases of pyloric carcinoma, first performed gastro-enterostomy, and a few days later, or when the patient had improved, did the resection of the pylorus.

On the first day of the congress there were also papers read and remarks made upon intestinal occlusion and intestinal stenosis by the gut being caught in a diverticulum.

In the adjoining rooms of the building there was an exhibition of important surgical instruments and appliances. Many prominent firms were represented. A very large space was devoted to the exhibition of Roentgen photographs, which have gradually become an indispensable auxiliary of surgery. All kinds of normal and diseased organs and members of the body were to be seen well photographed; recent as well as perfectly and imperfectly united fractures, abnormal developments of bone, foreign bodies, etc.

The second day was devoted almost entirely to Roentgen rays. Surgery especially has been benefited by this epoch-making discovery of the Würzburg investigator, and if there be any one who doubts this he would have been converted by the number of those who spoke in terms of highest praise at this year's congress.

The principal paper was read by Professor Kümmell, of Hamburg, upon the "Application of the Roentgen Rays in Surgery." "Thanks to the untiring and ceaseless efforts of physicians, techniquers, and clinical observers," he said, "the fears at first entertained that Roentgen's discovery would be of but little practical benefit for medical science have proven futile; on the contrary, although but one and one-half years have passed, brilliant results have been already obtained, and we may expect much more in future." Kümmel referred to the advances made in the searching for foreign bodies, in the recognition of pathological bone processes, etc. The rays penetrate plaster of Paris readily, and it is therefore easy to ascertain if a set fracture has been properly reduced and remains in position. Tuberculous, syphilitic, and other diseased bone processes, as well as calcareous changes in the blood-vessels, can with great certainty be recognized. Cases of improvement of lupus by means of the rays have been reported.

The other speakers also spoke highly of the Roentgen rays. It is worthy of note that Eugene Dorn (Berlin) has so modified the procedure by means of stronger light and more sensitive plates as to take photographs within thirty seconds.

At the close of the second day Professor Rehn (Frankfort-on-the-Main) reported a case of wound of the heart, successfully treated by suturing the organ itself. The patient was a young man who had received a stab wound in the heart. He was found unconscious in the street and brought into the hospital. Active stimulation revived him, and examination showed dilatation of the heart, dyspnœa, and a small irregular pulse. The external wound was enlarged, in order to get at the point of bleeding. The pericardium was observed to be wounded also, and this being enlarged the heart itself came into view, showing in the wall of the right ventricle a wound about 1.5 cm. long, through which dark blood continuously trickled. Professor Rehn quickly sewed the heart wound with a continuous deep suture, and at once the hemorrhage ceased. The patient made a good recovery. As an evidence of the integrity of his heart's action it need only be mentioned that he wandered about Berlin the two days he was here, seeing the sights from morn till eve.

In the discussion which followed, Professors Riedel, Körte, Bardenheuer, Lauenstein, and Rieder reported other but unfavorable cases.

At the commencement of the third day, an invitation from Moscow to visit the coming international medical congress was read. Assurances of a warm reception of the German surgeons were given.

Then followed a discussion of the "Operative Treatment of Hypertrophy of the Prostate." Helferich recommended castration, but would reserve this measure for the severer cases only, as frequently disagreeable psychical disturbances occur. Freudenberg (Berlin) recommended the galvano-cautery. Socin (Basel), in all probability the best authority on prostatic surgery, is opposed to all operations, especially castration. He recommended massage and medication, in addition to palliative treatment.

The afternoon session began with the election of Professor Trendelenburg to the presidency of the congress of next year. Then von Graf (Berlin) spoke of "Permanent Cure of Cancer of the Larynx, following Extirpation of the Latter." The observations and notes were made in v. Bergmann's clinic. Of twenty cases of total extirpation, only two remained permanently well. Better results were obtained when but half or less of the larynx was removed. Three patients were shown, one of whom, a woman, had her entire larynx removed in May, 1890. She has remained well ever since, uses a cannula and speaks hoarsely, but can perform hard work.

Next in order were papers on "Subcutaneous Suturing of the Patella," followed by the reading of others on "Character and Operative Treatment of Carcinoma of the Pharynx," on "Lupus of the Hands and Tuberculous Inflammation of the Lymphatics," subjects which are not of sufficient interest to report here.

After a number of various demonstrations upon the last day, the long and eagerly awaited report by Professor Gurlt, of the "Narcosis Statistics for the Years 1895–96 and 1896–97," was read. There were reported 58,769 narcoses, of which 27,029 were of chloroform, with 29 deaths; 19,856 of ether, with 3 deaths; 5,000 with Billroth's mixture (chloroform, ether, and morphine), 1,000 with bromethyl, and 600 with chloroform-ether, with no death reported. The total statistics, which extend over seven years and consider over 327,500 narcoses, contain reports of 134 deaths, *i.e.*, 1 in 2,444. Deaths from chloroform are the most numerous, viz., 1 in 2,039; from chloroform-ether the least, viz., 1 in 7,594. It has been observed of late that chloroform exercises an injurious effect upon the kidneys, and, furthermore, that an exanthem occurs after ether narcosis.

The compiler of these statistics was accorded a vote of thanks in recognition of his careful and tedious labors, and it was resolved to continue the statistics.

Other papers were then read and addresses delivered, on "Operative Procedures in Diseases of the Liver," by Müller (Aachen); the "Operation of Complicated Harelip," by Samter (Königsberg); "Joint Inflammation from Gonorrhœa," by Bennecke (Berlin); and an exhibition of numerous preparations and patients followed.

With these last the exhaustive programme for the day was concluded, and after a vote of thanks to the chairman the twenty-sixth surgical congress adjourned.

THE LIABILITY FOR MEDICAL SERVICE.

To the Editor of the Medical Record.

Sir: I have just had an experience the recital of which may be of interest and benefit to your readers.

Some months ago I was called up on my telephone to meet at once in consultation a physician well known to me, at an address some sixty blocks from my house. The voice of the person calling me up was unknown to me, but he insisted on my coming at once, although in my office hours, as the case was urgent. I went at once and saw the patient and the physician. The patient had unfortunately drawn her last breath as I entered the house. The husband asked me to send my bill to him, which I did in due time, but no attention was paid to it, nor to several successive bills, nor to a polite letter. Although the amount was small—only an ordinary consultation fee—I did not relish being ignored, and after waiting several months instructed my lawyer to collect it. Payment was refused and suit brought. The defendant, himself a lawyer, deliberately swore that he had not telephoned to me (although the physician assured me that he did), and that he had no recollection of seeing me at his house—which was a falsehood and rank perjury. But as I could not swear that he himself had telephoned to me to go to his house, his voice not being familiar to me, the judge dismissed the suit—an obviously unfair and absurd decision, as it was evident that I would not have

brought suit or sworn to the facts as stated if they were not true.

I would recommend physicians, therefore, to be careful to assure themselves of the personality and reliability of persons making appointments with them by telephone, when such persons and their voices are unknown to the physician. They may thus avoid being swindled out of a fee, as was done with me.

PAUL F. MUNDÉ, M.D.

May 21, 1897.

P.S. The attending physician was at the bedside of the patient and not present at my interview with the husband. He could not, therefore, corroborate my statement. As I did not imagine that the defendant would have the effrontery to deny my affidavit, I did not take the precaution to have the physician present as a witness at the trial—an unfortunate omission, which probably cost me the loss of the suit.

THE MALICE AND VINDICTIVENESS OF THE ANTIVIVISECTIONISTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: One of the easiest things to manufacture in the United States is—sentiment. Be the cause ever so unworthy, an appeal in its behalf, if cunningly worded and pictorially illustrated, will always find a responsive chord in the hearts of many of our good people, who, not overburdened with education and unused to deep independent thinking, are unable to analyze the merits of a case, and take everything they read for pure coin. If, in addition to this, we take into consideration the eagerness with which the fair and gentle sex catches at all sorts of fads, we shall easily understand why the antivivisectionists are making headway in this country. We could well afford to ignore the increase in the number of their adherents and to smile indifferently at the spread of their imbecile literature, if there was not a third factor in the field—namely, the fact that our legislators, State and national, are not all Solons and but very seldom suffer from an excess of erudition. Half a dozen letters from the wives of their constituents count more with them than the unanimous resolutions of all our medical societies, and this is the reason why we are at present so perilously near to having some stupid antivivisection legislation thrust upon us. It therefore becomes our duty, as physicians and scientists, to oppose such vicious legislation and to do everything in our power to enlighten the public on the subject of animal experimentation. We must show the people the great discoveries and improved methods which surgery and internal medicine owe to vivisection; we must show that its abolition would strike a death blow to the science of biology, embryology, physiology, and bacteriology; we must show the true motives and the character of the great vivisectors; we must refute the infamous lies and calumnies circulated about us in the "anti" literature; and, lastly, we must expose the Jesuitical methods of the antivivisectionists, their ignorance and bias, their disregard of human health and life, and their gross inconsistency in sanctioning the slaughter of animals for alimentary purposes, while hysterically condemning it for the purposes of science and mankind.

This done, there will be little danger of adverse legislation. The people are not fools; they are only misinformed, and if the subject be presented in the proper light there is no doubt that they will be quick in perceiving on whose side are truth and common sense.

With the above object in view, I engaged in a debate with several antivivisectionists in the *Twentieth Century* and I think I am justified in believing that it, *i.e.*, the debate, has done some good. While I received several scurrilous anonymous letters from incorrigible fanatics, I have also received many communications from all sorts and classes of men, thanking me for having opened their eyes and set them aright on the subject of vivisection. As a result of the debate I have also become enlightened as to the character and personality of most of the antivivisectionists. I used to consider them ill-informed, but well-meaning and kind-hearted people; now, after having seen their method of polemics, after having studied impartially their literature, I know them to be hard-hearted fanatics (as fanatics are likely to be), deliberate prevaricators, and impudent ignoramuses, who deserve no consideration and are to be handled without gloves. Many of their assertions, in fact, can be explained only on the hypothesis of mental irresponsibility.

In the present communication I want to call attention to one trait of the antivivisectionists: their vindictiveness, their attempt to revenge themselves upon the physicians who have backbone enough to assert their convictions and cannot be bulldozed into signing the petition for the total prohibition of vivisection. In their official organs they have a standing pledge, which reads as follows: "I pledge never to knowingly employ a physician practising or upholding vivisection." They urge their readers to sign the pledge, adding that "in time they will tell—on the practice of the vivisectionist physician." While we in the large cities can afford to laugh at such a threat, it is entirely different in the small places, where a man's practice may depend upon the good will of some influential and overofficious lady. This method of intimidation is certainly peculiar. I asked the antivivisectionists whether they thought it was morally right to threaten the livelihood of a competent and conscientious physician who believed that the discoveries made directly and indirectly through vivisection were of benefit to his patients; but of course there was no response. And then they get angry when I tell them that their moral obliquity is equalled only by their mental perversity. I have become quite indifferent, though, to their anger and to their attacks.

WILLIAM J. ROBINSON, PH.G., M.D.

119 EAST ONE HUNDRED AND TWENTY-EIGHTH STREET,
May 10, 1897.

THE INVITATION OF THE AMERICAN MEDICAL ASSOCIATION TO COLUMBUS.

TO THE EDITOR OF THE MEDICAL RECORD

SIR: In your editorial pages of May 1st present, you state that "Columbus, Ohio, wants the next meeting [that of 1898] of the American Medical Association. We have not learned who in Columbus has the presidential bee in his bonnet—perhaps no one," etc.

You are perfectly correct as regards our desire to have the meeting. The medical men, the board of trade, etc., are working to obtain and if possible will get it. We think for several reasons it may be to the advantage of the society to come here, and that we are possibly entitled to have it come once, if not oftener.

1st. In May and June the climate of Central Ohio is as pleasant as that of any part of the world, and the beauty of the country is very great.

2d. Columbus, situated midway between the eastern and western and the northern and southern States, is from location and extensive railroad connections an easy and comparatively inexpensive point to reach. By trunk roads (the New York Central, the Pennsylvania, the Baltimore & Ohio, Chesapeake & Ohio, Norfolk & Western, etc.) we are eighteen or twenty hours from New York; eighteen from Philadelphia, Baltimore, Washington, and Richmond; twenty-three

hours from Boston, twelve from Chicago, eight from Louisville, three and one-half from Cincinnati, six from Detroit, three and one-half from Cleveland, eight from Buffalo, six from Pittsburg, etc.—advantages not possessed by a great number of towns even of larger size.

3d. We have good and ample hotel accommodations for four thousand people, and our citizens are not niggards in hospitality.

4th. Though we have not so many hospitals and show places as are to be found in larger towns, we have enough in the Capitol, the State University, the State and private hospitals, libraries, etc., to interest and entertain such as may be interested, outside the proceedings of the society.

5th. As Columbus may be reached within ten hours from any part of the State, a meeting of the national society here would be favorably regarded and attended by many hundreds of the profession, who cannot (many of them) attend meetings farther away.

6th. The association has met in all of the larger cities, and in many not larger and not better prepared to receive it than Columbus.

There are many loyal and industrious members in Ohio, and we think we are possibly in a degree entitled to at least one meeting. We of Ohio have adorned the nation with four presidents, to say nothing of senators, judges of the Supreme Court, generals, etc., and there are men here (doctors among them!) ready to offer themselves as candidates as soon as His Excellency Major McKinley has become weary of his present position; but I know of no one who has even thought of becoming president of the American Medical Association.

STARLING LOVING, M.D.,
Chairman of Committee.

COLUMBUS, May 15, 1897.

ROBERT KOCH'S "FINE COMMERCIAL INSTINCT."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Allow me to offer the following remarks in answer to an item under the above heading in your issue of May 15th.

A remedy which is not patented, which carries no trademark, and the preparing of which is fully described, so that "every one can make it" (as Koch says), is not a "proprietary preparation, with exclusive rights conferred on a certain firm." This same doleful cry was raised against Behring's antitoxin, and to-day dozens of firms are manufacturing the same in America as well as in other countries, earning thousands of dollars for manufacturers and health departments.

As to the priority claims of H. and Ed. Buchner,[1] the plain facts taken from this article are as follows: In 1893 the chemist, Ed. Buchner, attempted to have a certain method of crushing bacteria patented in Berlin. The patent was refused. His method was not published by him until January, 1897, four years later, when Koch had been in South Africa inspecting the rinderpest since December 5, 1896. If Koch had learned of Buchner's method in 1893 through the patent office or through his commercial house, he certainly would not have waited four years to bring forth his new tuberculin. Besides, Buchner fully describes the important differences between his and Koch's crushing method.

Koch dated his article November 14, 1896, and arrived in Kimberly, South Africa, twenty-one days later, on December 5th. His reports to the secretary of agriculture at Capetown date up to February 10th, and he arrived from there at Bombay, India, in early April.[1]

He did not publish his article in November, but waited till April, 1897, because most likely he wished to give the commercial house time to put up the necessary machinery, to train men for the new work, and so to produce his own tuberculin in sufficient quantities to enable every practitioner to test it immediately after it was announced. No deviser of a new instrument, apparatus, or remedy has ever before announced his invention before it was ready for others to try it. Why should Koch act differently from us all?

Possibly he would not risk that dangerous substitutes be sold for months, as was the case with Behring's remedy in New York, and he may not have felt inclined to give an advisory board of prominent medical men in New York a chance to assist a leading daily paper to introduce his remedy among the general public as the invention of a French scientist, as was done here in daily sensational articles from December 9 to December 19, 1894.

But even medical history will repeat itself. After giving serum therapy to the human race, Behring's name became a favorite target for the envious attacks of great and small savants in Europe, and was suppressed publicly at first in this country, and then used as a medical football by habitual grumblers and western editors, while the French Academy of Medicine disgraced itself by sending him only the half of the price held by them in trust for the invention of a remedy for diphtheria, which half Behring naturally donated to charitable purposes before touching; and why then should Koch fare better than his pupil? If only history will repeat itself in the value of the two remedies, then Robert Koch, his friends, his enemies, and their patients will be satisfied in the end.

A. SEIBERT, M.D.

114 EAST FIFTY-SEVENTH STREET,
NEW YORK, May 24, 1897.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 22, 1897:

	Cases.	Deaths.
Tuberculosis	192	92
Typhoid fever	8	6
Scarlet fever	167	5
Cerebro-spinal meningitis	2	8
Measles	297	12
Diphtheria	296	34
Laryngeal diphtheria (croup)	8	9
Small-pox	1	0
Chicken-pox	40	0

Small-pox in Japan was quite prevalent during the year 1896. Of 3,800 cases reported from January to September, 1,234 were fatal. By the end of November fully 5,000 in the aggregate had been noted. The most of these cases were observed in the districts lying nearest to China and Formosa.—*Sei-I-Kwai.*

A Little Nonsense Now and Then, etc.—A correspondent with etymological proclivities writes: "The ending *oma* means tumor, as in adenoma, sarcoma, etc.; the prefix *dipl* means double, as in diplacusis, diplococcus, etc.; therefore, when a graduate receives his diploma, does he get a double tumor?" To some extent, yes; usually it is a case of swelled head and general inflation.

IMPROVEMENTS IN THE IRRIGATION TREATMENT OF GONORRHŒA.

By FERD. C. VALENTINE, M.D.,

PROFESSOR OF GENITO-URINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE; GENITO-URINARY SURGEON, WEST SIDE GERMAN DISPENSARY, ETC.

Goldberg,[1] in summarizing the results obtained by all authors on the irrigation treatment of gonorrhœa, shows that sixty per cent. of the gonorrhœas so treated were cured within ten days, thirty per cent. within two weeks, five per cent. required a longer period, because of indulgence in sexual intercourse or alcohol, or both, and the remaining five per cent. stand recorded as failures.

When it is considered that his figures embrace those of authors who wrote condemning this method, the average results are simply surprising. It seems inconceivable, in view thereof, how any other mode of treating gonorrhœa can still have a foothold in the profession.

The objections this method had to combat were valid only to a degree. They were principally the large amount of work imposed upon the physician and uncleanliness. The apparatus having now been simplified, the work is reduced to a minimum, can be more thoroughly performed, and only gross carelessness or inexcusable awkwardness will cause the novice to soil the patient, himself, or the office, by irrigations.

The results obtained by some five hundred American physicians from irrigating in gonorrhœa and other genito-urinary affections wrest this method from the realm of the enthusiastic promoter; the personal equation has ceased to be an element in its advocacy. Those who but test it are at once assured of the following facts:

1. Every urethra, not too tightly strictured, and every bladder can be irrigated without a catheter.

2. Irrigations, properly employed, will cure gonorrhœa quicker than any other mode of treatment.

3. Internal medication is futile; hand injections are useless.

Other arguments in favor of this method would be fitting in an article not limited to technique. In its description, elegance of diction is not sought; clear, succinct exposition is the only object in view.

Most of the directions will appear self-evident to the majority of practitioners; some may seem unnecessarily complicated. In order to omit nothing, I emulate that "infinite capacity for taking pains" which Carlyle offers as a substitute for genius.

For Anterior Irrigations.—1. Have the patient drop his trousers and drawers to his knees and fold his shirt upward.

2. Adjust a rubber apron twenty inches square, with a hole in its upper third, to allow the penis to pass through.

3. Close the stopcock of the apparatus and hang it on a convenient cuphook, or preferably place it in a basin containing mercuric bichloride, 1–6,000 (about one grain of bichloride of mercury in twelve fluid ounces of water).

4. Put the solution to be employed into the irrigator, at a temperature of 110° to 120° F.

5. Place the irrigator in the brass ring, which has been screwed to the wall nine feet from the floor. This suffices practitioners who have not many irrigations to perform daily. But in an extensive genito-urinary practice it proves inconvenient. For those so engaged, an elevating slide is devised. By it the irrigator can be easily lowered for filling and rapidly raised for use. The illustration fully explains its employment.

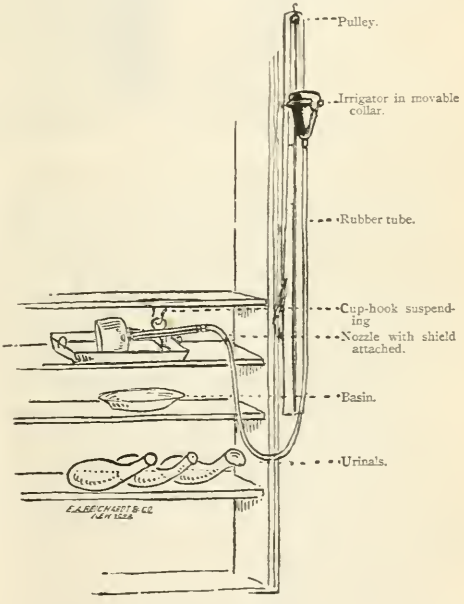

Fig. 1.—Convenient Arrangement for Author's Irrigating Apparatus.

6. When the irrigator is placed in its collar (or, if the elevator is used, raised nine feet from the floor) attach the proper nozzle. This is easily accomplished by holding the stopcock in one hand and inserting the nozzle into the free end of the rubber tube until it is firmly held there, but not so far back as to press upon the ball of the stopcock.

The selection of the nozzle naturally depends upon the size of the meatus. Experience has led to three forms for the male urethra.

7. Order the patient to empty his bladder entirely, unless he has very much pain on urinating.

8. Place the patient on a wooden chair, as far forward as he can comfortably sit, his shoulders resting against the back of the chair. Place his feat at the outer sides of the front feet of the chair. It will be

[1] "Die Behandlung der Gonorrhöe mit Ausspülungen von übermangansaurem Kali." Centralblatt für die Krankheiten der Harn- und Sexual-Organe. Band vii., Hefte 3 und 4.

desirable to have the patient throw his head backward, projecting his expirations upward, instead of into the operator's face. Giving this direction as part of the proceeding in all cases prevents those who are unfor-

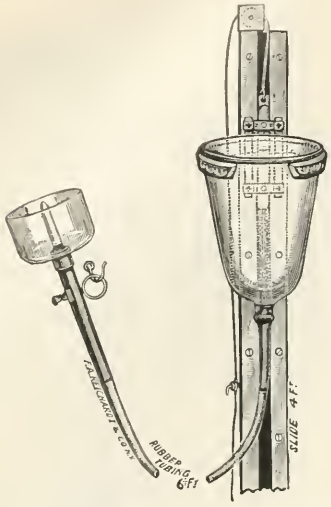

Fig. 2.—Showing Details of Mounting Irrigator and of Connecting Stopcock, Shield, and Nozzle.

tunate enough to have a malodorous breath from learning that an invidious distinction is made.

9. Hand the patient a tin washbasin, twelve inches in diameter, or preferably one of enamelled or agate ware. Let him hold it with both hands, slightly tilted toward himself, his penis resting in the basin.

10. Stand at the patient's right side. Raise his penis by your third, fourth, and fifth fingers of the left hand, and press it firmly but gently against the ball of your left thumb. This leaves the thumb and index finger free to manipulate the foreskin and glans, as may be required.

11. Take the stopcock with its shield in the right hand, the thumb resting upon the top of the bar, the index finger passed through the ring.

12. Contract the right thumb slightly, releasing the stopcock bar from its uppermost notch. Raise the thumb very slowly, allowing a very gentle flow of the solution to escape. Let this run upon the outer surface (skin) of the prepuce. Turn the penis until entirely clean exteriorly.

13. With the left thumb and index finger slowly retract the foreskin while the stream plays upon all its parts, until its mucous surface and the glans are thoroughly cleansed.

14. Hold the glans with the left thumb and index

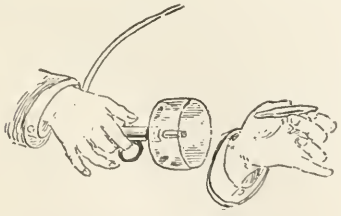

Fig. 3.—Inserting Nozzle.

finger slightly bent, everting the lips of the meatus, while the stream plays upon them. Still more opening the meatus and increasing the force of the stream, it is directed into the meatus.

15. When every vestige of discharge is washed from all visible parts of the meatus, the nozzle is placed closely to it, and the force of the stream gradually increased until its impact is felt against the left mid-

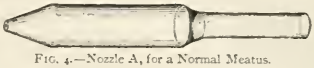

Fig. 4.—Nozzle A, for a Normal Meatus.

dle finger. By this time about one-fifth of the contents of the irrigator has been used. The remaining four-fifths are consumed in the following steps:

16. When the second fifth of the solution has flown into the basin, relax the grasp of the left middle fin-

Fig. 5.—Nozzle C, for a very Small Meatus.

ger upon the urethra. The force of the current being still further increased, it will strike the fourth finger of the hand holding the penis.

17 and 18. Relax the little finger, in the manner directed under 16.

After anterior irrigation it is well to cover the meatus with a layer of cotton soaked in mercuric bichlo-

Fig. 6.—Nozzle B, for a very Large Meatus.

Note.—Nozzle B is used only in posterior irrigations, to be described farther on.

ride, 1–6,000, and to direct the patient to renew this application after each urination.

For Posterior or Intravesical Irrigations.—Irrigation of the posterior urethra premises overcoming the compressor urethræ (shut-off muscle). The force of fluid that can accomplish this must necessarily overcome the sphincter vesicæ as well, as soon as the posterior urethra is filled. The sphincter vesicæ being but a feeble bundle of muscular fibres, irrigation

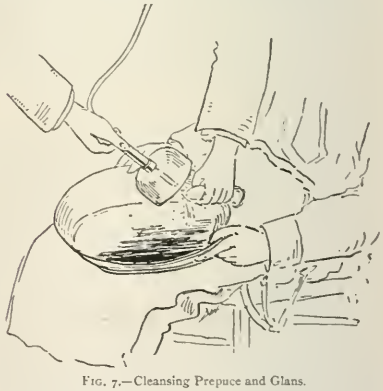

Fig. 7.—Cleansing Prepuce and Glans.

Note.—This illustration should show the patient seated on the front edge of the chair, his trousers dropped below his knees, his shoulders resting firmly against the back of the chair. The operator's left thumb and index finger should be contracted for manipulation of the prepuce and glans.

of the posterior urethra, which practically is a part of the bladder, cannot be dissociated from intravesical irrigation.

The detailed steps of a posterior or intravesical irrigation are:

(*a*) Irrigate the anterior urethra, before washing out the posterior urethra, as laid down under rules 1 to 18 *supra*, using, however, only half the quantities

of the fluid directed in rules 15, 16, and 17. The reason for this variation is in the copious double washing the urethra receives by the entrance of the fluid and its exit from the bladder.

(*b*) If the meatus is of average size, use nozzle A;

Fig. 8.—Anterior Irrigation in the Erect Posture.

Note.—Some patients prefer to have their urethras irrigated while standing; there is no objection to this. Others, who are very much afraid of pain, may be irrigated lying down. The details of irrigation in this posture will be discussed under Posterior Irrigation.

if very small, nozzle C, while for a very large meatus, nozzle B should be employed.

(*c*) Seat the patient as for anterior irrigation (see Fig. 7), except that his sacrum (not the tuberosities of the ischium) must rest upon the extreme front edge of the chair.

(*d*) Irrigate the anterior urethra; have the patient either sitting as described under *c*, lying down, or standing.

(*e*) Then, occluding the meatus with the nozzle, order the patient to breathe deeply and endeavor to urinate, preferably as if trying to "squeeze out a last drop." The deep respirations release the bladder from the superimposed weight of the abdominal and pelvic contents; the efforts at urination relax the compressor; in many cases, however, these aids become unnecessary after a first effort. Almost invariably the tips of the left fingers, resting upon the urethra,

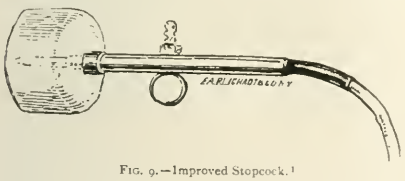

Fig. 9.—Improved Stopcock.[1]

Note.—The perpendicular bar should show two sharp notches anteriorly and one posteriorly.

will at once detect a decided purling as the liquid passes into the bladder through the now relaxed sphincters.

(*f*) After performing a few irrigations the surgeon's left hand grows accustomed to the sensation of the bladder filling, and before the patient expresses a desire to void it he closes the stopcock.

(*g*) Hold the stopcock in the right palm, take the basin with the right thumb on its inner, the right fingers on its outer surface. Extend the left hand, which has dropped the patient's penis into the basin, to the shelf on which the glass urinals are kept. Take one of them, and while removing the basin hand the patient the urinal. It requires but slight dexterity to do this so quickly as to prevent dribbling of the solution on to the apron or the patient's garments.

Fig. 10.

Note.—Ambidextrous surgeons may reverse 10 and 11 at their convenience.

(*h*) Order the patient to stand up, as the majority can thus relieve their bladders more quickly.

(*i*) The quantity of the fluid used necessarily varies with the size of the bladder. The average bladder will hold about two hundred and fifty centigrams (about seven and a half ounces).

(*j*) The first irrigation often yields quite a turbid and brownish fluid. This is due to the admixture of the vesical contents. If a very weak solution of potassic permanganate is used, it may come from the bladder almost colorless, a small quantity of urine will decolorize this drug.

(*k*) Occasionally the liquid will ballon the urethra, give the patient pain, and refuse to enter the bladder, despite all efforts. Then desist at once, and order the

Fig. 11.—Removing Pan and Handing Patient Urinal.

patient to urinate. It is surprising how small a quantity of urine can arrest irrigation. This being voided, the second attempt at irrigation will be readily successful.

(*l*) In most cases turning on the full stream at once will produce urethrospasm, entirely preventing irrigation. In such instances interrupt the operation and let the contents of the penis escape into the pan. Then again occlude the meatus with the nozzle and allow the fluid to flow into the urethra very gently. As soon as the urethra begins to distend, again order the patient to breathe deeply and to strive to urinate. With each respiratory effort allow the button of the stopcock to rise, and almost to close it at each inspiration. Every such movement will be accompanied

[1] I am indebted to Dr. Union Worthington, of Salt Lake City, for valuable suggestions in modifying the mechanism of the stopcock.

by the entrance of some fluid into the bladder. As soon as this is begun, the remainder of the irrigation will be easy.

Variations in posture: Many patients' bladders can

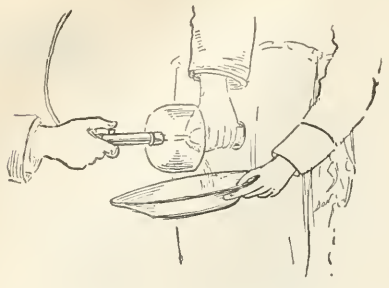

Fig. 12.—Intravesical Irrigation in the Standing Posture.

Note.—The drawing should show the operator's right thumb more elevated and the stopcock bar raised. The drops apparently spurting into the basin are supplied by the draughtsman's imagination, as none escape during such injection into the bladder.

be irrigated quite easily while they stand. As some people, however, faint very readily, irrigation in the upright position should not be performed save as a last resort in those very rare instances when the other postures have failed.

A patient who cannot be irrigated in the sitting posture, or who is prone to faint, should be treated in the recumbent position. Then no apron is used. The trousers and drawers are dropped almost to the ankles; the shirt and undershirt are folded upward. He is then laid upon a sofa or operating-table, his buttocks projecting far forward from an irrigating bedpan. For additional safety a washbasin may be placed between the thighs, inclined so as to divert any possible spluttering of the fluid into the bedpan's tin receptacle. The steps of anterior and posterior irrigation do not differ from those employed in the other positions.

Irrigating the Female Urethra and Bladder.—The nozzle used for this purpose is merely a nozzle A, of double length. Place the patient in the ordinary dorsal gynæcological position upon a Kelly pad. Wash out the vulva and vagina as in an ordinary vaginal irrigation. Place the left palm before the mons

Fig. 13.—Intravesical Irrigation in the Recumbent Posture.

Note.—This cut should show the patient lying flat on his back, his buttocks higher than his shoulders.

veneris, separate the labia with the index and middle fingers, to expose the meatus. Direct the point of the nozzle to the meatus and send a gentle stream against it. Gradually increase the force of this stream until the meatus and entire introitus vaginæ are thoroughly clean. Wedge a triangular pus basin between the patient's thighs until one point of the basin firmly compresses the fourchette. Insert the nozzle into the meatus, but do not occlude it, so as to allow the fluid to escape into the glass shield and thence partly into the pus basin and partly on to the Kelly pad. Increase the force of the stream while sinking the nozzle still farther into the meatus, until no more fluid escapes. The sphincter will quickly yield, and the fluid enter the bladder. Remove the pus basin; replace it by an inverted ordinary hand basin. Order the patient to empty her bladder. The escaping fluid strikes the hand basin and falls into the Kelly pad, and thereby is conducted into the bucket on the floor, into which its end has been inserted. Irrigation of the female urethra and bladder, conducted with all the above attention to detail, will be accomplished without soiling the patient's garments or even moistening her thighs. A heavy towel passed under the patient, immediately

Fig. 14.—Posture of Patient when Exposing the Meatus for Anterior Irrigation.

above the inflated rim of the Kelly pad, will serve to dry her buttocks after the pad is taken from beneath her.

Notes on Irrigation.—Very rarely is a patient found with such hyperæsthesia as to render irrigation impossible without a local anæsthetic. A drachm or two of a four-per-cent. solution of cocaine or eucaine will quickly arrest all sensation.

Anæsthetizing the Urethra.—Fill the syringe (preferably Kollmann's cocaine syringe, whose detachable tips can readily be sterilized). Inject a few drops slowly and the remainder with enough force to send it as far into the urethra as possible. Close the meatus with the left thumb and index finger and stroke the whole length of the urethra with the right index finger, from before backward. The fluid will soon pass beyond the peno-scrotal juncture. It then can be pressed toward the bladder along as much of the urethra as can be felt in the perineum. This procedure may be repeated once to insure absolute anæsthesia.

Painlessness of Irrigations.—Ordinarily anæsthesia is not required. A second irrigation is usually painless. In a large experience but one case (as the patient thought) required cocaine before each irrigation. The second alleged cocainization was with distilled water which quite sufficed to calm the patient's mind.

Cleanliness of Irrigations.—Any irrigation, properly conducted, should not soil anything except the surgeon's left fingers. These can be quickly cleaned of the permanganate stain with a saturated solution of oxalic acid.

Care of the Apparatus.—After each irrigation fill

FIG. 15.—Irrigation of the Female Urethra.

NOTE.—The dotted lines represent the pus basin.

the apparatus with clean water to carry off any small quantity of the solution that may remain.

Asepsis of the Nozzles.—1. Immediately after use, detach the nozzle, and place it in the basin.

2. Let hot water run over it.

3. Boil it in a solution of caustic soda for half an hour.

4. Take it from the solution with sterilized forceps, and place it in a solution of corrosive sublimate, 1–500 (sixteen grains to the pint).

5. Before use again rinse it in clean water.

The Solutions Used most frequently in anterior and intravesical irrigations are potassic permanganate, mercuric bichloride, silver nitrate, and cupric sulphate.

Potassic permanganate: In previous publications[1] I advocated the solutions proposed by Prof. Jules Janet, of Paris, to whom sufficient credit can never be given for popularizing the irrigation treatment. But the exigencies of business in our country, and perhaps greater urethral and vesical susceptibility here, have led me to change Janet's formularies in several regards. For the practitioner's convenience they are here tabulated, as changed:

In Acute Gonorrhœa.—

First	day,	first visit:	Anterior irrigation	....	1–2,000
"	"	7 P.M.	Anterior irrigation	.....	1–4,000
Second	"	9 A.M.	"	"	1–3,000
"	"	7 P.M.	"	"	1–4,000
Third	"	9 A.M.	Intravesical	"	1–6,000
"	"	7 P.M.	Anterior	"	1–6,000
Fourth	"	9 A.M.	Intravesical	"	1–3,000
Fifth	"	9 A.M.	"	"	1–3,000
Sixth	"	9 A.M.	"	"	1–3,000
Seventh	"	9 A.M.	"	"	1–2,000
Eighth	"	9 A.M.	"	"	1–2,000
Ninth	"	9 A.M.	"	"	1–1,000
Tenth	"	9 A.M.	"	"	1–1,000

This last is followed, at the same hour, by an anterior irrigation of 1–5,000.

In Chronic Gonorrhœa.—The conditions, as revealed by the urethroscope, govern the treatment fully as much as does the microscopic examination of the discharge in acute urethritis. Of course no one expects a chronic gonorrhœa to recover while the urethra is strictured or otherwise diseased.[1] But when no condition other than gonorrhœa affects the urethra the following formulary will apply, with such modifications as the individual cases may require:

First	day,	first visit:	Anterior irrigation	....	1–3,000
"	"	7 P.M.	Anterior irrigation	.....	1–6,000
Second	"	9 A.M.	Intravesical	"	1–4,000
"	"	7 P.M.	Anterior	"	1–4,000
Third	"	7 P.M.	"	"	1–2,000
Fourth	"	9 A.M.	Intravesical	"	1–3,000
"	"	7 P.M.	Anterior	"	1–2,000
Fifth	"	7 P.M.	Intravesical	"	1–3,000
			Anterior	"	1–1,000
Sixth	"	7 P.M.	"	"	1–1,000
Seventh	"	7 P.M.	"	"	1–1,000
Eighth	"	7 P.M.	Intravesical	"	1–3,000
			Anterior	"	1–1,000

If, after the above irrigations have checked the discharge it recurs, as occasionally happens, the whole course should be repeated. This failing to cure the case, the cause will soon be exposed by careful urethroscopy and then prove amenable to treatment.

In a large genito-urinary practice it is well to consult convenience in the preparation of these solutions. In neighborhoods where many physicians are using the irrigation method some druggists make fresh solutions of potassium permanganate, containing twenty grains to the ounce of water. The solution is convenient in quickly making the dilutions required. The irrigator holds a thousand grams (about fifteen thousand grains); consequently to make of the above solution a

dilution of	1	to	12,000,	fl. ʒ ss.	is required.
"	" 1	"	6,000,	fl. ʒ i.	" "
"	" 1	"	4,000,	fl. ʒ iss.	are "
"	" 1	"	3,000,	fl. ʒ ij.	" "
"	" 1	"	2,000,	fl. ʒ iij.	" "
"	" 1	"	1,500,	fl. ʒ iv.	" "
"	" 1	"	1,000,	fl. ʒ vi.	" "
"	" 1	"	500,	fl. ʒ iss.	" "

The objection to this solution is its instability. It will, however, not decompose within three or four days after it is made.

Practitioners who do not have occasion to perform

FIG. 16.—Intravesical Irrigation

many irrigations daily will find the two-grain tablets of potassic permanganate sufficiently convenient.

Mercuric bichloride frequently proves useful in ob-

[1] Valentine: "The Technique of Urethral and Intravesical Irrigations," Clinical Recorder, February, 1896. "Chronic Urethritis," New Albany Medical Herald, 1896. "The Rapid Cure of Gonorrhœa," International Journal of Surgery, October, 1896.

[1] This is exhaustively discussed in a paper entitled "Chronic Gonorrhœa; Its Scientific Treatment," written for the second Pan-American Medical Congress, held at Mexico, in November, 1896.

durate cases. It may be added to the above irrigating fluid in dilutions of from 1 to 50,000 to 1 to 20,000, as corrosive sublimate and potassium permanganate are not incompatible.

Silver nitrate in solutions of from 1 to 10,000 to 1 to 1,000 proves serviceable, especially after urethral dilatations.[1]

Cupric sulphate: In persistent urethritis without gonococci an anterior irrigation of solutions of cupric sulphate, from 1 to 2,000 to 1 to 500, often exerts a desirable influence as an occasional alternant with potassic permanganate.

Argonin: My experience with this drug is as yet limited. Early trials proved unsuccessful, probably because of faulty technique in dissolving it. Harold L. Lesser, Ph.G., pharmacist of the West Side German Dispensary, and Paul F. Metze, Ph.G., came to my aid, the former furnishing me with a ten-per-cent. solution for dispensary use and the latter with the same for my private practice. Only then did I begin to yield to the persuasions of Arthur Lewin, of Berlin, to test argonin, to which he attributes direct, specific gonococcocidal action. The results in some instances seem satisfactory in diminishing the discharge. I have used it up to five per cent. intravesically without the slightest disagreeable reaction. Its gonococcocidal influence, however, does not appear to exceed that of potassium permanganate. But whatever the drug used, the urethral and intravesical irrigations without a catheter are certainly the essential to its successful employment.

A detailed description of the conditions in which they are indicated would be beyond the scope of this paper. Suffice it here to say that, in addition to acute and chronic gonorrhœa, irrigations without a catheter should be employed after any and every instrumentation of the urethra or bladder. In not a single case does catheter fever (urethral fever) supervene, no matter how susceptible thereto the patient may be.

Due credit must be given Messrs. F. Alfred Reichardt & Co., of 27 Barclay Street, New York, for placing the resources of their establishment and workshops at my disposal in perfecting this apparatus. The many mechanical problems required to be overcome were met by valuable suggestions to the end of providing practitioners an easily manageable, effective outfit at a very moderate price.

242 West Forty-Third Street, New York.

Laminectomy for the Relief of Paraplegia Dependent upon Spinal Caries.—Willard (*Journal of Nervous and Mental Disease*, April, 1897, p. 223) expresses the opinion that the prognosis in cases of paraplegia due to pressure upon the spinal cord is hopeful unless the cord has been actually destroyed. Laminectomy for the relief of paraplegia dependent upon spinal caries should never be undertaken until at least one year of persistent treatment by rest, fixation, and extension (together with alteratives, etc.) has been most patiently tried. The dangers from the operation are shown by statistics to be great, twenty-four per cent. dying from the immediate shock, thirty-six per cent. within one month, and forty-six per cent. within one year. At least sixty-five per cent. either die or are not improved by the operation. The dangers are hemorrhage, prolongation of the operation, and manipulation of the cord. In spite of these risks the operation has its place in surgery, and is justified in selected cases when other measures persistently and carefully applied have failed.

THE CORRECTION OF DEPRESSED AND SADDLEBACK DEFORMITIES OF THE NOSE BY OPERATIONS PERFORMED SUBCUTANEOUSLY, WITHOUT THE AID OF METALLIC OR OTHER ARTIFICIAL SUPPORTS.[1]

By JOHN O. ROE, M.D.,

ROCHESTER, N. Y.

Mr. President and Gentlemen: Ten years ago I read before this society a paper on "The Deformity termed Pugnose and its Correction by a Simple Operation," which was a new operation, and the first one proposed for the correction of this deformity. In 1891 I presented for your consideration another operation for the relief of angular deformities of the nose; the method of performing this operation subcutaneously without wounding the skin was also entirely new. At this time I have the pleasure of presenting for your consideration a method, equally new, for the correction of saddleback and depressed noses by operations performed subcutaneously.

The procedures which I shall presently describe are applicable to cases in which the nasal septum is present, thereby affording support for the tissues that are transplanted for the correction of the deformity, for in these operations we must depend wholly or in part upon the support which we must necessarily obtain from the osseous and cartilaginous portions of the septum. In cases in which there is an entire absence of these natural internal supports, as we often find resulting from the ravages of syphilis, we must resort to some method of metallic or other artificial support.

In nearly all cases of deformed noses in which there has not been great destruction of tissues, as in those cases in which the deformity has resulted from an injury or from abscesses of the nose or nasal septum (and which is also sometimes the case when resulting from syphilis), there is present sufficient material out of which a symmetrical nose can be made. The deformity in these cases is mainly due to the fact that the tissues have become displaced and deformed, thereby giving to the nose an unsightly appearance. This is particularly the case when the deformity of the nose has resulted from an injury.

Depressed noses may be divided according to their cause into two classes, viz., idiopathic and traumatic.

(1) The idiopathic variety comprises those noses in which the deformity is due to a lack of development of some portion of the nose. When there is a lack of development of the central portion or the bridge of the nose, and excessive development of the tissues of the end of the nose, we have an exaggerated "*le nez retroussé*," or pugnose, termed the saddleback nose. When there is a lack of the cartilaginous portion of the nose, we have the flat or frog nose.

(2) The traumatic variety includes those cases which are the results of injuries from external violence, causing fracture and dislocation of the parts. The deformities that result from abscesses of the nasal septum, in which there is a destruction of the sesamoid cartilages which support the central portion of the nose, giving it the appearance of having been struck over the bridge with a small, round, or angular body—a poker, for instance—are also to be classed in this variety.

As I pointed out in my article on the correction of pugnose deformity, the beauty of the nose depends almost entirely upon its symmetry, so long as the disproportionate relations between the size of the nose and the size of the face are not too great. In correcting deformities of the nose, then, we have to study the symmetry and the relations of the different portions of

[1] Read before the Medical Society of the State of New York, January 26, 1897.

the nose to one another, rather than its symmetrical relation to the face. The nose which is originally proportionate to the face will, if deformed by the loss or displacement of tissues of any portion, appear very unsightly; while the same nose, if made one or two sizes smaller, will have a more or less handsome appearance if the proportionate relations of its parts are made perfectly symmetrical. Therefore in the correction of deformities of the nose, it is symmetry and not size that is to be considered. In this way it can be readily seen that the causes and conditions of depressed and saddleback noses are so various that the operations required for the correction of these deformities must be equally varied. No two cases will be found exactly alike or requiring the same operation. I cannot better make clear the manner in which these operations are performed than by describing different illustrative cases.

Case I. (congenital flattening of the end of the nose).—A young man from Cleveland, Ohio, aged eighteen years, was referred to me by his family physician for the correction of a deformity and flattened condition of the end of the nose, which was congenital, or at any rate had existed from infancy. This deformity of the nose was so conspicuous that people on the street and elsewhere would frequently turn to observe him. This was so annoying to him that he would rarely mingle in society, and he shunned people as much as possible. In this case the anterior and superior portion of the triangular cartilage was missing, and the flattening of the end of the nose and the consequent lateral bulging of the alæ gave it the appearance of a frog-shaped nose. Besides this, the frænum of the nose was attached so low down on the lip as to cause the end of the nose to slant backward, and the nostrils to stand prominently open, aided by the upward tilt of the end of the nose.

To correct this deformity it was necessary to adopt a special plan of operation in order to raise the end of the nose instead of depressing it, as in the case of pugnose and sometimes when the central portion of the nose alone is depressed. In order to reduce the width of the nose and to remove the flattened appearance, sufficient tissue was taken from the interior of the alæ to form a flap, which was carried upward and held in place under the skin at the tip of the nose. It required two operations at different times to accomplish this. In order still further to raise the point of the nose, the frænum was lengthened and its attachment set backward on the upper lip. This was done by cutting through the anterior column of the frænum on a line with the upper lip, then carrying the incision upward about half the length of the frænum and then backward, forming a stair, and then upward to a distance equal to the length of the first horizontal incision through the frænum, so that the lower end of the frænum would fit into the second stair, so to speak. The lower end of the frænum was then set into this second stair, and carefully stitched there. The skin on each side of the lower end of the frænum from which the anterior column had been removed was then raised and the edges were drawn together in front of this denuded surface, so that on healing no perceptible scar was left. Two or three minor operations were required to complete the work.

The result in this case is shown by the illustrations (Figs. 1 and 2), which are reproduced from photographs taken before and after the operations. So symmetrical and perfect was the nose that those acquainted with the young man would not suspect any deformity had ever existed.

A case of a depressed or flattened condition of the end of the nose from infancy similar to the above case, in a girl sixteen years old, I reported in a paper read before the American Laryngological Association in 1892, on "The Correction of Deformities of the Nose Resulting from Abscess of the Nasal Septum."[1] In this case the entire triangular cartilage was destroyed by what the history of the case would indicate to have been an abscess, the result of an injury, and the operations required for the correction of the deformity were very similar to the internal-flap operation in the case just mentioned. Illustrations showing the nose both before and after the operation are to be found in the article referred to.

Fig. 1.

Case III. (depressed bridge from an injury).—Mr. E——, aged nineteen, was referred to me, September, 1895, for the correction of a marked saddleback deformity of his nose, which had resulted from being struck over the nose with a baseball club four years before. On examination it was found that the nasal bones had been fractured, and the upper portion of the alæ of the nose and the sesamoid cartilages were driven upward and inward, and the sides of the nose bulged somewhat outward, giving to the centre of the nose a depressed and flattened appearance, as shown in Fig. 3. A large perpendicular ridge on the right side of the septum at the osseo-cartilaginous junction was also produced by the injury. This flattened condition of the centre of the nose gave to the end of the nose the appearance of being unduly prominent. None of the tissues, however, had been destroyed, but simply displaced from their normal position by external force.

In this case the indications were to use the displaced tissues for filling in the depressed portion, so as to give to the nose a shapely appearance. The displaced tissues found on the sides of the nose were restored to the top of the nose by raising the skin from the dorsum through an incision made from the interior of the nostril, and turning the flaps made by this displaced tissue upward to fill in the depression in the centre of the nose. This was completed by a flap made of the displaced cartilaginous tissue, constituting the ridge on the right side of the septum. In order to get this latter flap to the desired place on the dorsum of the nose, it was necessary to turn the flap twice to reach the spot. This was done by turning it and allowing the upturned end to become attached sufficiently to

Fig. 2.

[1] New York Medical Journal, 1893, vol. lvii., p. 319.

supply it with nutriment. The other end was then cut away and again turned upward. When the farther end had again become firmly attached, the lower end was

Fig. 3.

Fig. 4.

cut away and turned into place, which completed the filling of the tip of the nose very handsomely. The end of the nose still projected slightly above the line of the dorsum. This was lowered by removing sufficient of the tissue (in the manner of correcting pug-nose deformities) to bring it down on a line with the dorsum of the nose, making the nose perfectly symmetrical, as shown in Fig. 4. The nose was then held in place for a considerable period by an external form, until the parts were thoroughly healed, and remained in that position after the form was removed.

The appearance of the nose before and after the operation is illustrated by these enlarged photographs, which indicate the result more clearly than any description could do.

Case IV. (a saddleback or depressed nose, the result of an injury).—A young man, nineteen years of age, from Syracuse, N. Y., was referred to me by his medical adviser, June 10, 1895. When two years of age this patient fell from a table, striking on his nose and breaking it badly. The nose was very much swollen for two or three weeks, although little attention was paid to it. After the swelling subsided the nose began to grow very much depressed in the centre, a condition commonly termed saddlenose. As he arrived at maturity the deformity became more pronounced. The bridge and central portion of the nose were depressed and flattened, while the end was apparently much enlarged, giving the nose an unsightly appearance.

Fig. 5.

The operation for the correction of the deformity in this case consisted in lifting the skin from the dorsum of the nose, dissecting flaps from the redundant tissue of the end of the nose, including in the flaps a portion of the redundant cartilage, carrying these flaps along backward and placing them in position so as to fill the depressed portion of the dorsum of the nose. These flaps were held in position by pins and also by a retentive apparatus fitted to the dorsum of the nose. In this case, after the bridge of the nose was rendered comparatively straight, the end of the nose was still too large to make the nose symmetrical throughout. This enlargement of the end of the nose was reduced by removing sufficient of the redundant tissues, and the elasticity of the cartilaginous portion of the alæ near the top was overcome by free incisions made through the cartilage subcutaneously. The nose was then moulded to the desired shape by a form placed on the top of the nose, giving it the exact shape desired, and worn until the parts were healed and had become thoroughly fixed in the desired position. Figs. 5 and 6 illustrate the appearance of the nose before and after the operation.

Case V. (a saddleback nose, the result of an abscess of the septum).—A young man, aged twenty, from Hilliards, Mich., was referred to me, March 16, 1894, for the correction of a deformed nose. Four years before he had had an abscess in his nose, evidently an abscess of the septum, following an alveolar abscess about the incisor teeth. During the time that the nose was greatly swollen and the interior completely blocked up, the physician in attendance opened the swelling inside the nose and considerable offensive matter escaped. As soon as the inflammatory condition subsided, it was observed that the top of the nose began to drop in, so that the nose became very much flattened and depressed. In this case the abscess of the septum was more than an ordinary one, which usually destroys only the sesamoid cartilages on the top of the nose at the junction of the ala with the nasal bones. In this instance not only the sesamoid bones but a portion of the osseous and cartilaginous septum were destroyed, allowing the central border of the nasal bones to sink in, leaving the outer border of the bones unduly prominent.

Fig. 6.

In order to raise the centre of the depressed nasal bone, I raised the skin from the bones on both sides, making the incision from the inside of the nostril. Through this opening I introduced one blade of a pair of strong forceps, and with the other blade inside the nose I fractured the depressed portion and raised it up so as to make the external contour of this portion of the nose symmetrical, and held it there with a specially devised retentive apparatus, placed in the interior of the nose and resting on its floor. In the interior of the nose there was considerable displacement of tissues as a result of the abscess. The tissue was raised in the form of a flap and turned upward, and held in position by the aid of pins and a clamp on the top of the nose. The size of the end of the nose was reduced by removing a part of the tissues in the form of a flap, and turning it backward so as to fill in the gap left by the destroyed sesamoid cartilages. The cartilage of the ala was then, as in the previous case, cut through subcutaneously in three or four places, and a form was employed to hold the nose in the desired shape until the tissue became firm and permanently healed.

In this case four operations and much careful attention were required to complete the work, the result of which is shown in the illustrations (Figs. 7 and 8),

reproduced from photographs taken before and after the operations were performed.

Case VII. (a saddleback nose, the result of an injury during childhood).—Mr. C——, aged twenty, a student in Cornell University, was referred to me, August, 1895, for the correction of his unusually deformed nose. When a child he was accidentally dropped by a nurse, falling on his nose. But little attention was paid to it, although the nose was considerably swollen. As the child grew older it was noticed that the nose began to be deformed, and by the time the boy reached puberty the nose presented a very ugly appearance. The centre was depressed, and the end, which was disproportionately large, was turned very much to the left, giving to the whole nose a sort of twisted and distorted appearance. On examination the central portion of the nose was also found to be much flattened and the sides were more or less bulging. The lower portion of the nasal bones was turned inward, and the sesamoid cartilages were also so much lowered that it gave the nose the appearance of having been struck across the centre and broken by some round body. The turning of the end of the nose was due to a marked deflection to the left of the cartilaginous portion of the septum. The anterior part of the osseous portion of the septum was deflected to the right.

Fig. 7.

The process for correcting this deformity was by no means a simple one. It was first necessary to straighten the septum and put the nose in a straight line. This was done by the plan which I have adopted in similar cases and have already described.[1]

Fig. 8.

When this was completed the nose was brought up in a median line, and held there by an intranasal plug and retentive apparatus. The central depressed portion of the nose was filled in with flaps taken from the redundant and displaced tissue on the sides of the nose, and turned and fitted into the depressed portion. There was, however, not sufficient tissue to be had in this region to bring the central portion of the nose up on a straight line with the end of the nose, because the latter was unduly developed. This difficulty was met by removing a sufficient amount of the redundant tissue from the end of the nose to bring it down on a line with the central portion of the nose. The nose was then put in shape and held there by an external form until it was completely healed, so that the nose retained a symmetrical shape after all support was removed.

The exceedingly satisfactory result in this case was evident from the delight of the father on the return of his son to his home in the West. He afterward wrote me a very gratifying letter, expressing his appreciation of the result of the operation. The success of the operation is readily seen from the enlarged photographs which I show you (Figs. 9 and 10), representing the changes which took place in the appearance, not only of the young man's nose, but of his facial expression as well.

Fig. 9.

Case VI. (a crooked and depressed condition of one side of the nose from fracture and lateral displacement of the nasal bones and septum). — Miss B——, of New York, was by her medical adviser referred to me for the correction of a deformity of the nose, which resulted from being thrown from a carriage and striking on the nose and fracturing it, ten years before. She was so ill for a short time after that several complications were feared, and in consequence the nose was allowed to go uncared for. As a result of the fracture the right nasal bone was depressed and the left one displaced outward, making the nose very crooked, and producing the condition which would be termed by a blacksmith "an offset" in the middle of the nose, as shown in Fig. 11.

The condition of the nose was such that the refracturing of the bone and lifting the nasal bone on the right side and depressing the one on the left side were not advisable. The only resource left was a plastic operation. The skin from the dorsum of the nose was accordingly raised, and the bulging portion of the left nasal bone was carefully sawed off, leaving as much of the soft parts attached to it as possible. It was then carried over the bridge of the nose and placed in position on the right side over the depressed bone, completely filling the depression. Union of this flap with the bone was encouraged by denuding the bone of periosteum at this point before the flap was placed in position. It was carefully held in position until united and thoroughly fixed. The two

Fig. 10.

[1] "The Treatment of Deviations of the Nasal Septum," New York Medical Journal, 1894, vol. lix., p. 424.

sides of the upper portion of the nose were then perfectly symmetrical. The lower portion of the nose was distorted to the left by a deviation of the cartilaginous portion of the septum. This deformity of the septum was corrected, making the nose perfectly straight. A third operation was found necessary to remove a redundency of the ala on the left side. The nose was then carefully held in position by a form adapted to it until it had become thoroughly fixed in the desired shape, leaving the nose perfectly symmetrical, as shown in Fig. 12, much to the delight of the patient.

Fig. 11.

As I stated at the beginning of the paper, no two cases of nasal deformity are exactly alike or require exactly the same operation, for, no matter how much they appear alike externally, the conditions will be sufficiently varied to require a special study of each case before any operative procedures should be undertaken, as illustrated in the cases I have detailed to you.

There are three conditions which must be observed in order to insure success in these operations: (1) In the first place, although it is hardly necessary so to state, the utmost antiseptic and aseptic precautions must be adopted, for if suppuration in the wound should take place engrafted tissues would be destroyed, and not only the object of the operation be defeated, but the deformity of the nose would be increased thereby. (2) In the next place, the plan of the operation must be carefully studied in order that the tissues at our disposal may be utilized to the best advantage. (3) In the third place, great care and careful attention subsequent to the operation, which are as important as the operation itself, are required, for, no matter how well directed the operation may be, the object cannot be attained unless scrupulous attention is paid to the healing process.

These operations on the nose, therefore, are not attended with the immediately brilliant results possible in many operations performed on other parts of the body, which can be completed at one time, the wound requiring only to be maintained aseptic until the cure is complete. On the contrary, these operations on the nose require frequent and most careful attention. The parts must not only be held in place by retentive appliances, but the shape of the form of the dressing must often be changed from day to day as the swelling subsides and the union of parts takes place. It may be necessary to add a little internal or external pressure here and remove a little there until the fixation of the tissue is complete.

Fig. 12.

Frequently the principal or main operation must be supplemented by minor operations for the correction of slight defects. An unduly prominent portion may require lowering, a depressed part may require raising, and so on until the work is completed. We might say in these cases that eternal vigilance is the price of a perfect nose.

When considering the vast change made in the appearance of the nose by a slight alteration or departure from its symmetry, and the wondrous changes made in the facial appearance and physiognomy of the person by a disfigurement of the nose, it is readily seen why the nose is regarded as one of the most distinguishing racial characteristics.

THE TECHNIQUE OF STAINING BLOOD FOR MICROSCOPICAL EXAMINATION WITH EHRLICH'S TRI-ACID SOLUTION.

By ARTHUR JORDAN, M.D.,

RICHMOND, VA.,

ADJUNCT PROFESSOR OF HYGIENE AND SKIN DISEASES, UNIVERSITY COLLEGE OF MEDICINE; LECTURER ON HYGIENIC DERMATOLOGY AT THE WOMAN'S COLLEGE; LECTURER ON HYGIENE AT THE RETREAT FOR THE SICK, ETC.

On November 26, 1895, I read a paper before the Richmond Academy of Medicine and Surgery entitled "The Importance of a Microscopical Examination of the Blood in Disease—with Lobar Pneumonia in Illustration."[1] Since that time I have steadily urged the many decided advantages to be derived from this means of diagnosis, not so much in the ordinary "blood diseases," although it is very useful here, but more especially in such general diseases as pneumonia, tuberculosis, typhoid fever, malign growths, etc.

The real worth, apart from its diagnostic value, of this method of investigating the corpuscular elements of a fluid of the body which must necessarily be more or less susceptible to any pathological changes which may be going on in any of the diseased organs, is the ease with which it may be employed by the profession at large and the decided information that may be gained therefrom as the patient passes through the successive stages of his disease. After all, nothing recommends a technique more favorably than its simplicity and ease of application. This is what I claim for Ehrlich's tri-acid stain, used as I am in the habit of employing it.

Inasmuch as my object in explaining my technique will be to urge the practising physician to use it in his routine work, I shall give the procedure in detail, stating sincerely that if he is not successful it is due to a want of attention to the minutiæ. The various steps of my technique may be included under the following six headings, viz.:

First. The cleansing of the cover glass.
Second. The preparation of the lobe of the ear.
Third. The securing of the specimen.
Fourth. Allowing it to dry in the air.
Fifth. The fixation of the specimen.
Sixth. The staining of the same.

First, as to the cleansing of the cover glasses. I usually prepare enough to make from fifteen to twenty specimens, *i.e.*, from thirty to forty covers. I wash them first with ether and then with alcohol, using for this purpose an old clean linen handkerchief. After they have been well cleansed in this way they are put upon a clean piece of writing-paper or a prescription blank. Care should be taken not to handle them with the fingers after they have been made ready for use. If this precaution is neglected, it will be found that the staining fluid will not spread evenly and uniformly over them.

Second. I usually prefer the lobe of the ear, especially when my patient is a woman. It is less sensitive than are the fingers, its integument is thinner, and the patient is spared the sight of blood. The lobe or lobule is first thoroughly cleaned with ether and then

[1] Virginia Medical Monthly, vol. xxii., No. 10, p. 1,037.

with alcohol. I use considerable friction with the old handkerchief during this process, with the view of causing a local hyperæmia. The lobule is then pricked about its centre, sufficiently deep, with an ordinary pocket lancet, made aseptic by passing it through the flame of a Bunsen burner or that of an alcohol lamp several times, to cause the blood to well up and form a good-sized drop. No pressure should be used to make an increase in the flow of the blood, for such a procedure causes the corpuscles to become irregular in their shape. Of course the index finger can be prepared in the way I have indicated and the blood obtained from it, constriction having been applied to its proximal end prior to the puncture.

Now we are ready to secure the specimen of blood. A cover glass is carried from the paper to the lobe of the ear by means of a small pair of tweezers. It is placed lightly upon the drop of blood, and when withdrawn carries with it a considerable portion of the blood. This cover glass is then grasped diagonally on its corners between the thumb and index finger of the operator's left hand, with the drop of blood upward. A second cover glass is then placed upon the first with the tweezers in such away that it is square to the thumb and index finger. This arrangement allows them to be drawn apart easily. They are then pressed together between the thumb and index finger of the operator's right hand. Finally they are to be drawn apart by a rapid sliding motion from left to right, not by raising the upper one from the lower. The other specimens are obtained in like manner. To secure a good specimen by this plan will necessitate both care and practice, but with a little patience any one can secure a fairly good one in a very short time. It is at this point of the process that an artificial poikilocytosis is often produced. This should be borne in mind and taken into consideration in examining the cover. It is not very marked at any time, and the operator will find that it disappears in direct proportion as he gains experience and dexterity in manipulating the covers. The blood-stained sides of the cover glasses are turned up, placed upon the paper, and allowed to dry in the air. The time required for this is not long. By the time that all the covers have been smeared with blood, those made in the beginning will be quite ready for the fixation process. Working moderately fast, no time may be lost from the beginning of securing the specimen until it is ready for the microscope. This part of the technique will have consumed from three to five minutes.

The specimen may be fixed in either of two ways, both of which have given me uniformly good results. First, by equal parts of ether and alcohol. If the operator has the time and can wait on this method, I believe that it will give as good results as that obtained by heat. I allow the specimens to remain in this mixture of alcohol and ether from twenty to thirty minutes. This length of time I have found to be quite sufficient. However, some authors advise that they be left in the mixture for two hours and upward. I have never found it necessary to take so long a time, and I am of the opinion that a half-hour is enough for all practical purposes. It might be well to add that, the limits of time having been given as a guide, the operator may investigate the matter for himself. The second method is that by heat. This method has rapidity to recommend it, and indeed the material difference between the two methods, as I have come to observe, is a question of time, the former requiring more than the latter. I generally use a small oven about six inches square. It is very simple in structure and can be easily and cheaply made. It is made of copper and has a central shelf in its interior, upon which are placed the covers. At the back there is attached a metal ring, fitted with a thumb screw, which, sliding upon a rod, intended to support the oven, enables the operator to secure any desired distance from the flame. The thermometer is attached to the top. The door may be either sliding or hinged. The heat may be furnished by an alcohol lamp or by a Bunsen burner. The heat is gradually increased until the temperature reaches 120° C. (248° F.) and remains there for a few moments. The temperature must not pass beyond 120° C. After allowing the ether-and-alcohol mixture to evaporate from the covers or letting them gradually cool, according to which method has been used, they are then ready to be stained. Ehrlich's tri-acid staining fluid may be prepared according to the following formulæ:

Saturated watery solution of orange G.....	125
Concentrated watery solution of acid fuchsin, containing a twenty-per-cent. solution of alcohol	125
These are mixed and then is added :	
Absolute alcohol.....	75
Saturated watery solution of methyl green .	125

Or,

Saturated solution of orange G	50 cm.
Saturated solution of acid fuchsin.....	60 "
Saturated solution of methyl green	75 "
Distilled water	100 "
Absolute alcohol.....	50 "
Glycerin.....	15 "

These several ingredients are to be thoroughly mixed and allowed to stand fourteen days before using. A thick sediment forms at the bottom of the bottle, which should not be disturbed or shaken.

A few words about making the saturated solutions of the three coloring materials are necessary. I prefer using Grübler's stains, for they give me better results. Three four-ounce bottles are filled with distilled water and a small quantity of orange G. is put in bottle No. 1, a small quantity of acid fuchsin in No. 2, and a small quantity of methyl green in No. 3. As soon as the water has taken up the stain, an additional quantity of staining material is added, and this process is continued until a deposit begins to form upon the bottom of the bottles, indicating that the solution has become saturated. After they have become saturated they are allowed to stand for four days, and the solutions are not to be filtered. When the tri-acid solution is to be made, care must be used not to shake bottles Nos. 1, 2, and 3. Close attention to small details will be properly rewarded.

When used, this preparation stains the hæmoglobin yellow, the nuclei green, the eosinophile granulations deep dark gray, the neutrophile granulations intense violet. The hæmoglobin is colored by the orange G., the acidophile granulations by the acid fuchsin, the nuclei by the methyl green, and the neutrophile granulations by the acid fuchsin and methyl green. From this it may be seen that if any particular part of the cell is not stained sufficiently that special stain can be increased. The quantity of staining fluid made by the last formula will last an ordinary lifetime, for it does not become impaired by age.

The covers are stained with this fluid by passing over them a glass rod which has been previously passed into the centre of the bottle. After allowing them to dry they may be examined either dry or mounted in balsam. I prefer the former method, but believe that the beginner will secure better results by mounting in balsam. I have used this method of staining for two years, and find that it gives better results than any other which I have tried. From the time that the first specimen is begun, until it is ready for the microscope, fixation by heat will require from ten to fifteen minutes.

In concluding it may be well to observe that blood

mounted in this way may be sent by mail or express to a hæmatologist for examination under the microscope, without injuring the cells.

210 North Sixth Street.

THE CREPITANT OR VESICULAR RÂLE AN INTERPLEURAL SOUND AND NOT CAUSED IN THE PULMONARY TISSUE.[1]

By LOUIS H. JONES, M.D.,

Atlanta, Ga.

Even among the most intelligent and truthful of our patients, we can often attach but little importance to subjective symptoms; we are forced to rely for a correct knowledge and accurate diagnosis of a case upon such signs as we can elicit by a physical examination. If we are to draw correct conclusions, our methods must be accurate, our deductions must be logical, they must stand the test of careful scientific analysis, they must conform to known physical laws. Believing that, in our text-books on physical diagnosis and in the lectures of a majority of teachers of this branch, certain sounds heard in connection with diseases of the lungs are misinterpreted, I have thought it well to lay before the association some of the views held by a most distinguished physician now dead, and to add to his testimony the results of my own limited experience. Particularly do I desire to do this in regard to the origin, seat, and cause of what is known as the crepitant or vesicular râle. First let us see what the recognized authorities say:

Da Costa, in speaking of the vesicular or crepitant râle, says: "Its name indicates its seat. It is caused by agitation of fluid in the air cells or in the finest extremities of the bronchial tubes; or, to adopt a view now held by many, by the forcing open during inspiration of the air cells agglutinated by exuded lymph. The first stage of pneumonia is the state in which this râle is mostly engendered." Again, in speaking of pleural friction, he says: "It may be so much like crepitation that even long practice in auscultation will not enable us to determine at once whether the fine sounds we hear are the friction of a roughened pleura or the vesicular râles of an inflamed lung."

Loomis says of crepitant râles: "There are several views as to the production of these sounds: that they are due to the bubbling of air through a liquid in the pulmonary vesicles and terminal bronchioles; that at the end of expiration a viscid secretion glues the walls of the vesicles together, and their separation on inspiration gives rise to the crackling sounds; and that they are produced in the pleuræ independently of the pulmonary parenchyma."

Osler, in speaking of pneumonia, says: "Very early there is heard at the end of inspiration the fine crepitant râle, a series of minute cracklings heard close to the ear and perhaps not audible until a full breath is drawn. Whether this is a fine pleural crepitus, or is produced in the air cells and finer bronchi, is an open question." In speaking of pleurisy, Olser says: "There is another pleural friction sound which closely resembles and is scarcely to be distinguished from the fine crackling crepitus of pneumonia. This may be heard at the commencement of the disease, and also, as pointed out by McDonell, Sr., of Montreal, when the fluid has receded and the pleural layers have come together again."

Page says: "Crepitant râles are made in the air cells, and are the only vesicular râles that exist. They are very fine, uniform crackling râles, heard only at the (tip) end of inspiration, and are unchanged by coughing. They are caused by the forcible separation of agglutinated cell walls, as in the first stage of lobar pneumonia, or agitation of thin fluid in the air cells, as in pulmonary œdema. They are heard also in the third or resolving stage of pneumonia, when it is known as the *râle redux*, or râle that has returned or come back."

These expressions of opinion from the men who have stood at the top as diagnosticians for the past quarter of a century may, I think, be fairly taken as an expression of the most generally accepted belief concerning the cause and location of the crepitant râle; and, while the opinions quoted show that most of the authorities admit the possibility and even assert the existence during pleurisy of an interpleural sound not to be distinguished from the crepitant râle, yet they believe and teach that what is called the crepitant râle is a sound produced in the vesicles, and that it is indicative of a diseased condition of the pulmonary parenchyma.

Dr. James R. Leaming, in papers read before the New York Academy of Medicine more than twenty years ago, made the assertion that both the crepitant and the subcrepitant râles were sounds which had their origin in the pleural and not in the pulmonary tissues. This position he maintained most ably, and claimed that he had repeatedly demonstrated its correctness by post-mortem examinations. Early in my practice I read Leaming's work on the heart and lungs, and was so impressed with his clear and logical reasoning that I began questioning the correctness of what I had been taught as a medical student, and, as I had opportunity, I attempted to verify clinically his position.

Let us first look a moment at the structure of the lungs and the mechanism of respiration. The lungs are made up of tubes and of air cells or vesicles, the tubular or connective portion consisting of tubes which gradually grow smaller and smaller until they become microscopic and terminate in the air cells. The cellular portion of the lung is capable of great distention, and is always completely filled with air. The volume of this air may be augmented by the expansion of the cells; it may be diminished by their contraction; but the cells must always be full, they cannot be alternately full and empty. If partly filled with liquid, then air must occupy the remaining space. Were this not true, collapse of the lungs would inevitably occur, for the lung is always on the stretch, pulling, it is computed, with an elastic force of one-fourth to one pound to the square inch, and thus tending to separate the pleuræ and close the air cells; but, on the other hand, the air pressure on the interior of the lungs—that is, in the air cells—is fifteen pounds to the square inch. Now, that such a discrepany in pressure can be overcome and the cell closed by their elastic force is inconceivable; it is a physical impossibility. The lung is constantly being forcibly pressed by atmospheric pressure against the inside of the chest wall, thus completely filling the cavity of the thorax, whether in inspiration or expiration. If the cell walls come together, the parietal and visceral pleuræ must separate. What then becomes of the theory of the alternate separation and apposition of the cell walls covered with an exuded lymph?

Now let us look at the other theory, viz., that the crepitant râle is a sound caused by the bubbling of air through a liquid in the air cells or terminal bronchioles. In order that air passing through a liquid should cause bubbling, it must move with some degree of rapidity; there must be motion of the air in mass. Physiologists tell us that the air which is in contact with the respiratory epithelium is not sucked in and out with each inspiration, but that the air cells are constantly filled with residual air, which constitutes about eight-tenths of the total air capacity of the lungs.

[1] Read before the Medical Association of Georgia, at Macon, Ga., April, 1897.

The tidal air, entering the larger bronchi with each inspiration, meets in the bronchioles the residual air, and its current is checked, motion in mass ceases, and molecular motion takes its place; a rapid diffusion of gases occurs, the tidal air yielding up its oxygen and getting in exchange the carbon dioxide of the residual air. The conditions for such diffusion are well fulfilled in the lungs, and added to this we have the red corpuscles exerting their eager affinity for the oxygen, and thus hastening the change. We all know that under such conditions diffusion will be rapid, yet it will be only a molecular motion. Can we conceive it otherwise? Could it be possible that the tidal air could enter microscopic tubes and cells, overcoming the friction and displacing in mass a quantity of residual air, eight to ten times its own volume? Is not such a supposition opposed to all physical laws—is it not at variance with all physiology? Must we not abandon the idea of air currents in the vesicles causing bursting of bubbles? Was not the theory set up to meet supposed conditions rather than to accord with known laws?

Pathology teaches us that early in pneumonia there is an exudation into the air cells; experience has shown us that early in the same disease there is usually heard the crepitant râle; thus the two things came to be associated together without careful investigation and thought. Unquestionably there are cases of pneumonia in which the crepitant râle is absent during the stage of exudation, but is clearly and unmistakably present after complete consolidation has occurred. If this be true, the seat of the râle cannot be in the vesicles.

Time will not allow me to go into a detailed report of cases, but within the last few months I have seen two cases of pneumonia, cases classical in every respect save in the absence of the crepitant râle until after complete consolidation was present. The high temperature, cough, rusty sputa, complete consolidation, tubular breathing, were all present, yet no crepitant râle could be detected in the early stages; but after consolidation the so-called vesicular râles were abundant. With the appearance of the râles both patients began to complain of pain, the pain corresponding in location with the area over which the râles could be most distinctly heard.

We well know that very few cases of pneumonia, or indeed of any serious lesion of the lungs, occur which are not accompanied by an involvement of the pleuræ. If then we reason, *post hoc ergo propter hoc*, have we not both in pneumonia and in pulmonary phthisis the same ground for locating the crepitant râle in the pleuræ that we have for placing it in the pulmonary parenchyma? But are not the physical conditions for the production of the sound under discussion present when we have inflamed pleural surfaces covered with fibrous exudation, moving the one over the other, constantly attempting to separate, yet ever being held together by atmospheric pressure?

The human ear can locate with great accuracy the distance of a sound. Osler says of the crepitant râle: "A series of minute cracklings close to the ear." This is always true of the sound under discussion; it lacks the element of distance. While not a loud sound, yet the ear placed in contact with the naked chest wall will recognize that it hears a sound which is immediately beneath the surface, and not produced deep down in the lung tissue. The ear takes cognizance of distance, just as a muscle distinguishes between a light and a heavy body.

Careful and oft-repeated physical examinations, together with post-mortems when possible, must determine the question under discussion. We appeal to the profession to make such investigation, and not to accept without question the teachings of the day.

Progress of Medical Science.

The Chemistry and Pathology of Gout.—At the conclusion of the Goulstonian lectures recently delivered before the Royal College of Physicians and Surgeons of London, Luff (*Lancet*, April 17, 1897) announced the following propositions: (1) Uric acid is not normally present in the blood of man and other mammals, nor in the blood of birds. (2) This acid is normally produced only in the kidneys. (3) It is normally formed from urea, probably by conjugation of that substance with glycocin in the kidneys. (4) Uric acid is present in the blood in gout as the soluble sodium quadriurate. In its soluble form this is not a toxic agent. It deposits from the blood as sodium biurate, which acts passively and physically as a foreign body in the tissues or organs in which it is deposited. (5) The presence of uric acid in the blood in gout is due to its deficient excretion by the kidneys and to the subsequent absorption of the non-excreted portion into the blood from those organs. (6) Gout is probably always preceded by some affection of the kidneys, functional or organic, which interferes with the proper excretion of uric acid. The probable seat of the kidney affection giving rise to the gout is in the epithelium of the convoluted tubes. (7) In certain blood diseases and disorders accompanied by leucocytosis, uric acid is formed within the system from nuclein. Under such circumstances it passes at once into the blood and is rapidly eliminated by the kidneys. (8) The solubility of uric acid in the blood is not affected by a diminished blood alkalinity produced by the addition of organic acids. (9) The deposition of sodium biurate is not accelerated by a diminution in the alkalinity of the blood. (10) An increased alkalinity of the blood does not increase the solubility of deposits of sodium biurate. (11) The saline constituents of vegetables exercise a remarkable inhibitory power over the decomposition of sodium quadriurate. (12) The solubility of sodium biurate in the blood is increased by the presence of the saline constituents of vegetables. (13) The solubility of sodium biurate in the blood is diminished by the presence of the saline constituents of meat. (14) The gout-inducing properties of certain wines are not due to their acidity. Probably these owe their action to the effect they exercise on the metabolism of the liver.

Pulmonary Tuberculosis Communicated from Husband to Wife.—Murrell (*Lancet*, April 10, 1897, p. 1,018) reports the case of a woman, thirty-six years old, who came under observation with pulmonary tuberculosis. Inquiry elicited the fact that her family history was good and free from suspicion of tuberculosis. Her husband, when she married him, was apparently healthy, but his father and a sister had died from pulmonary tuberculosis. After a time he developed cough, spat blood, and ultimately died from pulmonary tuberculosis. During the last seven months of his life he was too weak to go out, and his wife nursed him incessantly. They had only one small room and the fire was kept burning day and night. The man expectorated a good deal and no directions were given as to the use of antiseptics. Soon after his death the wife noticed that she had a bad cough, and when she came under observation it was found that she had cavernous breathing, with whispering pectoriloquy at the apex of the right lung, and dulness and crepitation at the left. She stated that she was no worse off in consequence of her husband's death, but that, on the contrary, her means had improved, as during her husband's illness she had to keep him. As Murrell points out, this case is of no particular interest in

itself, but it becomes so when taken in conjunction with similar cases recorded in literature, as marking the change of opinion respecting the contagiousness of tuberculosis which has taken place. In the past such cases were regarded with suspicion and their publication excited hostile criticism; now they have become so common as to excite but little comment. Dr. Hermann Weber has given details of thirty-nine wives who became infected from marrying tuberculous husbands, and in several instances the husband infected more than one wife. The reason that the husband infects the wife more frequently than the wife the husband resides in the fact that when the husband is ill the wife nurses him, but when the wife is ill the husband, from the increased demands on his resources, has to pay closer attention to business and is less at home than usual.

Hereditary Contracted Kidney in Early Life.—Hellendall (*Archiv für Kinderheilkunde*, B. xxii., H. 1, 2, p. 61) makes the exceedingly interesting report of two children, dead at the ages of two years and six months respectively, and presenting characteristic lesions of interstitial nephritis with contracted kidneys. The father was healthy and was believed to be, with the mother, free from syphilis. The mother presented symptoms of chronic interstitial nephritis. Her mother and an aunt had died early in life with swelling of the feet, and one sister had died with dropsy. It is believed in the case of the children that the chronic nephritis was a primary process, and that it was probably of fœtal origin.

A Graphic Study of Tremor.—As the result of an extended study by graphic methods of tremor as observed under varying conditions of health and disease, Eshner (*Journal of Experimental Medicine*, vol. ii., No. 3, p. 301) expresses the conclusion that all muscular movements are made up of a series of elementary muscular contractions and relaxations in alternation, which may be appreciated as tremor in conditions of both health and disease. The differences between different tremors were found to be in degree rather than in kind, *i.e.*, no one form of tremor appeared to be distinctive of any one disease or group of diseases. No definite relation was found to exist between one form of tremor and any other. The frequency of movement was in inverse ratio to the amplitude, and *vice versa*. Habitual movements were performed with greater freedom from tremor than unusual movements. No material difference could be discerned between the movements of the two sides of the body, except in so far as related to habitual or unusual activity.

One-Sided Paradoxic Pulse with Inequality.—Gerhardt (*Berliner klinische Wochenschrift*, April 5, 1897, p. 285) has reported the case of a woman, sixty-nine years old, who had had measles in childhood, later gastric fever, two years before coming under observation pneumonia, and a year before influenza. For a long time there had been tremor of the left hand. Following an attack of vertigo succeeded by loss of consciousness, the right leg had been paralyzed. The pulse at the wrists was found to be irregular, and on the left much smaller than on the right. On simultaneous observation of the two sides during one minute the frequency upon the right was found to be 112, on the left 92. A second observation for half a minute the number was found to be 52 on the right, 42 on the left. There was no fever, but the respiratory frequency was 40 in the minute. Further investigation could not be pushed, on account of the sudden death of the patient a short time after she came under observation. Upon post-mortem examination, in addition to areas of softening in the optic thalamus and striate body in the left cerebral hemisphere, there were found recent fibrino-purulent pleurisy and pericarditis. Although the branches of the middle cerebral artery displayed thickening and atheroma, but slight changes of similar character were present in the aorta. The right subclavian artery had a diameter of 2 cm., the left a diameter of 0.8 cm.; the right carotid a diameter of 1.5 cm., the left a diameter of 1.4 cm. The pericarditis is held responsible for the paradoxic pulse, the narrowing of the left subclavian artery for the inequality. Comparative observations upon healthy persons showed that when pressure upon the vessels of the arm was made there was no change in pulse frequency when ordinary breathing was maintained, but when respiration was accelerated some of the pulsations were lost on the side on which the vessels were compressed.

Hæmoptysis.—Dr. J. M. Cotton (*Canadian Practitioner*, January, 1897), from his own clinical experience and knowledge of pathology, considers the following as the chief causes of hæmoptysis: 1. Hemorrhage from the pulmonary artery or its radicles. (*a*) Rupture of wound of the lung from external violence. (*b*) Active hyperæmia of the lungs—inflammatory, vicarious, or induced by violent effort or excitement. The active hyperæmia may be primary as regards the lungs, or may supervene or be attendant upon disease already present in them. (*c*) Mechanical hyperæmia of the lungs, secondary to heart disease or embolism of one of the pulmonary branches, or to pressure from tumors, such as enlarged bronchial glands. (*d*) Necrotic division of vessels in the course of softening of tuberculous or other consolidations in destructive lung diseases—phthisis, tuberculosis, cancer. (*e*) Aneurismal dilatation or simple erosion of branches of the pulmonary artery, exposed in the course of excavation of the lung, or ulceration of the bronchial mucous membrane. (*f*) Primary atheroma of the pulmonary artery within the lung. 2. Hemorrhage from the bronchial capillaries. Capillary hemorrhage from the bronchial mucous membrane. 3. Hemorrhage from the aorta or one of its great branches. Aneurism rupturing through the lung or into a bronchus.

Direct Intra-Abdominal Finger Compression of the Common Iliac Artery during Amputation at the Hip-Joint—McBurney (*Annals of Surgery*, May, 1897, p. 611) describes a method of hæmostasis that he has employed successfully in three cases of amputation at the hip-joint. First, as much blood as can by means of position or an elastic bandage be returned to the body from the limb to be amputated is so returned. Then an incision is made through the abdominal wall, about one and a half inches internal to the anterior spine of the ilium. Through this incision an assistant passes a finger and readily reaches and compresses the common iliac artery. In this way entire absence of blood current beyond the point of compression can be readily maintained throughout the course of the amputation. The operative field can be kept entirely free from bandage or appliance of every kind, asepsis is facilitated, and the amputation can be effected without other loss of blood than that which takes place from the vessels of the limb below the point of amputation. The method would seem to commend itself on account of its simplicity, its certainty, its aseptic character, and because it can be applied in cases in which the deeper tissues require to be severed at an unusually high level. The method has the further advantage that it permits identification and ligation of all of the smaller arteries in the stump: by lifting the finger for a fraction of a second a minute quantity of blood will escape and indicate the situation of the vessel.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 5, 1897.

THE ABUSES OF THE HOSPITAL PAY-SYSTEM.

It is quite evident as the outcome of the present discussion on the abuses of medical charity that, instead of a laudable desire on the part of the managers of the hospitals and dispensaries to agree upon a rational remedy for the evil, there is manifest a very strong disposition to fight for its continuance. At the bottom of this condition of things is the fact that the hospital and dispensary business is so much overdone that with many of the boards it is a mere struggle for existence against the demonstrated uselessness of existing at all. To pose as a worker for sweet charity is a coveted Christian privilege and a high social distinction. To the ambitiously benevolent man such aspirations are quite irresistible, and in order to realize them he is delighted to subscribe for a new hospital or a new dispensary, and figure as an executive on its managerial board. Naturally when he discovers, too late for a dignified retreat, that he has been misled as to the real necessity for his charity, he does all he can to defend himself and his position in the endeavor to demonstrate to the public that the scheme is a successful one. If the latter fails he fails. There are hundreds of such institutions throughout this and other countries that are managed solely on the principle of vanity of their managerial boards. Many of these drift in heavy debt every year for what are called running expenses, and have the effrontery to appeal for more public aid in consequence. The struggle for existence among the useless institutions begets a so-called generous rivalry in the race for donations, and thickens the air with the wing feathers of the charitable angels. Concerts, tea parties, theatrical performances, and church fairs, with the attendant extravagant demands upon the pockets of the well-disposed, complete the self-evident imposition, until truly charitable giving becomes an illusion and the purchase of mailed tickets becomes a snare. Most if not all of this is the tangible evidence of the present methods of bolstering many of the schemes which, save for their association with the name of charity, would have an entirely different designation. The major part of the money thus obtained is spent in securing building-sites in fashionable districts and in the erection of unnecessarily imposing structures. In nine cases out of ten it is more building than hospital—more empty show than real work. Examples of such miscalculation are to be seen in every city. We have several such in New York. With the appearance of great wealth, they are always pleading greater poverty than the veriest beggar who vainly clamors at their gates. They are even too poor to admit any but those who can pay. What can be said in proof of the actual need of a so-called charitable institution, with a two-million plant, whose wards are never full and whose expenses swell the yearly deficits from sixty to ninety thousand dollars? Another large institution lately completed, and also in the centre of a choice district, begs for money and for patients almost in the same breath. It is not necessary to multiply such examples of what is forced and useless medical charity, nor to prove one of the main reasons for its abuse.

If the deserving poor were the sole recipients of such bounties, there would be excuses for any means to such an end. The poor, however, are just as much cheated of their rights in the matter as is the majority of the benefactors who so innocently contribute to the charitable funds. "Here is a penny for the missionaries," said a subscriber, "and here is a dollar to pay the freight." The fellow at the other end of the line is taught by the interested distributor of the funds to be satisfied with what he can get.

When it is considered how much the number of unnecessary hospitals and dispensaries has to do with the existing abuse of medical charity, it is safe to say, on the basis of a calculation of the proportion of poor in any community that needs free medical treatment, that if half the hospitals and two-thirds of the dispensaries ceased to exist no really indigent person would suffer. Such a reduction in the number of institutions would possibly restrict the remainder to the working basis of charity as it should be—pure and simple. This would make the ideal charity hospital or free dispensary an institution that treated the poor and needy only. Approximatively speaking the perfect type of such charity is that afforded by institutions maintained by public tax and managed by municipal officers. Very few if any of the institutions controlled by private corporations are above bidding for pay patients. This is the natural penalty of claiming to be what they are not, and brings with it the temptation to do evil that good may possibly come. Hence there is generally a disposition to cater to the pay element in the wards and private rooms, and make proper charity a secondary consideration. It is not so much a question how sick or needy a patient may be, but how much he can pay. There is, then, just as much abuse of charity in an ostensibly charitable institution in the treatment of a pay patient for money as there is in declining or refusing free treatment to a needy one. It is a false pretence, whichever way we view it. The abuse is the more pronounced in proportion as it is nearer the extreme ends of the line. It is money first and charity last. There is seldom a spare bed ready for a poor patient when it can be occupied by a pay patient. Thus it often happens that the sufferer who is most in need of hospital treatment stands an even chance of not obtaining it. It is a common experience when admission is sought for a really deserving or an uninter-

esting case to discover that the hospital either does not treat such patients or that all the available beds are occupied. The majority of these institutions claim all their privileges as private corporations with discretionary powers when they wish to, and refuse admission to charity patients, but when public donations are in order they are more than anxious to vaunt their charity in the hope of obtaining a suitable proportion of the hospital fund. In spite of their best efforts in an apparently laudable direction, they make a very poor showing and prove that for most of their patients they receive pay, thus demonstrating that they are not *bona-fide* charitable enterprises. To meet their current expenses they are compelled to fit up more private rooms and bid for business by establishing medical and surgical boarding-houses. Rooms and suites of rooms are hired at prices ranging from fifteen to fifty dollars per week, with nursing and attendance free, and with the probable payment of a small and voluntary fee to the physician or surgeon who may be on duty.

The doctors connected with these so-called charities, who are in reality the only ones who give their services to the poor, are the last to be considered, and in many instances are forced to perform the unnecessary and extra work for the little or nothing which may be spared by the patient after the hospital bill is paid.

Not only is the medical staff swindled by this shameful diversion of what should be strictly legitimate professional fees, but the rank and file of the profession are openly robbed of their rightful incomes. If the staff complains it can resign, and the vacancies can be supplied the next day. The pay patient is first seen by the superintendent, whose business it is to get the most for the rooms, and is simply told he can make any terms with the attending physician or surgeon he may choose, which practically means that he may or may not pay for medical services. Not many months ago one of the managers of a large hospital plant in this city, in a public address, openly advertised the superior claims of his institution by eulogizing the economy of the private-room system against the unnecessary extravagance of being treated at home by the ordinary medical attendant. It is impossible to resist the conviction that such hospitals are merely managed as monopolies, to the great and growing detriment of professional business. In every other kind of work those who help earn the money share in the profits. But why should the doctor get paid for his hospital labor, when he is so willing to work for nothing and to be kicked in the bargain?

THE SIGNIFICANCE OF PALATAL DEFORMITIES IN IDIOTS.

There is perhaps at the present time too much tendency to regard any anatomical deformity or deviation, however slight, from the normal type as a sign of degeneracy. The anatomical stigmata of the hard palate have been attracting attention of late. For nearly thirty years the dictum of Dr. Down that the V-shaped palate was an infallible characteristic of the idiot was accepted without question. Dr. Kingsley, an American dentist, was the first to doubt the accuracy of this theory. He examined two hundred patients at Randall's Island, and later went to Earlwood Asylum in England, where with Dr. Down he examined the palates of the inmates, and decided that they did not present more examples of deformity than those of ordinary individuals. Dr. Walter Channing, who last year read a paper on "The Significance of Palatal Deformities in Idiots," at the meeting of the Medico-Psychological Association of Great Britain, agrees in the main with these views. Dr. Channing has devoted much time to a consideration of the subject, and also in all cases takes accurate measurements. He has proved to his own satisfaction, as well as to that of many others, the fallacy of the belief that the palates of nearly all idiots are V-shaped. Dr. Channing says that "there are probably as many deviations from the ordinary type of palate with normal persons as with idiots," and gives the following as his conclusions:

1. Two-fifths of the palates of idiots are of fairly good shape.

2. Palates of normal individuals may be deformed.

3. In the idiot it is a difference in degree and not in kind.

4. In either case it shows irregular development anatomically.

5. Palates of average children and idiots under eight years of age probably do not in the majority of cases markedly differ.

6. There is no form of palate peculiar to idiocy.

7. The statement that a V-shaped or other variety of palate is a "stigma of degeneracy" remains to be proved.

Dr. Frederic Peterson differs widely from these views and says: "The deformed palate, to my mind, is one of the chief anatomical stigmata of degeneration."

He further says: "I may not be able to say what Dr. Amadéegoux did of the ear, 'Show me your ear and I will tell you who you are, whence you came, and where you go;' but I will say, 'Show me your palate and I will probably be able to tell whether you belong to the great class tainted by heredity, comprising many insane, imbecile, feeble-minded, criminal, eccentric, epileptic, hysterical, or neurasthenic individuals." Statistics bearing on the classification of palates are unreliable and confusing. Talbot found forty-three per cent. of abnormal palates in one thousand six hundred and five inmates of institutions for the feeble-minded; Ireland found fifty per cent. Charon reported abnormal palates in ten per cent. of normal people, in eighty-two per cent. of idiots and feeble-minded, in seventy-six per cent. of epileptics, in eighty per cent. of cases of general insanity, in seventy per cent. of the hysterical insane, in thirty-five per cent. of cases of general paralysis. Clouston and others supply statistics supporting the view that in idiots abnormal palates are much more frequent than with persons of a normal type. Channing's statistics show that the deformed palate occurs as frequently in one type as the other, and he also joins issue with Clouston as to the mode of classification.

THE SERUM TREATMENT OF SYPHILIS.

In the March number of the *Russkiĭ Arkhiv*, Dr. Vieviorovski presents an elaborate study of the blood changes occurring in patients with early syphilis after receiving injections of serum taken from persons with tertiary manifestations. His investigations were made upon two patients with syphilitic roseola, who were first treated with serum from syphilitics with condylomata, and later, during a recrudescence of the disease, with serum from those with gummata. The difference in the effects of the serum taken from these two sources was a purely quantitative one, the gummatous serum being the more active.

Immediately after the first injection of from twenty to fifty cubic centimetres of serum there was an increase in the number of red corpuscles and in the amount of hæmoglobin, and in most cases a diminution in the number of white cells. During the continuance of the injections, while the symptoms of the disease continued, the red cells and hæmoglobin remained at a fairly constant level, within nearly normal limits, or were slightly increased. But as soon as the syphilitic symptoms disappeared there occurred a new augmentation in the amount of hæmoglobin and number of red corpuscles. The white cells showed a tendency as at first to decrease. In one case, in which the injections of serum were without effect in preventing the development of the symptoms of the disease, there was always a diminution in the number of red cells the day on which the eruption appeared and also the day preceding it, although the number had been considerably above the average prior to this. The amount of hæmoglobin remained invariable. It was only after several injections, and upon the day the eruptions disappeared, that the number of red cells and the amount of hæmoglobin were increased.

Dr. Vieviorovski believed that there occurred under the influence of the serum a rapid reparation of the blood which had been altered by the syphilitic toxin, this modification taking place very rapidly after the introduction of the serum, even before the injections had had time to influence in any way the symptoms of the disease. The effects of the serum were analogous to those of mercury when the latter has simply caused a disappearance of the symptoms of syphilis, but has not been pushed so far as to exercise its hæmatolytic action. The difference between the treatment by serum and that by mercury consists chiefly, the author thinks, in that the serum acts more promptly and occasions none of the destructive effects seen occasionally when mercury is employed in large doses or for a long period.

The experiments made by Dr. Vieviorovski, of which we have been able to give only a bare outline, were most interesting and, except for their small number, quite conclusive. They at least incite to further trial, and justify the hope that we may find in hæmatotherapy a valuable aid in the prevention of the serious and destructive lesions of the so-called tertiary stage of syphilis.

The New York Herald comes out strongly in favor of the doctors in their fight against the abuses of medical charity.

News of the Week.

Amendment to the Nebraska Medical-Practice Law.—The Nebraska State legislature, just before adjournment, passed the bill amending the medical-practice act, requiring the State board of health to recognize diplomas only from medical schools which require a preliminary entrance examination, or the equivalent thereof, and attendance upon at least four annual courses of lectures of not less than six months each (no two within the same year), before granting the degree. The governor signed the bill at once. The efforts of the regular physicians, representing the State Medical Society, the Omaha Medical and the Creighton Medical colleges, to incorporate an examination feature in the bill, were frustrated by the efforts of the combined irregulars of the State.

Dr. John R. Ely, of this city, has been appointed instructor in pathology in the Yale Medical School.

Dr. Allen Blair Bonar has resigned the position of resident physician to the Incurable Hospital on Blackwell's Island, and has moved to New York City.

Obituary Note.—Dr. Anthony Eugene Stocker died at Philadelphia, on May 23d, at the age of seventy-eight years. He was graduated from the medical department of the University of Pennsylvania in 1840, and at the outbreak of the civil war entered the army as a surgeon. He was for many years surgeon to the Pennsylvania Hospital and the Blind Asylum.

A Medical Victim of the Paris Fire.—Among those killed in the disaster at the Bazar de Charité was Dr. Henri Feulard, a well-known dermatologist, who, after saving his wife, went back into the burning structure to rescue his little daughter. In seeking to save some other persons who asked for his help, he perished in the flames. He was only forty years of age, and had already made an enviable reputation in his specialty. He was a member of the French Dermatological Congress, and was on the editorial staff of the *Annales de Dermatologie et de Syphiligraphie*.

The Charges too High.—The committee on exhibits of the British Medical Association in Montreal had an experience similar to that of the builders of grand stands at the recent Grant parade in this city. The correspondent of *The Lancet* writes that the Victoria Skating Rink was secured, and the floor space laid out in an attractive lithographic plan, and high prices were asked for space, on the supposition that exhibitors would be tumbling over one another in their anxiety to secure places. As, however, there has been no hysterical clamor for space, the prices have been brought down. The contractor for the handbook has been disappointed also in the advertising patronage he has been able to secure. This has caused delay, but the book will be issued all the same.

Dr. J. W. Prendergast, ex-health officer of Cincinnati, who was indicted by the grand jury for blackmail, the charges being made by the Fraser Medical Company of New York, has fled from the city.

He was to appear in the criminal court on May 24th to answer to the charge, but instead of appearing sent a letter to his attorney, in which he said that public sentiment had been so aroused by reason of developments of crookedness among officials recently that no accused official could have a fair trial. He further said in the letter that he was going to the West for a month or two, and at the end of that time would certainly return for trial. His bond of $1,000 was declared forfeited.

The Need of Closed Street Cars.—The health board has added to the sanitary code a section prescribing that every passenger railroad in New York City shall at all times of the year run at least one closed car in every four cars run. The board has received numerous complaints about open cars in rainy summer weather.

An Antivivisection Bequest.—The will of Mrs. Ellen B. French, of Beloit, Wis., bequeaths $5,000 to Beloit College, on condition that no vivisection shall ever be practised in any of its departments. If the stipulation is violated, the trustees are to pay over the amount to the American Humane Education Society of Boston.

Dr. John B. Hamilton, the editor of the *Journal of the American Medical Association*, devoted nearly half a page recently to the expression of his dislike for Dr. Walter Wyman, surgeon-general of the United States Marine Hospital service. The latter, however, continues to do his duty in the same efficient manner that has always characterized his official career, and has found time to make several valuable contributions to medical literature.—*Ohio Medical Journal.*

The Plague.—Mr. Julian Hawthorne, who was sent to India to describe the scenes of the famine and of the bubonic plague, returned recently to this country. He spent a fortnight in Bombay and a fortnight in the famine district among the native villages. Vast numbers of Hindus and Bengalese, he says, have died from starvation, and he further asserts that the government figures represent not more than one-sixth of the actual deaths from the plague.

No Degrees for Women at Cambridge.—The University of Cambridge, England, at a meeting on May 21st, rejected by a vote of 1,713 to 662 the proposal to confer degrees upon women. The refusal was largely the work of clergymen of the Church of England, who flocked to Cambridge from all parts of the country in order to put themselves on record as opposed to the new woman. The students amused themselves by suspending opposite the senate house an effigy of a woman in bloomers on a bicycle, and over the gateway of one of the colleges was a transparency inscribed: "Get you to Girton, Beatrice. Get you to Newnham. Here is no place for maids."

Foreign Dogs Not Wanted.—The British board of agriculture, moved thereto by the hydrophobia scare now afflicting England, has issued an order that no dog shall be allowed to enter Great Britain after September without a special license issued by the board of agriculture, which can be obtained only after going through many formalities. Details for the identification of the dog must be given, as well as the address of the owner, where the animal is going to land, the route by which it is to travel, etc. In case of violation of any of the provisions of the order the dog will be liable to six months' quarantine at the expense of its owner.

The Medical Society of the County of Kings, which recently celebrated its seventy-fifth anniversary, has secured a lot at Bedford Avenue and Dean Street, Brooklyn, upon which it will erect a building for its permanent home.

"The Medical Register" is a new monthly journal issued under the auspices of the faculty and society of alumni of the Medical College of Virginia, under the editorial management of Dr. E. C. Levy.

The Duchess of Teck has more confidence in British medical men than some of her royal relatives. She recently was taken ill with strangulated umbilical hernia, and was successfully operated upon by Mr. Allingham, without waiting for a surgeon to be brought from Germany.

A Twenty-Six-Year-Old Grandmother.—Dr. H. O. Hyatt tells in *The Philadelphia Polyclinic* of a girl who bore an illegitimate daughter one month before her thirteenth birthday. This daughter menstruated at eleven years, was married at twelve, and herself bore a son one month before reaching the age of thirteen. The girl grew four inches in height after giving birth to this child, and has since borne seven children. The writer says that she is in fair health, and shows no signs of premature age.

Dr. Charles E. Sajous, editor of the "Annual of the Universal Medical Sciences," who has lived for some years in Paris, will return soon to Philadelphia. He has been appointed professor of laryngology and dean of the faculty of the Medico-Chirurgical College of Philadelphia.

The New Woman and the Wheel.—A writer in a St. Louis contemporary says that the bicycle "is equally if not more beneficial to young girls with scanty, delayed, or irregular menstruation, who are developing into manhood, than any other deviation from the normal that the female sex is afflicted with." The opponents of the wheel contend that this is just the trouble, that girl riders develop into manhood.

A Medical-Aid Section.—It is announced in *The Journal* that an effort will be made at the Philadelphia meeting of the American Medical Association to complete the organization of a medical-aid section for the benefit of disabled physicians and of the widows and orphans of physicians, members of the section, with the co-operation and indorsement of the several State and municipal medical societies; the friends of such a section hope to organize, and have appointed all the officers required to make the section a corporate body of the association.

Society Reports.

SEMICENTENNIAL CELEBRATION OF THE AMERICAN MEDICAL ASSOCIATION.

The Forty-Eighth Annual Meeting, Held at Philadelphia, June 1, 2, 3, and 4, 1897.

Tuesday, June 1st—First Day.

THE meeting was called to order promptly at ten o'clock by the president, DR. N. SENN, of Chicago.

Prayer was offered by the REV. LEVERETT BRADLEY, D.D.

Addresses of Welcome.—The HON. CHARLES F. WARWICK, mayor of Philadelphia, greeted the association on behalf of the city, and said that never before had he welcomed so large a body of doctors. He spoke of Philadelphia as the home of medicine; that it was here that Gross, Pancoast, Agnew, and Leidy had made themselves reputations, not only medical, but national and worldwide. He had heard, he said, men denounce both God and the doctors, but they never asked for any one so promptly as they did for both when they happened to be sick. In the name of Philadelphia he welcomed his hearers heartily, and hoped that their deliberations would result in blessings for mankind.

In the absence of His Excellency the Hon. Daniel H. Hastings, the HON. CHARLES EMORY SMITH, formerly minister to Russia, welcomed the association on behalf of the State of Pennsylvania. He expressed his regret that the governor was unable to be present, but said that he felt sure he would be excused when it was known that he was holding a very important clinic at Harrisburg. The patients were not really so very sick, but they were nevertheless considerably diseased, and, unlike the cases coming before the profession, with these it was the governor's duty not to save but to kill, and to do this required the most drastic treatment; he was therefore detained at Harrisburg in the work of amputating gangrenous legislation, and was using the scalpel with great industry and considerable skill. Mr. Smith said that he was a substitute drafted at the very last moment, but would say for the governor in a few words that the State of Pennsylvania, as well as the city of Philadelphia, welcomed the association within her borders. He spoke of the association as a representative of that profession which came the closest home to the hearts of the people, and said that the great State of Pennsylvania welcomed them for what they had done and for what they were doing for the good of humanity, and he expressed his conviction that this meeting would mark an epoch in the history of medicine.

DR. H. A. HARE, chairman of the committee of arrangements, announced a long programme of entertainments which had been provided by the citizens and physicians of Philadelphia.

The President's Address.—DR. NICHOLAS SENN, of Chicago, then delivered the annual address, taking for his theme, "The American Medical Association, its Past, its Present, and its Future." He said that Philadelphia was an appropriate place for the meeting of the American Medical Association, since it was here, on July 4, 1776, that the most precious document of the American people, the Declaration of Independence, was signed, and heroically defended by America's greatest physician, Benjamin Rush; it was here that the first music of the Liberty Bell was heard, which would continue to echo over our fair and free country for all time. Besides being the birthplace of the American Medical Association, Philadelphia remained the centre of medical education, and its citizens, beginning with Benjamin Rush, had always been loyal to the cause of medicine. He recalled the names of Dr. N. S. Davis, of Chicago; Dr. Stillé, of Philadelphia; Dr. Johnson, of St. Louis; Dr. Atwater, of Springfield, as the few remaining men of those who were most helpful in laying the cornerstone of this national institution. Of these men, Dr. N. S. Davis was the father of the association, and Dr. Stillé had been for many years its faithful secretary. He also paid a tribute to those who had labored earnestly in the early work of the association, and who had since joined the silent majority.

A much-needed reform in medical education had been brought about largely through the influence of the association, nearly all medical schools now requiring a four years' course and an attendance of eight months in the year, and as a result of this reform our medical schools were now quite on a par with those of the old world. Some of the very best practitioners of the United States were men who had graduated in our own schools, and the orator thought it required no stretch of the imagination to predict that this country would become the centre of medical education within twenty-five years, and that instead of, as formerly, men crossing the ocean to Europe to complete their medical education, those of European countries who desired to perfect themselves in the science and art of medicine would be forced to come to America.

The orator then spoke at length of post-graduate education, which he said was within reach of every one and was to be had for the asking by seeking membership in medical societies. It was an acknowledged fact that the best education was but an entering wedge to the successful practice of medicine, and the successful and then necessarily progressive physician was and always remained an earnest student. Polyclinics and post-graduate medical schools, each with its multitudinous professional staff of men themselves just graduated, had done excellent work, despite their deficiencies, in fostering and favoring specialists, but they never could or would take the place of medical societies. A man who had been living far from his fellows might gain some advantage by attending these schools and brushing up his knowledge a little, but the only really rational post-graduate work consisted in reading current literature and acquiring a knowledge of disease from a pathological standpoint through attendance upon local medical societies. Not a single day should pass that the physician did not absorb something useful from medical literature or from the study of some specimen under the microscope. The fruit of such individual efforts, however, belonged to the medical profession, and should be brought into the proper channel through medical societies or through the medical press. Time and money spent in attending the meetings of the several county, State, and national associations would be well spent. The multiplication of medical societies of all kinds had gone on with the greatest speed. Specialists had their own societies, and much good was accomplished through them; but they were necessarily restricted in their usefulness, and a man's first duty was to belong to his local society. In this society the young graduate should listen and say little for two or three years; by the end of five years he might begin to talk, and then he was ready for work in the State society; in the national association, however, he should, while being present, not be heard until ten or twelve years had passed since his graduation, and even then he should not be heard unless he had something valuable to say on a scientific subject. Medical societies are intended for scientific work, and the great majority of physicians who attend the meetings do so for the sole purpose of receiving or imparting knowledge. These are the men of worth, but there is another class that is not wanted;

this class contains the political doctors, the wire-pullers who are always on their feet to the detriment of the scientific work of the society. These men appear more for the purpose of being seen and making themselves heard, and so killing precious time, than to promote the legitimate work of the society; they seldom read papers or take part in the scientific debates. The general meetings of this American Medical Association had on many occasions, the orator said, resembled more a political caucus, or a stirring debate in the Senate, than the calm proceedings of a scientific body.

One of the growing faults at present threatening the usefulness of the association is the offering of too many papers, and the speaker warned his hearers that a bulky volume of transactions is no indication of good work accomplished—indeed, often the very contrary. There is, however, much good medical writing, and Dr. Senn thought we might take just pride in the rapid growth and high standing of our American medical literature. The time, he thought, was at hand when we would be able to pay our obligation to Europe with compound interest, and when the students on the other side would have to look to America for their text-books. He urged the creation of a fund for a number of prize essays, and believed that thereby the future of American literature would be assured. The *Journal* of the association, he said, had passed through the trial stage and was a power for good, and might some day be a rival of the *British Medical Journal*.

At the time the Medical Association was organized, the profession of the country was in a trying position; the standard of medical education was at the lowest depth. The code of ethics, which was formed and passed by a unanimous vote in 1847, was liberal in its tone and lofty in its sentiments, and required nothing more than would be most willingly subscribed to and carried out by any one having the good of the profession at heart. The speaker considered it the cornerstone of the American Medical Association, and upon its removal the association would be no more. The code of ethics, Dr. Senn said, had fulfilled the purpose for which it was intended, and he believed that at the centennial celebration fifty years hence, our successors would be thankful to us for handing it down in an unaltered form.

Dr. Senn spoke feelingly of the efforts of Dr. Gihon in connection with the Rush monument fund, and thought the association could not afford to let the semicentennial celebration pass without securing funds for a suitable monument to the memory of Benjamin Rush.

A suggestion which the orator offered was that during the meetings of the association lectures should be given on bacteriology, histology, etc., and lectures of this nature, if illustrated fully and well, he believed would secure a large attendance.

Another suggestion was for an association dinner for the entire association, to be held the second evening of each session, to be arranged for by the committee of arrangements, but to be paid for by the members who eat it.

He also discussed the need of a permanent home of the association, an editorial office, pressroom, and a circulating library.

Upon motion, the thanks of the association were then voted to Dr. Senn for his able address, and it was referred to the proper committee for action upon the suggestions contained in it.

Report of the Rush Monument Committee.—Dr. E. L. Gihon reported that the Rush monument fund was now only $4,016.19. In stirring words he eulogized Dr. Rush as the one to whom American physicians owed the greatest gratitude and who was deserving of the homage of every lover of his country, because of the courage he always exhibited and because of his martyrdom. He said, however, that he was almost discouraged, and the association must now decide whether its original intention to erect a suitable monument to this hero be carried out, or whether a small bust on a plain granite pedestal be put up in Washington as a measure of the honor which American physicians and patriots wish to pay to Benjamin Rush.

Dr. Cutter, of New York, moved that the association appropriate each year $1,000 until the necessary amount was raised.

Dr. Graham, of Denver, moved as an amendment that the sum of $100,000 be raised by members of the association, and he gave his pledge that Colorado would give $2,000 of this amount.

This aroused enthusiasm, and contributions of $2,000 were pledged by Illinois, New York, Pennsylvania, Ohio, and Missouri, and the representatives of the other States promised to devote their best efforts to the raising of a sum proportionate to their abilities. Many delegates promised individual subscriptions of $100 each.

It was moved and seconded that the editor be instructed to keep a standing appeal in the *Journal* until the money is raised.

Dr. Henry P. Newman, the treasurer of the association, then read his report. The past year, he said, was one of the most prosperous in the history of the society, and the membership was steadily growing. The balance at present in the treasury amounted to a little over $5,000.

Amendments to the Constitution.—The following proposed amendments to the constitution were then taken up and voted upon:

Art. IV.—Officers. Amend to read "Each officer shall hold his appointment for one year, and until another is elected to succeed him."

Executive Council. "That there be made an executive council of five, consisting of the three officers of the executive committee and two officers chosen by election. Of this council of five, one must belong to the section on practice of medicine and one to the section on surgery and anatomy. To this executive council shall be delegated all the duties of the executive committee during the interval between the meetings."

Art. IX.—Conditions for further representation. "Any State or local medical society, or other organized institution whose rules, regulations, and code of ethics agree in principle with those of this association may be entitled to representation on the advice or agreement of the judicial council."

To change the name of the section on dermatology and syphilography to that of "cutaneous medicine and surgery."

The consideration of the first of these proposed amendments, which was directed against the secretary of the association, and concerning which there had been much acrimonious discussion at previous meetings, was indefinitely postponed. The other amendments were carried without discussion.

Wednesday, June 2d—Second Day.

The meeting was called to order by the president at 10 A.M.

The minutes of the previous meeting were read and approved, and the chairman of the committee of arrangements made the announcements for the day.

Address in Medicine.—Dr. Austin Flint, of New York, then delivered the annual address in medicine, taking for his subject, "Stercorin and Cholesteræmia." Dr. Flint said, that looking into the future, it seemed possible that our successors might fix upon the month

of May, 1946, as the true centennial of the American Medical Association, dating its origin from May, 1846, when a convention of representatives of the profession, held in New York, proposed the foundation of a national association, which was formally organized in 1847. He remarked that 1946 would be the centennial of the application of anæsthesia to surgery, and the third jubilee of the crowning glory of the eighteenth century, the completion of the discovery of vaccination, when the terrible scourge of small-pox was virtually subdued, and suggested as lines of further progress within the next half century immunity from tuberculosis, typhus and typhoid fevers, scarlatina, diphtheria, and other infectious maladies, and the disappearance of these diseases. He thought it not too much to say that the convention of May, 1846, marked an era in the history of medical organization in the United States. It had become necessary that the medical profession should be unified and separated from those practising under sectarian designations, particularly as at least one sect was beginning to secure the confidence of men otherwise intelligent, and assumed to practise medicine on a scientific basis. While medicine had never been an exact science, it had always been progressive. Fifty years ago medicine perhaps merited the reproach of being the least exact of all sciences; but its progress within the last fifty years has been so prodigious that it is now in advance of them all. He called attention to the possibility of bacteria study by the use of the Abbé illuminating apparatus, and to the exact knowledge of physiological and pathological histology by the use of delicate and precise instruments used in cutting thin sections, and by staining, which fifty years ago seemed unattainable. Although the diagnosis of certain diseases fifty years ago was acquired only by long practice and large experience, with our present methods properly employed it is impossible to make an error in many of the diseases which formerly presented difficulties. It is not enough to say that pathology has been revolutionized, but a new pathology has been created, and with it have come an intelligent hygiene, prophylaxis, and therapeutics, based upon exact scientific knowledge. As no human imagination fifty years ago could have pictured the condition of medicine today, so it is impossible to imagine the progress of another half-century. Never since medicine became a science has medical history been made so fast as now. Between the writing and delivering of this address, scientific labor might give birth to a discovery destined to revolutionize some department of medicine, as Pasteur, Koch, and their followers have revolutionized therapeutics, and as Lister has created a new surgery.

Dr. Flint thought it a matter of congratulation that the name of the body was early changed from "National" to American Medical, for we have good reason to be proud of American medicine, and our great representative association may properly claim a distinctive title, particularly when, as American discoveries, might be mentioned at random the discoveries in gastric digestion, anæsthesia in surgery and obstetrics, the successful ligation of the innominate artery, the operation for vesico-vaginal fistula, ovariotomy, and intestinal anastomosis, to say nothing of minor advances in medicine and surgery. He hoped to see beginning with the second half-century of the American Medical Association a more complete unity of the profession through its authority and influence. He thought that uniformity of legal qualifications to practise medicine in different States could best be secured by making every State society actually, as well as nominally, a branch of the American Medical Association, with permanent committees from each State organization to constitute a central legislative body, the object of which should be to secure uniform medical laws in all the States, making any State license valid for all, and a matriculation certificate for one State good for matriculation in all schools represented in the Association of American Medical Colleges.

Stercorin and Cholesteræmia.—In his remarks on this subject, Dr. Flint said that while the presentation, on this occasion, of researches made and published thirty-five years ago—viewing the question from a physiological standpoint—called for an explanation and perhaps an apology, none was required if their great importance in relation to the pathology of the liver be considered, especially as cholesteræmia was by no means accepted as a distinct pathologic condition. Were it not that stercorin had just been re-discovered in Germany by two eminent physiological chemists, who made no mention of its full description in 1862, and have even called it by another name, the author said he probably would not have repeated and extended his original observations. But, under the circumstances, he thought that he might properly, as an American investigator, make his reclamation before the American Medical Association. The author stated that although his paper published in the *American Journal of the Medical Sciences* in October, 1862, received an "honorable mention" and substantial recognition from the Institute of France, and his observations were verified and extended by French and German investigators, many writers on physiology and pathology, even the most recent, had failed to recognize such a substance as stercorin and spoke of its function as obscure or unknown. In an American text-book of physiology, published in Philadelphia in 1896, cholesterin is described as a constant constituent of the bile, very widely distributed in the body, and eliminated by the liver cells from the blood. "That it is an excretion is indicated by the fact that it is eliminated unchanged in the fæces." Stercorin was not mentioned. As a matter of fact, cholesterin, he said, did not occur in the human fæces in health, and its presence in this situation was exceptional. He gave the process of extraction from the human fæces of the original stercorin, specimens of which he obtained in 1862 and still has in his possession. The author thought that the opinion expressed by Hoppe-Seyler, Hofmann, and others, that stercorin was simply impure cholesterin, could not have been based upon a practical knowledge of this substance, declaring that stercorin had a well-defined formula—$C_{27}H_{46}O$—which had been calculated and verified by the formation of esters. Its crystals, he said, are different from those of cholesterin, and are invariable in form, arrangement, and color. Its methods of extraction are practically the same as those used in the extraction of cholesterin. In view of these facts, Dr. Flint thought that to assume that stercorin was an impure substance one must deny a positive scientific basis to organic chemistry. It had been shown by recent as well as original observations that cholesterin was changed into stercorin in passing down the intestinal canal, and this change, Dr. Flint had found, involved processes incidental to intestinal digestion.

Passing to the pathological relations of cholesterin, after examining three specimens of normal blood and finding the proportion of cholesterin from 0.445 to 0.751 of one part per thousand, examinations were made of the blood of patients with simple jaundice and of those with icterus gravis. In a case of simple jaundice, terminating in recovery at the end of about four weeks, the blood contained 0.508 of one part per thousand, well within the limits in normal blood. In a case of jaundice with cirrhosis, terminating fatally with serious nervous disturbance, the blood taken six days before death contained 1.580 parts per thousand of cholesterin, an immense increase over the normal

proportion. In this case, on post-mortem examination, the liver was found contracted, and the gall-bladder was shrunken, containing only about seven cubic centimetres of bile. The question of cholesteræmia, Dr. Flint stated, had been much discussed since 1862, for the most part with scant approval or without acceptance. A case of "grave jaundice" was reported in 1872 by Picot, in which he determined a great increase in the proportion of cholesterin in the blood, 1.804 parts per thousand. Many attempts have also been made to produce toxic effects by injecting cholesterin into the blood, but most of them have been unsuccessful on account of mechanical obstruction of the blood-vessels. Koloman Müller, however, in 1873, succeeded by injecting cholesterin rubbed with glycerin and mixed with soap and water. In five experiments on dogs, injecting in each 0.045 gram of cholesterin, he produced a complete representation of the phenomena of "grave jaundice." It is possible, Dr. Flint thought, that light would be shed upon the pathology of cases of acholia, in which there were grave nervous symptoms without jaundice, if it be admitted that there is a condition called cholesteræmia. Biliary salts not being found in the blood, the symptoms could not be accounted for by disturbances in digestion. If the theory of cholesteræmia be accepted, he thought a wide field of inquiry opened in this direction, and that ere long "biliousness" and "liver complaint" might be spoken of with definite idea of their pathology.

Dr. Flint said it should be borne in mind that the liver was by far the largest gland in the body; that it secreted a fluid known to have a double function, one connected with digestion and the other with the elimination of cholesterin; that the blood from the digestive tract all passed through this organ, where it underwent certain changes; that it probably stored up the products of amylolytic digestion in the form of glycogen; that it arrested certain poisons, and that it was the chief organ concerned in the production of urea which was discharged from the kidneys. The pathology of hepatic diseases, however, remained obscure, notwithstanding the varied known uses of the liver, the cause and mechanism of the formation of gall stones not even being known.

The term acholia, as used in pathology, was said to mean now very little and conveyed no distinct idea of the cause of the nervous symptoms accompanying this condition. The term cholæmia was generally regarded as almost synonymous with jaundice.

The quantitative estimation of cholesterin in the blood, the author stated, was not difficult and did not require more than from four to six or eight grams of blood. The only tedious manipulations were the drying, saponification, and weighing, which were readily done in a well-appointed laboratory. Some process might be devised, it was thought, to expedite this extraction. Dr. Flint thought that if examinations of the blood were to be made in cases of obscure nervous disturbance, epilepsy, and other similar disorders, cholesterin might be found to play an important part in their pathology. He thought very suggestive the fact that bromine readily combines with cholesterin, taken in connection with the wide use of the bromides in diseases of the nervous system, and suggested the possibility that the bromides promoted the elimination of cholesterin, an insoluble substance and one which formed few combinations. These points Dr. Flint thought well worthy of the consideration of pathologists and therapeutists, and emphasized the suggestion that the physiological and pathological relations of cholesterin offered a wide and perhaps fruitful field for further observations.

Address of President McKinley.—After the reading of Dr. Flint's paper and the extending of a vote of thanks for the valuable and instructive discourse, the association was addressed by the President of the United States, who spoke as follows: "Mr. President, Ladies, and Gentlemen: Although summoned to this city for another purpose, I deem myself most fortunate to find this honorable association in its semicentennial meeting on the same day, and I cannot refrain from taking a moment from the busy programme mapped out for me by Dr. Pepper, whose assurance I had before coming here that it should be a day of rest. I cannot refrain from pausing a moment that I might come into this brilliant presence to meet the learned gentlemen here assembled, and to pay my respectful homage to the noble profession which you so worthily represent. You have my best wishes, and I am sure the best wishes of our countrymen, for the highest results of your profession, and my warm and hearty congratulations upon this, your fiftieth anniversary."

Address of Governor Hastings.—Following the address of the President, the association was addressed by the governor of Pennsylvania, who said that it was with great regret that he was compelled to be absent from the opening session of the association, but though twenty-four hours late he gave just as warm a welcome and as cordial as if he had met the members upon the borders of the city to welcome them to the commonwealth. He said that Philadelphia and the State of Pennsylvania were greatly honored by the presence of the distinguished organization, and that although the people were very much occupied in matters tending to the development and upbuilding of the city and State and United States, yet there was always room for such a splendid American organization as this. Two weeks ago there was unveiled in this city the greatest monument that had ever been erected to perpetuate the memory of Washington, and only a few days ago another statue was unveiled to perpetuate the memory of Philadelphia's, of Pennsylvania's greatest philanthropist, Stephen Girard, and to-day the Chief Executive of this nation came here, primarily and above all, to pay his respects to this great national organization, and secondarily to attend the inaugural of the Philadelphia Commercial Museum, which in his judgment was the initial movement in an enterprise that would grow until it should be not only a Pan-American institution, but one which would take in all the commercial nations of the earth. He said he spoke as a layman, and merely gave an impression of what the common every-day people, who are subject to the ills which the physicians cured, saw in the noble profession of medicine of this country which was worthy of the highest emulation. The lawyer had in his profession an antagonist worthy of his steel; the work of the Christian teacher was done in the full glare of the sunlight of the people; but with the physician it was different; he was judge and jury and opposing counsel—and sometimes executioner. From his court there was no appeal in this world. Sickness and the fear of death, he said, made cowards of us all in the sick-room, and the physician was the autocrat whose voice, direction, instruction, and prescription were taken generally with the simplicity and the confidence of a babe. He portrayed the ideal physician, whose presence in the sick-room was as the morning sunlight, his voice a benediction, his touch an inspiration. To him children turned, and the marks of pain changed into the expression of love and confidence; the aged revealed to him the secrets of this life and their hopes of the life hereafter; mothers forgot their vigils of the night in loving anticipation for the restoration of their dear ones, or perhaps in the contemplation of the inevitable.

The development of medicine he considered had been greater than that of any other science. He thought it a mistake that monuments were not erected

to the great masters of medical science in this country, and marvelled that so many diseases had been discovered of which we were previously ignorant. He recalled a story of a physician in the fourteenth century, who had said there were three diseases of the skin—one was that disease which could be cured by the use of sulphur, another that which could be cured by the use of mercury, and the other disease was that trouble with the skin which the devil himself could not cure.

He expressed his satisfaction that there was a better feeling existing among the different classes of medicine in this country than formerly. He had read, he said, that in ancient times a doctor came to a distinguished physician and said he had cured numbers of people by a method of his own discovery, and wanted a conversation with the distinguished physician. The great physician had the conversation with him, and afterward threw him out of the window. That kind of peaceful and pleasant consultation had been going on in the medical profession ever since. If he had his way, he said, he would build monuments to all the great medical teachers and discoverers. What proud position the American Medical Association was destined to take among the scientific bodies of the earth, none could tell; one generation passed away, another came, but a true physician followed the true Teacher of medicine, He who was the first Healer of humanity, the lowly Nazarene.

The Antivivisection Bill.—Dr. H. C. Wood urged in forcible style upon the members of the association the necessity for working against the passage of Senate bill No. 1,063, the object of which is to prevent animal experimentation. After giving a history of past legislation on the subject he emphasized the necessity of each member taking a personal interest in opposing the sinister and persistent efforts of the antivivisectionists. The latter appealed to public sentiment on entirely false premises, and were very ingenious in misconstruing motives, very apt in perverting facts, and always ready to interfere with judicious legislation. It was only by persistent efforts of individuals and medical societies that the opposition could be successfully combated, and the sooner the profession should appreciate this fact in all its true significance the better.

Thursday, June 3d—Third Day.

The meeting was called to order by the president at one o'clock. After the reading of the minutes of the previous session a report was presented by the committee on the organization of a relief association, and it was moved that the president appoint a committee of one from each State, to establish such an association. The report of the trustees showed a satisfactory condition of the treasury, and also of progress in the circulation of the *Journal*. The failure of a bank having jeopardized some of the funds of the association, it was determined that the board of trustees secure a charter, in order that the association may have a legal standing to sue or be sued.

Address in Surgery.—Dr. W. W. Keen, of Philadelphia, then delivered the annual address in surgery. After acknowledging the unsolicited honor from the medical profession in the United States of being chosen to deliver the semicentennial address in surgery, Dr. Keen gave a review of the work done in the last fifty years, and contrasted the state of surgery and of surgical teaching in 1847 with that which exists in 1897. He considered that to recount what had been achieved in these "fifty years of science" was not only a pleasure but an immense incentive, since by the progress made in the last fifty years could be in some measure anticipated the enormous and probably even still greater progress to be made in the next half-century. The time also, he thought, was opportune; last year were celebrated the centennial of vaccination and the semicentennial of the first public administration of ether. He stated that Sydney Smith's bitter query in 1820, "In the four quarters of the globe, who reads an American book? . . . what does the world yet owe to American physicians or surgeons?" was answered a quarter of a century later, and made all these "four quarters of the globe" our grateful and everlasting debtors.

Dr. Keen thought a most important factor in the improvement in surgery and in all departments of medicine was the immense advance made in medical teaching, and said that fifty years ago no text-books appeared in the catalogues of the Jefferson Medical College, the University of Pennsylvania, Harvard University, and the medical department of Columbia University. Even so late as 1860, when the orator began the study of medicine, there were no laboratories except that of anatomy—the dissecting-room—and he doubted that of the two hundred odd men who graduated with him in 1862 twenty had ever looked through a microscope or handled a test tube, palpated a tumor or auscultated a chest; and he wondered that any of them who graduated in the first twenty years of the half-century being celebrated ever learned enough to prevent some from rivalling Saul, who had slain his thousands, and the more nimble from being rivals of David, who slew his ten thousands, and their becoming possibly more than respectable practitioners was due to later incessant midnight labors rather than to early opportunities. He spoke of the graded four-years' course in the majority of medical schools, and of the post-graduate course in hospitals, in which after receiving their diplomas young men spend a year or more in actual practice of their profession, as evidences of great progress. Equally valuable, too, to the older medical staff, Dr. Keen considered these hospitals, and thought it not too much to say that every city or town establishing a hospital was repaid a hundredfold in the improvement of its medical men.

Forty years ago, with the exception of Pancoast's "Operative Surgery," every one of the text-books in use was the work of a European. Gross' "System of Surgery" was first published in 1859, and was a work far in advance of most of the surgical text-books then in use. The literary labors of American surgeons consisted chiefly in translating foreign surgeries or in annotating American editions of English text-books, but many distinctly American surgeries had been written within the last two decades, and the orator thought that we might say without undue national vanity that they are the equals of any similar European works. He said that the genius of our institutions was such that we could never look for government or State endowments of laboratories, but must depend on the far-sighted and broad-minded liberality of our wealthy fellow-citizens for the establishment of such laboratories and the consequent opportunities for investigation and discovery.

Allied to medical teaching and the most important adjunct to medical literature, Dr. Keen considered the establishment of extensive medical libraries, and said that in this, as an American, he was proud of his own country, for no foreign nation could point to any such medical libraries as have been developed within the last thirty years.

Dr. Keen then spoke of the scientific progress in this half-century of surgery as having separated us from the past. Great theologians, such as Calvin or Jonathan Edwards, were they recalled to life, could discourse as learnedly as ever of predestination and free will; great preachers, as Beecher or Spurgeon, could stir our souls and warm our hearts as of old; great jurists, as Justinian or Marshall, could expound

the same principles of law which hold good for all time; great forensic orators, as Burke or Webster, could convince us by the same arguments and arouse us by the same eloquence that made our fathers willing captives to their silver tongues; but to-day, so rapid has been our surgical progress, a Sir William Ferguson, a Pancoast, or a Velpeau, all of whom have died within the last thirty years, could not teach modern surgical principles nor could he perform a modern surgical operation. Even our every-day surgical vocabulary would be unintelligible jargon to him; and our modern operations on the different organs of the body would make him wonder whether we had not lost our senses, until, seeing the almost uniform and almost painless recoveries, he would thank God for the magnificent progress of the last half-century which had vouchsafed such magical power to the surgeon. Another lesson was taught by the splendid index catalogue of the library of the surgeon-general's office, in that, in law, the jurist or attorney deals with statutes and practices and to some extent with principles which are for the most part local; an American lawyer could not plead a case in Germany, nor a German lawyer in Russia, nor a Russian lawyer in Italy. An American or an English divine would be an alien in language and religion in Hindoostan, a Hindoo equally an alien in China; but surgery is one and the same the world over; a new remedy discovered in Japan is equally efficacious in Philadelphia, a new operation devised in America is equally applicable in Egypt. The index catalogue, which is a catalogue for all countries, contained them all; and this, with our noble stand as a profession against patenting any instrument, any operation, or any method of treatment, made every sick or injured man the physician's brother, and made the physician his keeper under every sky and clothed in any skin.

Foremost among the important studies which the past fifty years had seen established on a firm foundation is that of pathology and pathological anatomy, and the orator thought it not a little credit to America that the first work on pathology in the English language was written by a young American doctor in a then small Western town as early as 1839. In spite of Gross' book, however, pathology and pathological anatomy were almost unknown sciences in 1847. The Pathological Society of Dublin was founded in 1839, that of New York in 1844, that of London in 1846, and that of Philadelphia in 1857. The microscope, and especially microscopical methods of staining, section-cutting, and the like, were then in their infancy, but without these aids no accurate views of pathology could be entertained, and what is now the heritage of every first-year student was beyond the possibilities of the most advanced teacher of fifty years ago. Allied sciences have been put under tribute to surgery, and the discovery of the Roentgen rays and the advances of electricity as a means of diagnosis engender the hope that other forces and other means of investigation quite as marvellous may well be expected within the next fifty years.

Dr. Keen spoke of the startling and revolutionizing effect of the introduction of anæsthesia in the year before the organization of the American Medical Association—first of ether in America in 1846, and then of chloroform in Edinburgh in the following year—and he said that what this had done for the amelioration of the horrors of pre-anæsthetic surgery very few now living could appreciate.

Antiseptic surgery also was mentioned as a later revolution in surgical methods, which came in so gradually that the special day or year of its introduction could not be named, but the name of Lister, *primus inter pares*, was honored throughout the entire surgical world, and his recent distinction as the first medical peer of the United Kingdom was an honor conferred not upon Lord Lister alone, but upon the entire profession, and worthily marked a new departure in the recognition of medical science by the British government. Decried first as a "fad" or as "nothing more than surgical cleanliness," antiseptic surgery, the orator said, had now won its way over the entire world, and, although there are still a few laggards in the surgical army who do not practise modern antiseptic or aseptic surgery, the overwhelming majority of the profession recognizes that the world owes a debt to Lord Lister which no honors can pay.

Mention was also made of bacteriology and orrhotherapy as outgrowths from the practical development of antiseptic surgery, which had arisen as a wholly new science and method of practice and which bade fair to revolutionize our modern therapeutics. Like the antiseptic method, they have been of gradual growth, but modern laboratory research had verified the crude suspicions and shrewd guesses of thirty years ago, and transformed them into the certainties of modern science.

Consideration was also given to animal experimentation as having had a large share in the development of modern surgery. The whole question of the introduction of animal ligatures was begun in America by Physick, who used buckskin, and by his follower, Dorsey, who used kid and cut both ends short; by Hartshorne, who used parchment; and by Bellenger and Eve, who used the tendon of the deer. The use of these substances began principally by experiment upon animals, in order to determine accurately the behavior of such ligatures in the tissues. What a boon to humanity this single achievement had been could be appreciated, the author stated, only by his professional hearers. Dr. Keen considered that modern cerebral surgery also owed its exactness and success almost wholly to cerebral localization and antisepsis, both of which were first studied by experiment upon animals, and later by the application to man of the knowledge so gained. Bacteriology would not now exist as a science, nor would accurate modern surgery and a large part of modern medicine be possible, had experiments upon animals been prohibited, as some zoöphilous women, who love dogs better than men and women and even little children, desire.

The development of modern surgery has naturally been on two lines: First, that of scientific progress, based especially on pathology, bacteriology, embryology, and comparative anatomy; and secondly, within the last twenty-five years especially, there has come what might be called pre-eminently the era of the operative surgeon, due more especially to the introduction of anæsthesia and later of antisepsis.

In conclusion, Dr. Keen said that what the future has in store for us we could only dream. Two diametrically opposing tendencies are prominent in modern surgery—namely, radical interference with disease, so that there is scarcely now a single organ or portion of the body not within our reach; and, on the other hand, a remarkably conservative tendency in cultivating remedial rather than radical surgery. Joints so diseased as once to require amputation are now treated conservatively with the best results. Ovaries, a portion of which can be preserved, are kept in the abdomen; kidneys once doomed to extirpation are now partially removed, and bones so diseased that they once required amputation are now excised and the limb is preserved.

Jubilee Exercises.—Dr. N. S. Davis, the founder of the association, then appeared upon the stage, escorted by the presidents of many of the State medical societies and of the State boards of medical examiners. Dr. Davis was presented to the president of the

association by Dr. JOHN B. ROBERTS, chairman of the committee on anniversary exercises, who said that some fifty years ago at a meeting of the New York State Medical Society there appeared for the first time a young delegate from Broome County. Observation during his collegiate course had opened his eyes to the fact that there were radical defects in the methods of medical education. To remedy these evils and to organize the profession of the United States into a professional brotherhood with a common purpose, a common dignity, a common ethical standard, and a common humanity, he determined to use all the vigor which he possessed. It was his desire to separate medical teaching from medical licensing, and to organize the profession in connection with a central medical body. That his labors despite much opposition had been crowned with success was shown by the existence of a medical examining board in nearly every State in the Union and State medical societies in all parts of the country. The presence of the gentlemen who accompanied him to-day and the registration of two thousand delegates and members attested the approval given to the efforts of the ever-young man, Dr. Davis, whom the speaker then presented to the association.

DR. DAVIS, after being greeted in a few words by the president, then delivered his address. He recounted at some length the history of the origin of the association, spoke eloquently of the principles on which it was organized and the objects it was designed to accomplish, and concluded with a recital of how far, in his opinion, these objects had been attained during the half-century of the existence of the society.

DR. ROBERTS said that diligent search had shown that there were surviving only four of the original members of the association—Dr. Alfred Stillé, of Philadelphia; Dr. John B. Johnson, of St. Louis; Dr. David F. Atwater, of Springfield, Mass.; and Dr. N. S. Davis of Chicago.

Dr. Stillé was not present, but letters were read from Drs. Atwater and Johnson.

What the State Medical Societies Have Done for the People.—DR. GEORGE BEN JOHNSTON, president of the Virginia State Medical Society, spoke for the presidents of the State medical societies, and said it was worthy of note that every State in the union had to-day its medical society, and that, although their ages differed, all were filled with the same spirit and vigor of youth. In the aggregate, he said, they were stronger than the nation's standing army, and all were modelled after the same general plan and had common purposes in view, chief among which were a high code of ethics, the dissemination of useful knowledge, and the protection of public health. He stated that while on the one hand the tendency of increased personal intercourse among the members was to establish sound principles, to excite emulation, and to elevate all to the standards of the best, on the other hand the scientific meetings brought forth the highest talent of the separate societies, with the result that annually scores of valuable contributions were made to medical literature, the scope and importance of which could not be overestimated, and thus the societies acted as great educators, producing and diffusing useful knowledge. It was, however, from another standpoint that Dr. Johnston asked especial consideration of State medical societies. He set forth a great result in practical legislation achieved by these societies in stating that there were but few who could not recall the deficiencies of State laws regulating the practice of medicine existing until very recently almost without exception in every State in the Union. In most States, he said, there was formerly no requirement for a license beyond the mere payment of the tax, but to-day all was changed and now there was scarcely a State in which there was not a sufficient and well executed law by which only qualified men were admitted to practice. He said that the self-constituted doctor and the empiric were rapidly passing away and their places were being filled by competent, intelligent, educated men. The enactment of such laws as now exist was procured through the efforts of the State societies acting independently of each other, and there never was any well-directed attempt at co-operation, which accounted for the dissimilar character of the various statutes and the varying nature of the prescribed machinery for executing them. Yet in every case the object was the same—to furnish the people with only properly equipped practitioners. This called into existence many State examining boards, whose function was to select qualified men. It was soon made apparent that even many holding diplomas were not qualified. Careless and inferior schools saw their graduates excluded from the privilege of practice and their classes diminished, the effect of which was to elevate the standard of medical education. It soon became obvious that these legislative measures had come to stay, national bodies having taken them up, and the second annual meeting of the National Confederation of State Medical Examining and Licensing Boards was a legitimate and natural outgrowth of the efforts of the individual societies. Although yet scarcely more than embryonic, he thought the function of this confederation was well defined, and that it must become the leader in uniform laws regulating the practice of medicine. He also expressed his conviction that State societies ought to confer and co-operate with it to increase its strength and usefulness.

The State boards of health, Dr. Johnston stated, had in most instances been established through the instrumentality of the State medical societies, and were of inestimable value to the public in the way of promulgating the laws of hygiene, the prevention of epidemics, the suppression of those already existing, and the conduct of commerce in times of public fear. The results of the labors of the State societies were improvement in the material from which medical men are formed; the better preliminary education of medical students; the higher technical education of doctors; the binding together of the best medical colleges in a league, the aim of which was to elevate the standard of medical education; the enactment of laws which admit only properly equipped men to enter the practice of medicine; the rapid disappearance of the pretender and the ignorant quack, and the presence in every village or hamlet of a medical man whose character and attainments entitle him to rank with the best of his community, whose professional acumen and honesty fit him to discharge the duties of his high calling with confidence, skill, and success, and whose trained faculties constitute him the guardian of the public health.

Resolutions of sorrow for the death of Dr. Jerome Cochran, of Alabama, were adopted.

Officers.—The nominating committee put in nomination: *President*, Surgeon-General George M. Sternberg, U. S. A.; *First Vice-President*, J. M. Mathews, of Kentucky; *Second Vice-President*, W. H. Thompson, of Indiana; *Third Vice-President*, S. H. Wiggin, of New York; *Fourth Vice-President*, Thomas J. Happell, of Tennessee; *Treasurer*, Henry P. Newman, of Illinois; *Secretary*, William B. Atkinson, of Pennsylvania; *Assistant Secretary*, W. A. Jayne, of Colorado; *Librarian*, George W. Webster, of Illinois; *Chairman of Committee on Arrangements*, J. W. Graham, of Colorado.

To deliver the address in medicine, J. H. Musser, of Philadelphia: in surgery, J. B. Murphy of Chicago; in State medicine, Samuel C. Busey, of Washington, D. C.

Denver was selected as the next place of meeting.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

(Continued from page 788).

AMERICAN SURGICAL ASSOCIATION.

Second Day—Wednesday, May 5th.

Operative Treatment of Irreducible Dislocations.—DR. EDMOND SOUCHON, of New Orleans, La., read a paper with this title. His study was based on one hundred and forty operated cases. All irreducible dislocations, recent, simple, or complicated with fracture, that were operated by reduction or resection, have given good results with two exceptions, in which death does not seem to have been due truly to the operation alone, but to complication of shock, unusually severe at that. Irreducible dislocations, old, simple, and forward, operated by resection through an anterior incision, are the most frequent, fifty-six cases against thirty-three by arthrotomy and reduction. Results remote show a great mortality in resection from injuries to vessels, mostly from sepsis, but this is avoidable with special care. The fatalities in reduction are due to sepsis, now preventable. The disadvantages of reductions are necrosis of the cartilage and of the bone of the head, calling later for sequestrotomies and resection. This probably is due to the greater dissections and denudations of the head and surgical neck necessary to reduce than simply to resect the head. Reduction is a more desirable operation than resection, because it preserves the head and all the movements depending thereupon: but the necrotic consequences are serious drawbacks, as is also ankylosis, which sometimes follows the reduction. The anterior incision is the one to be made in all forward dislocations. Cases reported as operated by subcutaneous section of fibrous bands, of tendons, of muscles, and by osteotomy, have given good results, but they are very few. Old and downward dislocations, four in number, were all treated by the axillary incision with resection, *i.e.*, removal of the fractured head more or less loose in the axilla, with favorable terminations. In one case, however, the head was "pegged back" and reduced, with a good result. One downward dislocation (Despré's) was treated by osteoclasis, but it was a failure, no false joint forming. Yet there are cases on record of forward dislocations in which the bone was fractured near the head or through the surgical neck during efforts at reduction, and which yielded a fair enough result. Old and backward dislocations in the adult have been reported twice. They were operated by resection with a very ordinary result. Congenital irreducible dislocations have been operated upon several times; they were old backward dislocations. Two cases were operated upon by reduction: one subject died; the other had to have the sequestra removed, and then did well. The result in the third case is not stated.

DR. J. EWING MEARS, of Philadelphia, thought the term irreducible should be changed to unreduced when applied to dislocations. He did not think any case irreducible when operative interference could be employed. He thought it was an important and practical point to decide when a dislocation should be termed an old one. He would term a dislocation an old one when it was deemed inadvisable to make manipulation efforts, *i.e.*, at the end of about six to eight weeks. He would make it a rule not to attempt to manipulate after that time. operative procedures should then be instituted for its relief. The speaker discussed the indications for operative interference in old dislocations, which were two in number—disability and pain. In operation for disability he advised section above the surgical neck. There was danger of limiting or destroying the action of the internal and external rotators. If the disability was not marked, he advised the use of massage and other measures. For the second indication, pain, it was undoubtedly the duty of the surgeon to interfere.

DR. JOSEPH RANSOHOFF, of Cincinnati, said it was only when dislocations were complicated that primary reductions were attended with difficulties. The speaker summarized in regard to the advisability of operative interference as follows:

1st. Immediate operative interference is indicated when ordinary methods of manipulation have failed.

2d. In irreducible dislocations operations should not be delayed until irremedial changes have taken place in the capsule or about the humeral head.

3d. In old standing cases the conditions found must determine the choice between arthrotomy and resection.

4th. In unrecognized dislocations of long standing, one year or more, only grave symptoms must be recognized as indications for interference.

5th. Special attention should be given to the prevention of sepsis—sepsis so often causes death, or by destruction of the humeral head or obliteration of the joint cavity has frustrated the very object of the operation.

Tendon Transplantation.—DR. E. H. BRADFORD, of Boston, read a paper on this subject. He said that infantile paralysis is the despair of the neurologist and has not been called to the attention of the surgeon as it should have been until recently. Tendon transplantation is of value only in the lower extremities. Over fifty cases have been operated upon in this country and the results are gratifying: the operations should be looked upon as being of great value. The speaker discussed briefly tendon transplantation for various conditions. He illustrated and briefly described his method of transplanting one of the peroneal tendons from the outer to the inner or paralyzed side, so giving a live muscle to reinforce a weakened or dead muscle. When the muscles attached to the tendo Achillis are paralzyed, one of the tibials or one of the peroneal tendons, or both, can be transplanted and stitched to the tendo Achillis; if necessary the latter can be first shortened. He wished to call attention to the fact that the sartorius muscle when paralyzed does not lie in its usual position, but is dropped more toward the posterior surface. Transplanting the sartorius on to the rectus femoris has been done with satisfactory results. We should remember that the rectus femoris has but little tendinous structure, it being made up almost entirely of muscular structure. This should make us the more cautious in sewing to make it strong enough to withstand the strain submitted to it. The results of tendon transplantation have been good and have stood the tests of time. One should be sure that he had a live muscle to deal with. This is easily determined in the adult, but in children it is often attended with great difficulty. It is important to know that the tendon transplanted is sufficiently strong to do the work. One should use good judgment in selection of cases. All cases have been followed by immediate improvement after operation. The question will arise: Can muscle which has been transplanted stand the work for any length of time? Cases which have been under observation for years have answered that question satisfactorily. Results have been particularly good in the lower extremities. The patella

sometimes slips to the outer side, owing to elongation of the ligamentum patellæ; when this condition exists it is important to shorten this ligament and also to transplant it to the inner side. He detailed the operation he had done with satisfactory results. The ligamentum patellæ was almost divided by an oblique incision running from above downward and inward. The inner triangular portion was switched off to the inside and fastened to the fascia of the leg. In an instance of this kind the operation, as first suggested and performed by Dawbarn, of New York, might be done. Dawbarn transplants the whole tubercle of the tibia to such another position on the tibia as will correct the displacement.

The Surgical Treatment of Suppurative Pericarditis.—Dr. John B. Roberts, of Philadelphia, read a paper with this title. He said that in 1876 he had suggested that pus in the pericardium be treated by drainage, and that this method had now been adopted in a considerable number of cases. He had collected a total of twenty-six cases of suppurative pericarditis treated by incision and drainage; ten subjects had recovered and sixteen had died. This made the ratio of recovery 38.4+ per cent. The results were, however, much more favorable than this would indicate, because of the sixteen subjects that died nine were septic when operated upon, and therefore not likely to survive. The remaining seven fatal cases all had complications, such as empyema, cardiac disease, or lesions of the lungs or pleura. He had obtained hints of one or two more cases, which he hoped to add to his table. Pericardotomy with drainage was advocated as the only method of treatment; and was to be employed as soon as the diagnosis of pyo-pericardium was made. Diagnosis between pus and serum in the pericardial sac could be made only by an exploratory puncture with a trocar or aspirating needle. The best point for the exploratory puncture was said to be in the xiphoid fossa of the left side close to the angle where the xiphoid cartilage and seventh costal cartilage unite. Irrigation of the pericardial cavity was advocated in shreddy membranous effusions, but not in cases in which the pus readily escaped through the incision and drainage tube. The danger of wounding the pleura and causing a complicating pleuritis by direct infection had led the author to devise and advocate a method of resecting the costal cartilages, which he believed was a valuable improvement in technique. He made a trap-door opening into the chest, by resecting portions of the fourth and fifth costal cartilages, and turned the chondro-plastic flap upward on a hinge. Thus he exposed the internal mammary vessels, lung, and pleura, which were pushed to the left without injury, uncovering the pericardium, which was then readily opened. A demonstration of this new operation was made on a cadaver.

Third Day—Thursday, May 6th.

Origin of Appendicitis.—Dr. Dudley P. Allen, of Cleveland, presented a paper with the above title. In operations for appendicitis in chronic cases unattended by abscess or inflammatory adhesions, the writer had observed, first, that in almost all cases there was a bend or flexure of the appendix; second, that at the point of flexure there was also a stricture; and third, that distal to the stricture were marked distention of the appendix and great thickening of its walls. Microscopic sections of the appendices thus removed show, first, that there were no evidences of inflammatory processes externally; second, that the muscular coats both longitudinal and circular were greatly thickened, in some cases to about five times their normal thickness. The stricture of the appendix sometimes entirely occluded its lumen. On the supposition that the bend in the appendix was the first step in appendicitis, its further progress could be explained as follows: the bend embarrasses the escape of the contents of the appendix into the intestine, just as a bend in a piece of rubber tubing prevents the flow of water through it. In order to empty itself of its contents, the muscular walls of the appendix are compelled to perform an extra amount of work. This produces a very marked degree of muscular hypertrophy. As a result of the pressure thus caused by the effort of the appendix to empty itself, the mucous coat at the point of flexion becomes eroded and inflamed, and the functional stricture finally terminates in an organic stricture. The effort of the appendix to empty itself causes recurring attacks of pain, which are similar to those of biliary or nephritic colic. When the appendix has discharged its contents the pain ceases. After a time, either on account of the increasing stricture or an impacted concretion, the appendix is no longer able to empty itself. Distention then increases to the point of perforation, and peritonitis ensues. The reason for assuming that the bend in the appendix is primary rather than secondary is that it is found bent in many cases in which there are no external evidences whatever of inflammation. The varying positions occupied by the appendix make it evident that it has no regular position. The variation in position is accounted for by the development of the appendix and cæcum during fœtal life. The cæcum originally occupies the right hypochondriac region. From this it gradually descends into the right iliac fossa. Both cæcum and appendix have their own mesentery. The process of descent causes a change in the relations of these organs to each other, and with this change in certain cases a bend of the appendix takes place. If this bend is sufficient to make the emptying of the appendix impossible, there gradually ensue those conditions of obstruction which terminate in appendicitis. The conclusion of the writer is, therefore, that appendicitis is in most cases a disease which results from gradual processes having their origin in fœtal development.

The Technique of Intracranial Surgery. — Dr. L. M. Tiffany, of Baltimore, read a paper on this subject. The speaker made a sharp distinction between traumatic and pathological operations, which were different in technique and outline. In the one, the general conditions were not known and we must operate at once; in the other, we could take more time and general conditions could be studied. The best way to gain access to the brain was by an osteo-cutaneous flap; the larger flap was the best flap, which should be fashioned in such a way as to give the best possible nervous and blood supply. If the opening is not large enough, it should be made so; he emphasized the importance of large openings. The operator must decide for himself the method of opening, whether by chisel, forceps, or saw. After operation upon the sides of the head, there is but little depression to be noted, whether bone is replaced or not. The time taken in opening the skull he considered to be of great importance. He thought it best to do operations in two stages. In the first stage, the bone should be attacked; in the second, the soft parts should be operated upon. The dura should be divided at a certain distance from the bone, to allow suturing. He usually considered the dura the same as a serous membrane anywhere. He referred to the great importance of cleanliness. In regard to hemorrhage from the skin, he had not had to resort to putting a ligature about the head. He used the hæmostatic forceps and a T-shaped bar. In hemorrhage from the bone, he had never found it necessary to plug; crushing bone with forceps usually sufficed to control it. If

hemorrhage occurred from the dura, he used ligatures; if from a large sinus, he sutured; otherwise he used pressure by gauze packing. He almost invariably used floss silk, of very fine pieces. Gauze packing had served good stead in one instance he related, in which the blood welled up enormously; many yards of gauze were used. In all operations about the head he preferred chloroform. Congestion of the head is marked with ether, but not so with chloroform. He had observed that during etherization the veins of the forehead swelled up very much, and that when he ordered a change to chloroform to be made this swelling disappeared. In regard to the recognition of the brain area presenting, he referred to cerebral topography and electric stimulation by instruments made for Dr. Keen, which were of great service. One could not recognize the consistence of any growth until one cut down upon it. Time and again had fine instruments been passed into a growth without its being recognized. The best instrument for determining the consistence of any growth was the finger. In speaking of the removal of intracranial structures, he said we did not know much about it. The restoration of function of cranial structures did certainly take place. He drew a fast line between encapsulated and infiltrated growths. With the latter the patient never does well, but usually dies. When the dura was adherent to the growth and was removed, the lost dura could be replaced with gold foil. In closing the wound, one could use bone, celluloid, and other material, but he only used gold foil. He had seen patients two years after operation, and they had done well with gold foil. He never entirely closed a wound when the operation was extensive; he always felt safer when drainage, as by gauze, was instituted. If he was certain that hemorrhage was entirely arrested, he might close the wound. He always sewed with silkworm gut, which held extremely well and never with him had caused suppuration.

Dr. W. W. Keen, of Philadelphia, opened the discussion. Two years ago, when abroad, he was struck by the fact that no disinfecting was done until the moment of operation. The patients were not uncommonly subjected to examination by members of the class and disinfection was done afterward. He did not know the results which followed as regards sepsis. He certainly believed in disinfection before operation. In regard to the best way of gaining access to the brain, it depended upon what we wished to do; for instance, for abscess he used the trephine; for tumor, it was necessary to make a very large flap, and as a rule he used Pyle's chisels, which he considered superior to Hartley's. With them he could remove one-quarter of the skull at one operation, or even one-half, as reported. The dental engine he did not use, for the reason that he was not accustomed to it and had not the manual dexterity necessary to run it; it was liable to penetrate cerebral substance. The chisel took longer. He did not trust dentists to use the engine, on account of their not being acquainted with asepsis. He thought the great objection to the chisel was the difficulty of its use and the length of time taken in penetrating a thick skull. In speaking of the question of replacing bone after operating, he said he had done so and never had met with disaster. The bone once lost its vitality in a case intrusted to an assistant. The care of the bone must be scrupulously attended to. If bone was not replaced, a membrane filled the aperture without much deformity. The speaker emphasized the importance of Dr. Tiffany's division of the operation into two stages; he thought the second operation should be done one or two months after the first. A prolonged interval is better than the brief one allowed heretofore. No surgeon ever meddled with a fresh wound; the second operation should certainly be delayed until the wound was healed. The two great difficulties to be overcome were: (1) Length of time necessary in opening by chisel; and (2) hemorrhage. The hemorrhage was the most dangerous of all problems of intracranial surgery to be solved.

Dr. R. F. Weir, of New York, wished only to emphasize certain points. First, in regard to hemorrhage from the scalp, he did not believe it was always easy to control. He had tried a number of devices. Rubber bands were serviceable, but pads should be placed in the temporal fossæ. Another point he called attention to was the matter of opening the skull. This was not to be accomplished quickly. He had given up the use of the chisel. He had found the skull one-fourth of an inch thick. He seldom resorted to the use of the osteoplastic flaps, for the reason that in these operations he operated mainly for acute traumatisms, malignant and tuberculous tumors, and in these cases he did not wish to replace a flap which was liable to cause the patient any trouble afterward. In exploratory incision he followed Horsley and used the electric saw. He first took out a button of bone, then passed through this the dura protector, and then set the saw to work. The objection to the saw was that it spattered so. The flap was then turned down, and was done in less than ten minutes. As a rule, he left the wound open. He had used a celluloid plate. Gold foil he had used twice; granulations might penetrate the gold foil.

Dr. J. Parmenter, of Buffalo, uses the gouge and hammer in entering the skull, which permits speed. The disadvantage claimed for it is the cerebral commotion which is thought to follow, but which he does not believe in; he has never seen that result follow. The surgical engine and electric saw he has used. If the cranial bones are vascular he does not object to the use of the latter, but if they are non-vascular he does object to its use. He makes a crucial incision through the dura. The Esmarch bandage about the head causes venous congestion. He controls hemorrhage from the scalp by means of sutures so placed as to compress the vessels. Bleeding from bone he controls by crushing the bone with sequestrum forceps. Sinus wounds he controls by lateral ligature. If the hemorrhage is from the cortex he tampons; this is the only practical way of arresting the hemorrhage. He has tried solution of antipyrin, but this may leave injurious after-effects. In regard to the recognition of the brain area, the electrical test is only one method we can use with assurance. He spoke of the bad practice some surgeons have of pushing fingers in between the dura and the brain. He never drains the wound if he can avoid it. He believes drainage is less necessary than we are apt to think it.

Dr. S. J. Mixter, of Boston, believes in making extensive skin flaps. In opening the skull, the trephine must often be used. He thinks it a great mistake to use the large trephine, on account of its being so awkward and clumsy; the trephine should not be over three-fourths of an inch in diameter. The use of the chisel is especially convenient about the line of the squamous suture. He advocates dividing the operation into two stages. He advises that a piece of gold foil, gutta percha, etc., be placed beneath the skin flap to prevent adhesions during the interval. Hemorrhage from the lateral sinus he has seen a number of times, and never has there been any trouble that slight pressure would not overcome. If the hemorrhage is from the deep sinus, the question becomes more important. The speaker then referred to the amount of pressure the brain will stand from packing. The question may arise as to whether a fatal result may not be due to the pressure on the brain.

Ureterectomy.—Dr. Christian Fenger, of Chicago, spoke briefly on this topic. He referred to the

(1) primary operation, in which the ureter is removed simultaneously with the kidney (Kelly, Tuffier, Postnikow, and Elliot); (2) secondary operation, in which after nephrectomy the removal of the ureter of the same side becomes necessary (Reynier, Poucet); (3) total operation, in which the entire ureter is removed (Kelly, two cases; Reynier); (4) partial operation, in which only a portion of the ureter is removed (Tuffier, Kelly, Postnikow, and Poucet). Of the methods of operation, he referred to: (1) Transperitoneal (Kelly, 1893; Postnikow, 1892). (2) Extraperitoneal (Kelly, 1895, two cases; Tuffier, 1891; Elliot, 1896; Reynier and Poucet). (3) Sacral. (4) Transvaginal (Kelly). Ureterectomy has been performed for: (1) Tuberculosis. (2) Suppuration in the dilated ureter. (3) Hydro-ureter, non-infected dilated ureter. A primary total ureterectomy was performed by Kelly in 1896. A primary partial ureterectomy was performed by Tuffier in 1891, by Kelly in 1893, and by Postnikow in 1892. A secondary total ureterectomy was performed by Reynier in 1892. A secondary partial ureterectomy was performed by Poucet in 1894.

Dr. A. T. Cabot, of Boston, said that in 1891 he read a paper on the anatomical relations of the ureter. The ureter could be reached by the Israel incision, which was the one he preferred. He thought that the transperitoneal method was at fault. He saw no reason for invading the peritoneal cavity when it could be avoided. Removal of a portion of the ureter had been done repeatedly. The question arose: Shall we remove the last few inches of the ureter or not? He could not see any special advantages in Kelly's operation of transplanting the end of the ureter into the vagina. In operations of this sort we had not yet had sufficient experience to guide us. It seemed to him that the operation of ureterectomy was hardly called for except in extensive suppurations or in cases of tuberculosis. In tuberculous cases the ureter should be cut off as low as can be, and the remainder taken off later if necessary to complete the operation.

Successful Treatment of Sarcoma.—Dr. J. McFadden Gaston, of Atlanta, Ga., read a paper with this title, and described a recent case. The proportions of the tumor underwent a gradual and constant diminution, with some induration continuing near the right horizontal ramus of the pubic bone after it had disappeared entirely from all other parts, and after the incision had completely healed over. The edge of this induration became distinct to palpation as separated from the bone during the latter part of the year 1896, and it was a consoling inference that the bone was not involved in the disease. The positive electrode with the medication had been applied above the line of the cicatrix, and the negative electrode had been placed over the indurated tissue between the cicatrix and the pubic rim of the pelvis, so as to bring about the removal of this deposition. On the 1st of January, 1897, no trace of induration was any longer present, but to make assurance doubly sure he had thought it best to keep up treatment. He was prepared by the foregoing considerations to make the following inferences:

1. The diagnosis of sarcoma being made by clinical observation and confirmed by the microscope, there ought not to exist any question as to the nature of the disease.

2. The evident adherence of the tumor to the abdominal viscera, and especially to the front wall of the abdomen, precluded surgical interference with the knife, and thus placed the case under the class of inoperable tumors.

3. There being a reasonable ground to expect some benefit in malignant growths from medicinal treatment, the combination of mineral and vegetable alteratives afforded the best prospect of relief in this condition.

4. The history of the treatment of benign tumors with the continuous galvanic current gives encouragement for its application in cases of a malignant type, and especially in that variety of neoplasm, known as sarcóma, in which its efficacy has been recently tested.

5. It is not requisite to employ a destructive or disintegrating effect of the continuous electric current to secure the favorable action upon tumors, and the process of electrolysis may be initiated with a few cells and gradually increased, without disintegration at either electrode.

6. This treatment may be commenced with the needle at the positive pole and the sponge electrode at the negative pole of the Waite and Bartlett battery, and so placed as to pass the current through the substance of the tumor. After the daily application thus for a week or ten days, the needle may be used with the negative pole and the sponge with the positive pole, the applications being made on alternate days.

7. The employment of cataphoresis, in which medication is applied upon the positive sponge electrode, while either the needle or another sponge electrode is connected with the negative pole, induces some irritation of the skin where the medicine is applied and conveys its properties into the substance of the tumor.

8. While the exact estimate of the force of the electric current would promote scientific results, the clinical observation of the effects upon the tissues subserves all practical purposes in the treatment of tumors by electrolysis and cataphoresis; and it is not requisite to be provided with the appliances for measuring the voltage and amperage or ohms of resistance in the use of a battery.

9. The time occupied in accomplishing a cure by the moderate current of electricity is greater than that which would be taken in a more violent application, yet the freedom from any destructive process renders the former more satisfactory to the patient.

10. This case, added to those already reported, in which medicated electricity has been efficient in the removal of malignant tumors, should warrant the profession in resorting to this mode of treatment. The writer can further vouch for the efficacy of internal medication with electrolysis and cataphoresis in the treatment of sarcoma.

11. Theoretical views in regard to the origin of malignant tumors should not prove a barrier to the adoption of general and local measures of treatment, which have been employed with satisfactory results in a case clearly diagnosticated to be sarcoma. Clinical observation in the progressive development of this neoplasm, with macroscopic and microscopic tests, clearly indicate its malignant character.

12. The process of atrophic decomposition and resorption of the sarcomatous structure under the operation of the medicated electric current favors the expectation that tumors of a carcinomatous nature may undergo like changes with similar treatment. We are therefore warranted in resorting to cataphoresis as a tentative measure of treatment for all kinds of malignant neoplasmns.

A Preliminary Comparison of Methods and Results in Operative Surgery at the Sea Level (New York) and in Places of High Altitude (Denver).—Dr. Charles A. Powers, of Denver, read the paper. After briefly outlining the general climatic conditions of Colorado, the author cited details of two hundred and forty-eight operative cases which had been under his care there, contrasting them with similar cases seen in surgical work in New York City. Certain modifications are found to obtain, particularly in the administration of anæsthetics and in operations upon the tuberculous. Differences, are, however, but slight, the author summing up his provisional conclusions as follows: (1) Operative surgery in dry climates having an altitude of one mile or thereabout is to be pursued

on the same general lines which govern it at the sea-level. However, (2) care must be exercised in subjecting those recently from a lower altitude to severe or prolonged surgical procedure, especially if the patient be a pulmonary invalid or if he exhibit cardiac weakness. And (3) it would seem that those who are thoroughly acclimated bear operation rather better when at home than when they go to tidewater, and this again is particularly true of patients afflicted with pulmonary tuberculosis. (4) Ether must be employed with greater caution and is more of an irritant to the respiratory mucous membrane. Chloroform may find wider employment than at the sea level. (5) The loss of blood seems to be rather less in the high, dry climate, possibly excepting cases in which the operative field is the seat of chronic inflammation. (6) Shock also seems to be less pronounced; patients rally rather more quickly after operation. In the tuberculous this feature seems to be marked. (7) Aseptic wound management must be the same in all regions. Infection when it occurs doubtless makes less progress in a dry atmosphere than in one containing a greater degree of moisture. (8) It is believed that accumulated statistics will show that operations for surgical tuberculosis are attended by a greater permanency of healing in the high altitudes, and that patients presenting such lesions, but whose lungs are yet free, do all possible to ward off pulmonary invasion by taking up their abode in such a climate as that of Colorado.

Symptoms and Treatment of Hepatic Abscess.—Dr. George Ben Johnston, of Richmond, Va., read a paper with this title. The subjective symptoms of hepatic abscess are pain in the region of the liver, usually constant and radiating backward and to the right shoulder, of dull aching character; less acute when the abscess is deep seated, but more acute when the abscess is near the surface and perihepatitis is present. Sharp pain caused by movement of the liver in the respiratory act may provoke dyspnœa. Profound depression and lassitude are out of proportion to the gravity of the disease and appear early, and insomnia may be an enduring symptom. Restlessness, headache, and irritability of temper are present in some cases. Sometimes lethargy and somnolence supervene. An abscess on the upper surface often produces irritating cough which the recumbent posture increases. The digestive disturbances are loss of appetite or perverted appetjte. The breath is often fetid and eructations are usually present; nausea is a variable symptom, and there may be vomiting after the ingestion of food. Diarrhœa or constipation may exist or alternate. The tongue is fiery red or denuded, and glazed or heavily coated with yellowish-white fur, in which case the margin and tip are usually very red. The most invariable of the objective symptoms is enlargement of the liver, as evidenced by bulging of the right hypochondrium. There is pronounced muscular rigidity over the affected region. On palpation, a large, smooth, and elastic tumor is felt. Fluctuation is often present and is then a most valuable symptom, but it is demonstrable only when the abdominal walls are very thin and relaxed. Jaundice occurs only when the common bile duct is occluded by pressure or when catarrh of the ducts is present. The posture is almost characteristic. Right-side decubitus is maintained when the abscess is near the front or on the under surface of the organ. If it is on the diaphragmatic surface, the body will be raised and inclined to the right. The thighs are flexed on the abdomen. Progressive emaciation is a conspicuous feature. The temperature is erratic in its course. Subnormal temperature is frequent. This in the presence of other symptoms is suggestive of hepatic abscess. It is not so apparent in other septic processes. The urine is of deep color, high specific gravity, and usually contains abundant deposits of urates. The most constant and therefore most valuable symptoms are: history in which dysentery and chill appear, general malaise, pain and tenderness over the liver, enlargement of the liver, hectic, sweats and rigors, right-side posture, erratic temperature, progressive emaciation, and gastric disturbances. The treatment should be prompt, bold, and radical. No measure is successful which fails completely to evacuate the abscess and allow free drainage. This can be done with precision and safety only by incision. Aspiration, puncture with trocar, direct puncture with scalpel, opening by caustics or thermo-cautery are uncertain, insufficient, dangerous, and unsurgical. Entrance to the liver may be transperitoneal or transpleural, but the latter increases the gravity of the situation. The line of incision is to be determined by the position of the abscess. If adhesions are found between the liver and the abdominal wall, the abscess may be opened immediately, an aspirator needle being used to locate the cavity with accuracy. If there are no adhesions the operation may be done in two sittings, the wound being packed and the adhesions forced; or it may be single, the margins of the hepatic wound being stitched to a deeper portion of the superficial wound. In passing through the pleura, resection of one or more ribs is necessary. The pleural incisions on the parietal and diaphragmatic surfaces must correspond, the cut margins being sewed together with continuous suture of fine catgut forming a "buttonhole," through which the diaphragm is opened and the operation continued. The opening into the liver should be as free as is consistent with safety. If the cavity is large, drainage may be provided by the use of one or more large drainage tubes and a light gauze packing. Packing suffices for small cavities. Healing is usually rapid. If slow, constitutional treatment and stimulation of the abscess walls by two-per-cent. carbolic solution will usually hasten recovery.

Officers.—The following officers were elected: *President*, Dr. Theodore F. Prewitt; *Vice-Presidents*, Drs. J. McFadden Gaston and Maurice H. Richardson; *Secretary*, Dr. Herbert L. Burrell; *Treasurer*, Dr. G. R. Fowler; *Recorder*, Dr. De Forest Willard.

The next meeting of the association will be held at New Orleans as near April 20th as possible.

ASSOCIATION OF AMERICAN PHYSICIANS.

Second Day—Wednesday, May 5th.

Pancreatitis Followed by the Formation of a Cyst.—Dr. A. McPhedran, of Toronto, read this paper. The speaker first saw the patient in 1891. He had repeated attacks of pain over the region of the pancreas, which grew in frequency. He went away for the summer to the seaside and came back worse. Gall stones were diagnosed and an operation was advised. On September 6th he had intense pain, prostration, and vomiting. These lasted for three days. Fever was 105° F. Then he began to improve but was still uncomfortable. He was given Carlsbad salts and ordered a light diet. On October 5th he had decided pain again over the pancreas. On October 8th a large cyst appeared on the epigastrium extending to the right over the pancreas. An operation was done and the temperature sank to 99.5° F. A clear serous liquid was obtained. At the bottom of the wound the pancreas was felt as a hard mass. The liver was normal. The gall bladder was not reached. The opening was closed without drainage. The pulse was 130; temperature, 101.5° F. He had cyanosis and dyspnœa ten days later. The fluid was a clear serous liquid with some purulent characters, and was probably the result of fat necrosis. The pancreas seemed to be increased

in size. In January he was much improved and went to his office. He suffered from indigestion. The urine was free from sugar. In the following March another operation was performed and a cyst with walls two millimetres thick was found. The fluid was thick, or flocculent, and alkaline, and contained albumin. There was no digestive ferment present. A good recovery was made, but a fistula persisted. The discharge was free and the skin was excoriated. The fluid now looked like pancreatic secretion, and it possessed some digestive powers. The general health continued good. The sinus still persisted, and the discharges continued. The first attack and subsequent ones were undoubtedly due to the beginning trouble in the pancreas. He referred to the simple, the hemorrhagic, and the suppurative pancreatitis, and mentioned the work of Fitz and others. The contents of the cyst were interesting.

Angina Pectoris.—Dr. J. H. Musser, of Philadelphia, read a paper on the relation of angina pectoris to dilatation of the heart. He said that patients who have had an attack or attacks of angina pectoris are relieved of the paroxysms if dilatation of the heart supervenes. Often, if dilatation persists, the patient may live for years and no other paroxysm occur. It seems the pain, as long ago pointed out, is due in large part to the stretching of a tense ventricle from intracardiac pressure. Such stretching is not so likely to occur in dilatation, because of "safety-valve action" in the heart. The idea appears to explain the infrequency of angina in the young; in mitral valvulitis with regurgitation; in women, possibly; and in the occupants of infirmaries and hospitals. In the latter class the vigor of the heart muscle is lessened from lack of food, etc. Certainly it is not because of the absence of atheroma of the coronary arteries, for endarteritis is very prevalent among senile, usually alcoholic, perhaps syphilitic inmates of the hospitals and almshouses. If the contention is true, the diagnosis, prognosis, and the treatment tentatively admitted are influenced thereby—the diagnosis, in that angina-like paroxysms in dilatation of the heart are probably not due to true angina pectoris; the prognosis, in that, if, as rarely happens, an undoubted attack of angina occurs in a case of valvulitis with dilatation, and even failing compensation, on the one hand the patient is not likely to perish from the angina, because of the safety valve, while, on the other hand, it indicates that there is sufficient strong muscle fibre to insure cardiac recuperation. Further, if a patient subject to attacks of angina presents signs and symptoms of dilatation, the angina will disappear, or at least never be so severe as to terminate fatally. That the pain is due to intracardiac pressure is more possible, because of the presence of dilatation of the heart in angina sine dolore.

Dr. Wharton Sinkler, of Philadelphia, said that the question of the cause of pain in these cases was of great interest. Dr. Musser's explanation does not seem to explain. We have also a pseudo-angina with great pain, and he related a case which simulated closely true angina, and in which one grain of morphine at a dose was given to relieve the pain, but which failed. In this case he had no evidence of disease of the heart at any time.

Dr. H. C. Wood, of Philadelphia, asked what was the cause of increased ventricular pressure in these cases. They can come from the condition of the heart itself. If angina pectoris is due to increased intraventricular pressure, we would expect the arterial system to play the chief rôle and not the heart. The action of nitrite of amyl is interesting in this connection. It relieves the aorta and takes away the resistance of the heart. Digitalis has a curious effect; and its use suggests this theory: If angina pectoris can be stopped by hypodermic injections of the nitrite of amyl, we can, if we give enough aconite, do away with intraventricular pressure altogether. If this is true, digitalis must be death to the heart in angina pectoris.

Dr. E. G. Janeway, of New York, mentioned a case of a man who had sudden pain over the heart and pain on the right and not on the left side. He was ashy pale. Dr. Janeway made a diagnosis of pericarditis and thrombosis of the coronary arteries, and partial rupture of the heart. The patient seemed to be getting better, when one day he sat up in bed and said he was going to get up, and fell over dead. The autopsy showed disease of the coronary arteries with rupture of the septum of the left ventricle and thrombosis of the right coronary artery. Dr. Musser's theory did not explain all this.

Pericarditis.—Dr. F. C. Shattuck, of Boston, said that pericarditis is often overlooked. The disease is well known. Rheumatism is the most frequent cause. Endocarditis and pericarditis often coexist when they are not suspected together. Often, especially in children, one does not see the beginning of the disease. It often comes from pneumonia. There is a very frequent association of pneumonia and pericarditis. In fifty-seven cases of pneumonia in his ward, twenty came to autopsy, and thirteen of them had pericarditis; five were detected during life and eight were not found in life. Thirteen were affected on the right side and six on the left. Osler reports only five in one hundred autopsies. The symptoms are not to be relied on. There may be none, especially if the effusion is dry or small. The primary disease is so severe as to mask complications, which are often less severe than the original disease. The less severe the original disease, the greater the necessity to look for complications. The diagnosis must rest on the physical signs. The friction sound is circumscribed. and may disappear between the examinations. He has often been chagrined by bringing cases before his students and finding no friction. Pleuro-pneumonia friction may be of pericardial origin. In many cases the pericardial effusion was looked for carefully and not found. In some cases no autopsy could be obtained and in one case the undertaker told him that when he embalmed the body a large amount of fluid came out of the pericardium. Dry pericarditis is hard to detect. The shape of the dulness is in his experience not pyriform or triangular, but similar to that of general enlargement of the heart. He does not find this triangular shape of the sac, but by percussing the cadaver carefully and sticking in pins at the edge of the dulness he is able to map out the heart itself. The change in the percussion note is important. He does not find the chest bulging out in pericarditis, as had been stated it did. The heart and lungs are pressed away from the chest walls. In six cases there has been repeated and sudden collapse. The diagnosis should not be difficult. Treatment other than rest is of little use. The effusion increases or diminishes with or without medicine. Opium for pain and alcohol are indicated. Blisters are of no use. Ice packs may be used for the comfort of the patient. With this treatment in seven cases six ended successfully, and he knows he saved two subjects who otherwise would have died. Absorption may follow the withdrawal of a small amount of the liquid. There is no hard and fast rule when to aspirate and when not. Each case must be treated on its own merits. He uses a moderate-sized cannula with trocar and side switch. His point of election in tapping is in the fifth interspace, one or two inches to the left of the left nipple. In one case he withdrew sixteen ounces of fluid, and in another thirty-six.

Dr. James T. Whittaker, of Cincinnati, spoke

of the latency of the disease. It is often unrecognized until the post-mortem is done. He thinks that a clear pericardial fluid due to tuberculosis will be found in many cases. He lets the stethoscope hang in the ears, just touching the recumbent patient, and he gets very delicate results in auscultation. Every case he suspects he taps in the second or sixth interspace, and often finds fluid there when he can get it nowhere else. He always feels the impulse of the heart against the cannula and knows he is in the right place.

Dr. Peabody, of New York, mentioned a case in which he introduced the trocar, and the cannula was stopped by a piece of cartilage.

Dr. H. A. Hare, of Philadelphia, said the danger of injuring the heart in tapping was not so severe as many believed. He had stabbed several dogs in the heart, and got no fatal results unless the heart centres were wounded, and they were not often struck. He examined these dogs later and found the heart wound healed and a little blood in the pericardium. He had a case of acute articular rheumatism which later developed pericarditis. He tapped twice and once punctured the heart. Later the man died and the heart wound was found healed. He asked if members thought that digitalis was the best heart stimulant to give.

Dr. Rotch, of Boston, said that Dr. Hare's work agrees with what he has done. It is hard to make a diagnosis, and the usual signs fail. The heart is floated up on the effusion. Tapping is done below and to the left with safety. It is better to avoid the heart if possible. He referred to a case, and said also that he had found that often there was a dull spot behind at the angle of the scapula where tapping could be done.

Dr. Norman Bridge, of Los Angeles, Cal., referred to several cases in his practice in which the effusion was slight and the diagnosis was very difficult.

Dr. James Tyson, of Philadelphia, said he had always found the triangular or pyriform dulness in pericarditis, and thought that Dr. Shattuck was almost too literal. We ought not to let the blister go in the treatment of pericarditis. It will save tapping sometimes.

Nervous Deafness in Diphtheria.—Dr. J. C. Wilson, of Philadelphia, reported a case of this unusual disease. The disease was in a married woman, aged thirty-three, with a follicular tonsillitis. There were sore throat, moderate fever, occipital headache, tinnitus aurium et cerebri, and albuminuria. She gave no history of syphilis. On the fourth day there were a dense pellicular exudate on the right tonsil, conjunctivitis, increased deafness, and albuminuria. The isolation was complete, and although antitoxin was injected later there was total deafness with slight vertigo, although some idea of sounds by contact could be obtained. He thought it was a disease of the labyrinth. There were great chemosis and gradual defervescence by the thirteenth day, at which date there were partial paralysis of accommodation, together with paresis of the extensor muscles of the head, persistent headache, slight vertigo, and absolute persistent loss of hearing. He found on looking up the subject that sudden, total, permanent bilateral deafness is very rare. Antitoxin was given three hours after the clinical diagnosis, and there was no reaction and no effect on the temperature.

Types of Œdema in Infancy and Early Childhood.—Dr. J. P. Crozer Griffith discussed the obscurity which attends many cases of œdema occurring at this time of life. He referred first to the possibility of nephritis being present in earliest infancy, and then took up the question of the production of nephritis by congenital syphilis. He reported two cases seeming to be proof of the occurrence of this form of renal disease, and referred to some instances from medical literature. The existence of nephritis in an infant as one manifestation of general septic infection was instanced by the report of a case. Œdema consecutive to heart disease and to marasmic conditions was then touched upon, and then that going by the name of œdema neonatorum. The relation of this condition to sclerema neonatorum was next considered, and an instance of the latter reported. He then reviewed the cases of sclerema occurring in America. Next angioneurotic œdema as seen in infants and children was reviewed, and the various reported cases were abstracted. He reported two instances occurring in his own experience. Finally instances of œdema of entirely doubtful origin were taken up. Two unusual cases were detailed.

Chronic Nephritis, Unassociated with Albuminuria.—Dr. D. D. Stewart, of Philadelphia, read a paper on this subject, which he said was a continuation of others which had been published in 1893 and 1894. It dealt with an unrecognized form of chronic nephritis with distinctive symptoms, in which albumin even in traces by the commonly employed tests was persistently absent from the urine, and yet uræmic symptoms were common. Although unable to present the result of a necropsy in a personally observed case of this sort, a portion of a kidney removed in life threw some light on the pathological condition present.

Cumulative Action of Digitalis.—Dr. H. A. Hare, of Philadelphia, read a paper recounting the results of some experiments undertaken to find out what effect the continued giving of digitalis would have on the musculature of the heart and vessels. He put twelve pigs, all of about the same weight, six in one pen and six in another. They were all fed alike, and to six he gave the tincture of digitalis until he was giving them fifteen minims three times a day. He then made observations on the two sets of pigs, and noticed that the non-digitalis pigs remained of the same size and were like pigs in general, while the digitalis pigs were very lively, wanted to jump out of their pens, and had grown so markedly that farmers noticed it. He then killed them, and found the hearts much enlarged their muscles increased, and their walls thicker. He said the cumulative action of digitalis was the more or less sudden development of the muscular action of the heart with gastric distress.

Dr. William Osler, of Baltimore, thought that the effects of cumulative action are excessively rare. When a man gives only two or three drugs he does not like to have any of them called in question. He gave digitalis largely and with a free hand, and he had never seen any bad effects. He thought that all observant physicians knew the digitalis pulse, which might be 40 at the wrist and 80 at the heart. In a case of chronic valvular disease he had given ten minims three times a day for three years, and had never seen any ill effects from it. The cumulative effects might occur, but they were so rare that they need not be considered.

Dr. E. G. Janeway, of New York, had looked up the records in cases of sudden death, and found that many of the subjects had been taking digitalis. They were cases of slow heart and slow pulse. Sudden deaths, he thought, were often due to the use of the drug and not to disease, and this was especially the case in pneumonia and in Bright's disease.

Dr. H. A. Hare said, in conclusion, that Dr. Osler had proved exactly what he did not intend to prove, for, when the heart pulse was 80 and the wrist pulse 40, there was no surer evidence of the cumulative effects of the drug. He said distinctly that the effect of the drug was cumulative and not the drug.

Third Day—Thursday, May 6th.

Neuroses of the Abdomen.—Dr. Norman Bridge, of Los Angeles, said that these reflexes are hard to understand. They give the patient annoyance and often cause suffering, and some even simulate grave diseases, and may continue for months and years. A common neurosis is increased peristalsis, causing a passage of gas from the bowels and diarrhœa. This form is frequent. It is a diarrhœa of the colon, and it is hard to understand why it follows so closely each meal when the passage is the remains of the previous meal. This diarrhœa is a reflex one. The emotions may bring it on, such as fear, diffidence, etc. It has attacked surgeons about to operate, and clergymen have been known to experience it when taking a new charge. The exciting cause is extra-abdominal. There may be formation of gas after a meal; there is intestinal indigestion, with flatulence and the passage of wind, and this escapes after meals with borborygmi. Women have it, and suffer from pain in the top of the head. Mental excitement may cause a similar collection of gas. Another reflex is slight sciatic pain on both sides, which is relieved after a passage from the bowels. Another reflex is "growing pains" from an overloaded condition of the stomach and bowels. A free evacuation will stop it. Prurigo of the legs is another reflex with the same cause, and is cured by the same treatment. Urticaria or rash from the ingestion of crabs, fish, strawberries, etc., is a well-known reflex. Asthma is a reflex from the spasm of the bronchiole muscles. Convulsions in children are usually from reflex causes. A good treatment for insomnia is an enema at bedtime.

Dr. William H. Welch, of Baltimore, referred to urticaria as a reflex phenomenon, and mentioned the work of Dr. Gilchrist in his laboratory, who has been studying a class of cases in which a slight scratch on the skin causes a rash. Dr. Gilchrist has cut out small pieces of the skin within five minutes after the irritation, and has found serum and emigrated leucocytes, and in fifteen minutes he has found a large collection of leucocytes. There must be something outside that attracts the leucocytes, but it is not clear. Reflex phenomena do not explain it. There must be something of a chemotactic action which attracts them.

Dr. Charles G. Stockton, of Buffalo, said there are two points which should be noticed in discussing this subject. One is the post-prandial diarrhœa, if it may be called that, which occurs with sufficient frequency and has a sufficiently regular pathological course to deserve a name. There is not only a hurried evacuation of the intestines after a meal, but later there is gastric anacidity. The stomach seems to lose its acidity. Again, in a number of his cases with this diarrhœa he has noticed a striking error of refraction in the eye. The diarrhœa may not depend on the error of refraction, but the two are certainly connected. Also he has noticed a painful neurosis in the abdomen and parts below; a descent of the abdominal organs will cause pain, and the fixing of a floating kidney, for instance, has caused a cure.

The Roentgen Rays in Thoracic Disease.—Dr. Francis H. Williams, of Boston, had been using the *x*-rays in about four hundred cases of thoracic disease, and had been greatly helped by them. He could examine the patients in any position, but he usually had them brought in on a stretcher, and with the Crookes tube below and the fluoroscope above he examined the thoracic organs.

Dr. Reginald H. Fitz, of Boston, showed some well-executed radiographs of aortic aneurisms.

A Case of Acromegaly.—Dr. Osborne, of New Haven, reported a case of acromegaly. A man, forty-seven years old, first came to the hospital complaining of swelling of the lower extremities. He grew better, but becoming worse again came to the hospital, where he subsequently died. He had had the disease for twenty-three years, and suffered first with tinnitus aurium. Gradually the face and extremities showed signs of the disease, and all parts of the body were hypertrophied. The photographs showed the condition of the face, the hands, and the feet. Dr. Osborne also showed the curved and anchylosed spinal column, the sternum with ribs, the clavicles, and part of the bones of the hands and feet. The heart weighed two pounds nine ounces, probably the heaviest heart on record. In nineteen cases which he had collected there was an enlargement of the thyroid, so that the trouble in this case was probably complicated with myxœdema. The pituitary body was enlarged, as is usually the case in acromegaly.

Fat-Splitting Ferment in Peritoneal Fat Necroses.—Dr. Simon Flexner, of Baltimore, read a paper on this subject. He said that the view has gained ground that the disseminated forms of necrosis met with in the peritoneal cavity, as well as the more circumscribed lesions in the pancreas itself, may result from a perversion of the pancreatic secretion. Since it has been shown that trypsin when injected into the peritoneal cavity does not set up this condition, the suggestion that steapsin might possibly prove to be the chief cause has been ventured. A suitable human case having presented itself, he undertook to prove the presence of this body in the fat necrosis and its absence from the normal fat. His conclusions were: 1. In peritoneal fat necrosis, the body is demonstrable. 2. It is present in the early stages and may disappear later. 3. The ferment is the direct cause, but this cannot be proved. 4. The escape of pancreatic secretion is the origin of the necrosis.

An Epidemic of Cerebro-Spinal Meningitis Caused by the Diplococcus Intracellularis Meningitidis (Jaeger).—This was a joint paper by Drs. F. H. Williams and W. T. Councilman, of Boston. Dr. Williams related the clinical history of the disease. There had been a small epidemic of cerebro-spinal meningitis in Boston, and he had studied the disease and treated it by lumbar puncture, withdrawing the fluid from a little below the spinous process of the second lumbar vertebra, and the fluid had been studied by Dr. Councilman. Weichselbaum, of Vienna, was the first to make out the organism in this affection, and published a series of cases. In some cases it had extended from an acute otitis media. Staphylococci, streptococci, and diplococci had been found by Councilman. He had found the organisms in seventy-seven cases in cultures from the cerebro-spinal fluid. He had also found it in nine out of twenty at the City Hospital, and in sixteen out of thirty at the Children's Hospital. The spleen was enlarged in some cases. He had found it also in the nasal sinuses, and once in an abscess of the tonsil. The organism grows best on blood serum.

The Earliest Possible Recognition of Tuberculosis.—Dr. James Whittaker, of Cincinnati, first showed a sample of the new tuberculin of Koch, which he had just received from Europe. He dwelt on the importance of recognizing the disease before physical signs reveal it. He said the use of tuberculin is very important. Few persons understand it. It is successful in cattle. It has been objected to on the ground that a reaction is obtained when there is no tuberculosis. Klemperer has said we have no right to diagnose tuberculosis just because there are tubercle bacilli in the body; but that is a bad argument. The test will react if bacilli are present. We begin with five milligrams, and give as high as two centigrams. Failure to get the reaction shows the absence of tubercle bacilli. Virchow's objection is that tuberculin may arouse latent tubercle bacilli and cause

the disease. It should not be used in too large doses or too late in the disease. There is a great prejudice against it, but it is a valuable remedy. Trudeau, Denison, and Klebs use it in a modified form. He has used it in one thousand cases, and has never seen any harm come from its use. It is a safe means of diagnosing doubtful cases. Klebs, Jr., says he gets a reaction in every case of chlorosis.

Dr. F. C. Shattuck, of Boston, had used it in his hospital, and had seen no harm from it. One difficulty is that persons react from it in whom there is no evidence of tuberculosis and in whom no reason for the reaction can be found. He mentioned the case of a patient with a supposed tumor in the epigastrium. The reaction was typical. The autopsy showed a cancer of the stomach and other organs, and at the top of the right lung there was a small cheesy nodule, which was insufficient to give any signs or symptoms. If tuberculin were regularly used, the number of cases would be increased and also the number of recoveries.

Dr. A. L. Mason, of Boston, said it had been used in the Boston City Hospital, and it had been valuable in determining the disease prior to laparotomies for tuberculous peritonitis.

Some Products of the Tuberculosis Bacillus and the Treatment of Experimental Tuberculosis by Antitoxic Serum.—Dr. E. A. de Schweinitz, of Washington, described two of the products obtained from tuberculosis cultures, one of these a crystallizable acid, and their probable bearing upon the progress of the disease. A brief sketch of some experiments showing the relationship of the attenuated tuberculosis bacillus to immunity was given, followed by a description of some methods for the production of antitoxic serum and its experimental application. The injection of living cultures was first practised on animals. The horse is the best animal. At no time has it produced toxic effects, but it has been very carefully used. Good results are to be expected from it.

Primary Renal Tuberculosis.—Drs. D. D. Stewart and A. O. J. Kelly, of Philadelphia, presented a communication in which the diagnosis, frequency of occurrence, and source of infection of tuberculosis of the kidney as a primary affection were discussed, and an unreported case of Dr. Stewart's, in which a limited primary tuberculosis of the pelvis of the left kidney occurred in a case of chronic nephritis, was presented.

(To be Continued.)

Ventro-Fixation.—Dr. W. A. Newman Dorland (*University Medical Magazine*, December, 1896) closes a paper on this subject with the following propositions: 1. From an obstetric, as well as gynæcologic point of view, the operation of ventro-fixation (as compared with other operative measures) for the cure of uterine displacement is the most desirable in its results. 2. If improperly performed, any of the operations of anterior fixation of the uterus may exert a deleterious effect upon subsequent pregnancies. 3. This evil influence increases in direct proportion to the low implantation of the fixation sutures; hence the vaginal operations are especially dangerous. 4. The abnormal conditions noted include pain and traction at the site of the incision, premature termination of the gestation, difficulties in micturition, excessive nausea and vomiting, abnormal presentations of the fœtus, mechanical obstruction to labor, uterine inertia, cervical rigidity, uterine rupture, placental anomalies, and post-partum and puerperal hemorrhages. 5. Over half of the subsequent gestations and labors offer some abnormal condition. 6. About fourteen per cent. of the women suffer from abortions or miscarriages, and over twelve per cent. show dystocia in varying degrees, after hysteropexy, while over twenty-seven per cent. abort after vagino-fixation.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DEATH OF WALTER RIVINGTON—LOSS TO MEDICAL REFORM—DEATHS OF DRS. NUGENT, M'DOWELL, AND RICHARDSON—THE MERCER'S HOSPITAL DISPUTE—ADJOURNED DISCUSSION ON RED-MEAT DIETARY.

London, May 14, 1897.

A grievous and unexpected loss has fallen on the cause of medical reform. Walter Rivington died on Saturday, in his sixty-second year. You will remember that he was a candidate at the last election for the General Medical Council, and had he been earlier in the field, and his committee ready to incur the necessary expense, no doubt he would have been elected. But many voters were pledged before they dreamed that Rivington would be induced to stand, and many others did not receive his committee's circulars. His election would have been a suitable crown of a career so largely devoted to the work of reform and to all efforts to benefit his profession. Mr. Rivington was a distinguished graduate of the London University, taking numerous gold medals and other honors. He was B.A. in 1858, M.B. in 1863, and M.S. in 1864. His curriculum was at the London Hospital, to the staff of which he was elected in 1863, being already F.R.C.S. At the same time he was made demonstrator of anatomy and two years later succeeded to the lectureship. He occupied this chair until 1884, preferring it to others, but that year he took that of surgery. He became full surgeon in 1870 and held the appointment for the full period of twenty years, and was then made consulting surgeon. As a teacher Mr. Rivington was always exceedingly popular. His great stores of knowledge, combined with much humor, enabled him to make the dry bones of anatomy live, and students appreciated the painstaking teacher whose accuracy was as remarkable as his gift of imparting knowledge. Hundreds are mourning to-day for the man who lightened their educational labors. So, too, all medical reformers are lamenting the loss of a leader who had sacrificed much in the cause and was ever ready to espouse the cause of justice. His work on the civil rights defence committee I have more than once alluded to. That was his most recent effort, but from the beginning of his career he has been the same determined, active, fearless, but courteous champion of right, even when his personal interests were likely to suffer. From 1879 to 1883 Mr. Rivington was an examiner to the Royal College of Surgeons and in 1891 was elected to the council on the reform platform. "Would that he had lived to be president!" is the exclamation of college reformers. Last year he was elected to the fellowship of the university against Lister. Mr. Rivington had great literary power. Twice he carried off the Carmichael prize, and his two essays are a mine of medical history to which future writers on the medical profession must be indebted. These essays are full of information and remarkable for accuracy, as well as for the style in which they are written. Accuracy and fulness also characterize his surgical contributions to the societies and journals. Any of these may be taken up with the assurance that they are complete and exact up to the date of their appearance. As a surgeon his great experience gave confidence to his surgical judgment. As an operator he was perhaps a little unequal, due to the cautiousness inspired by fulness of knowledge. When all was clear, he was as brilliant in the operating-theatre as in his academical career.

Dr. G. L. Nugent, of Dublin, died on the 4th inst., aged forty-one years. He was registrar of the College of Physicians, and the president and fellows have passed a resolution of "regret at the death of their esteemed and valued colleague."

Dr. Ephraim McDowell, of Dublin, died on Friday last from, it is supposed, an overdose of a narcotic which he had been accustomed to take for the relief of insomnia.

Dr. A. J. Richardson, of Brighton, died from tetanus, which, according to evidence at the inquest, he had predicted he should die of on the following Sunday, although when he said so there were no symptoms. At his request antitoxin was injected. Tetanus afterward developed, and he died at the time he had predicted. The attack was attributed to a bicycle accident.

The question whether the medical staff of a hospital should be liable to dismissal by a committee is likely to come before the law courts, for the dispute at Mercer's Hospital, Dublin, has assumed a more acute phase, and the board has formally dismissed the whole staff and has invited the physicians and surgeons to apply for re-election. Its object, of course, is to get rid of Mr. O'Grady, who has given offence by informing the board of various shortcomings in its duties and declined to submit to its threats. Mr. O'Grady himself has been invited to apply for re-election, and replied that he has no intention of discontinuing his services, but he does not admit the power of the board to dismiss the staff, and that he will take steps to test the legality of its proceedings and to prove that it was in consequence of his demands for inquiry into serious charges that his dismissal is attempted. Mr. O'Grady has all along demanded inquiry; the board has obstinately refused, and there seems now nothing for it but a resort to law to show whether an incompetent board has power to dismiss an individual by dispensing with the services of the whole staff. I do not know whether any of the dismissed gentlemen will apply for re-election, and, if they do not, whether other Irish practitioners will degrade themselves by offering to take their places.

The adjourned discussion on red-meat diet took place at the Medical Society meeting on Monday last. You will remember that Mr. Armstrong had advocated an exclusive red-meat dietary in gout. Dr. A. E. Garrod pointed out the differences in various cases and said no single explanation could be applied to all, and he thought that Mr. Armstrong's method could have only a very limited application. Dr. Luff said there was no difference between the metabolism of animal and vegetable proteids, so there could be no objection to a meat diet in this respect. He repeated some of his criticisms on Dr. Haig's views offered at the last meeting, and pointed out many inconsistencies in that gentleman's statements. Dr. Haig, you will remember, declares that uric acid enters the system in meat, but Dr. Luff, who is a specially skilful chemist, tells him that the acid has never been found in meat, and as to xanthin the tests proposed by Dr. Haig are of no use. Mr. Freyer followed, but in a far less serious vein. He opposed Dr. Haig's restricted diet as much as Mr. Armstrong's, and recommended the rejection of all extreme restrictions, on the plea that it was better to enjoy all things in moderation. Dr. Maguire attributed the greatest influence to the vitality of the individual. When a man was strong he said the excretion of urea went on naturally, but only let his vitality be lessened and a reversion to the lower plane of excreting uric acid took place. Mr. Armstrong in the course of his reply mentioned a patient who had been under Dr. Haig's dietary for six months, but whenever he was worried or at all out of health uric acid appeared abundantly, and he would like to know what Dr. Haig thought was its source. He admitted that his treatment is appropriate only in a small proportion of cases, perhaps not more than three per cent.

Surgical Suggestions.

Fixation Abscess produced by oil of turpentine, ether, or nitrate of silver in subcutaneous injection so as to provoke inflammatory reaction, has recently come up, reminding one of the olden use of the seton, pea, etc., to produce supurative revulsion. The method has its dangers and may induce nephritis. It has been chiefly used in severe puerperal affections, purulent pleuritis, pneumonitis, etc.

Extirpation of the Rectum.—Dr. Byford (*Annals of Surgery*) gives the following advantages of the vaginal method: 1. The vagina can be made to take the place of the extirpated portion of the rectum. 2. The excision can be done as high up as by the sacral method, and with less traumatism, and, in case the peritoneal cavity is opened, with less danger. 3. An intraperitoneal exploration of the tissues about the rectum can be made before disturbing the rectum. 4. If the operation has to be abandoned after the incisions are made, the wound is less formidable and in a better place. 5. The patient is more comfortable after the operation than after the sacral methods.

Exophthalmic Goitre.—Fatal termination in six cases; recovery complete, or almost complete, in seven; improvement in seven; condition much the same in three; patient alive and following her occupation (exact condition unknown), one case. These conclusions furnish statistics which, I believe, represent fairly well the course of the disease.—R. T. Williamson, *British Medical Journal*, November 7th, 1896.

Obstetrics.—Twice I have seen life restored by intravenous saline injections for hemorrhage. Hemorrhage from the umbilicus I checked in two cases, by transfixing the base with harelip pins. Directly the child is born, I irrigate the child's eyes with boric acid, in solution 1–60, and wash the umbilical cord with the same, covering it with salicylic wool.—J. W. Dunbar Hooper.

Auscultation of the Œsophagus.—According to Frederick Treves' "System of Surgery," vol. ii., p. 546, this much-lauded method of diagnosis has not yielded the results which were expected of it. Indeed it may be doubted whether it ever yields as much evidence as the passage of a bougie. As first proposed by Hamburger, it consists in causing the patient to swallow some water or thickened fluid, such as gruel, and then listening either with the stethoscope or directly with the ear over the course of the œsophagus behind. It is not difficult to detect the stoppage or slowing of the food current at the seat of stricture, but no evidence of the nature of the stricture or other diseased condition is afforded by this procedure. Nor is much more information to be gained from the œsophagoscope, and the surgeon is compelled, therefore, to rely on his educated sense of touch and the bougie, coupled with such general indications as the special features of the case may supply him with.

Hemorrhoids and Anal Fissures.—Dr. Schmey (*Zeitschr. für Aerzte*) has used a two-per-cent. solution of nitrate of silver in many subjects of hemorrhoids and anal fissure, and has had uniformly good results. Daily brushing with this solution obviated the necessity for operation. In one case of coccygodynia, which

no treatment could relieve, the author, applying the brushing with the solution with great success to piles with which the patient suffered, found that after eight brushings the coccygodynia had also disappeared. In one case of fissure of the anus accompanying hemorrhoids, which rendered the patient sleepless by reason of the pain, the same solution effected a cure.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 29, 1897:

	Cases.	Deaths.
Tuberculosis	222	117
Typhoid fever	12	4
Scarlet fever	215	17
Cerebro-spinal meningitis	0	8
Measles	213	7
Diphtheria	310	39
Laryngeal diphtheria (croup)	2	3
Small-pox	8	1
Chicken-pox	24	0

Spread of Venereal Disease.—The departmental committee, presided over by Lord Onslow, the president and the council of the College of Surgeons in Ireland, investigated and reported upon venereal disease among the British troops. Their report was such an appalling one that at a recent meeting of the council of the Royal College of Surgeons in Ireland the following was unanimously adopted: "We, the president and council of the Royal College of Surgeons, Ireland, being deeply impressed by recently ascertained facts concerning the development and alarmingly increased prevalence of venereal disease among the British troops in India, and also the apparently exceptional virulence of the malady there, are strongly of opinion that the time has arrived when some active steps should be taken by the government to check the disease, not alone in the interests of those primarily affected, but of their immediate descendants, and of the community at large in India and the United Kingdom."

Eating.—Children should be trained to eat slowly, no matter how hungry or what important business is pressing. Much safer a little food well masticated than a hearty meal swallowed in haste. Cold food is even more difficult to digest than hot, if taken too rapidly. The normal temperature of the stomach is about 98° F.; food has to be raised to this temperature before digestion can take place.—*The Medical Council.*

Tuberculosis in Infancy.—Tuberculosis was formerly supposed to be a rare disease in infancy, but recent investigation proves this supposition to have been false. From statistics collected it appears that intra-uterine infection in cases of tuberculosis is very rare, the child often escaping even when the mother is suffering from active disease in an advanced form. Infection through the alimentary tract is also very rare, and will not explain more than one or two per cent. of the cases. The distribution of the lesions in tuberculosis of infancy and early childhood points conclusively in the vast majority of cases to infection through the respiratory tract.—L. Emmett Holt.

Vocal Hygiene.—Dr. Thomas F. Rumbold (*St. Louis Medical and Surgical Journal*, February, 1897) says, in regard to paresis of the uvula, that if this organ is not under the control of the voice user the voice must be imperfect. Let a person stand before a window, open his mouth, and inspect his uvula, aided by a small hand mirror. If he sees that the uvula moves freely up and down—that is, contracts and relaxes itself—then it is in a normal condition; but if he cannot cause it to move—that is, contract—then it is debilitated, and this debility is due to inflammation in the pharyngo-nasal cavity.

Unconsciousness from Constipation.—Very stout women have suddenly become unconscious from a long-continued constipation. A physician relates a case in which unconsciousness, with stertorous breathing in the night, simulated an apoplectic attack. By the aid of mustard to the feet and abdomen, with ice to the head, and a large enema of soap, water, and castor oil, a large evacuation was procured, with speedy return to consciousness.—*Health Magazine.*

Diazo Reaction in the Diagnosis of Typhoid Fever.—Solution A: Hydrochloric acid, 50; distilled water, 1,000; sulfanilic acid, q.s. ad sat. This solution should be most thoroughly saturated, allowed to stand some days before being used, and shaken up from time to time. Solution B: Five-tenths solution of sodium nitrite in distilled water. Should be kept in a cool place and black bottle, and renewed every week or ten days. Solution C (test solution): One part of solution B; one hundred parts of solution A. This solution should be freshly made for each day's testing. Method of applying test: Equal parts of the solution C and the suspected urine are thoroughly shaken up together in a test tube, and from one to two cubic centimetres of ammonium hydrate allowed to flow gently down upon the surface. If the reaction be present, a beautiful crimson or carmine band appears at the junction of the ammonia with the mixture. Upon shaking, a pink tinge is imparted to the foam. The following rules are all-important: 1. The urine must be fresh and filtered. 2. The urine must be acid. 3. The true color is red, and when the urine is shaken the foam should be slightly tinged with pink. 4. The test solution C is to be freshly prepared each day, and accurately measured. A medicine dropper and a marked test tube will insure this. 5. The sodium-nitrite solution must be accurately made, and renewed at intervals of a week or ten days, and be not stronger than 0.5 per cent. 6. The color band should be held against a white background, the light falling upon it from behind the observer. It must not be held against the light. 7. The exact method of procedure must be conscientiously carried out. 8. The test is to be made during the height of infection. It occurs sometimes in acute tuberculosis, septicæmia, and in carcinoma. It is chiefly important from the fact that a failure to find it gives a strong presumption against typhoid fever, as it is found in about ninety-five per cent. of all cases of that disease. This is Dr. Green's modification of Ehrlich's diazo reaction.—*Southern California Practitioner*, March, 1897.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CLIMATIC CONDITIONS IN RELATION TO HEALTH.

BY GEN. A. W. GREELY.

CHIEF SIGNAL OFFICER U. S. ARMY.

TEN years since it was pointed out that the spirit of the day demands the taking and collecting of such meteorological observations as may lead to a thorough knowledge both of local sanitary meteorology and of the fitness of local climates as a means of alleviating human suffering and the saving of human life.

When in charge of the meteorological service of the country, efforts were made by me toward national action along this line through co-operation with the Marine Hospital service under Dr. John B. Hamilton, who long ago published charts, without discussion, however, and data in his weekly "Abstract of Mortality Data." Lack of appropriations has caused the discontinuance of the charts inaugurated by Dr. Hamilton, but the data still appear. It is significant of the truth of the saying that a prophet is "not without honor save in his own country," that when the weather bureau initiated its monthly publications of *Climate and Health*, the efforts of the signal corps, of the Marine Hospital service, and of Dr. Baker of the Michigan board of health, were ignored, and the credit of this idea was officially given by Secretary Morton to England, as originating in a subordinate Cornwall County council's reports. After a year's issue of *Climate and Health*, this publication of the department of agriculture was suspended as not being within the law; but it is hoped that it will be renewed.

The attitude taken by the meteorological side of the weather bureau as to the influence of climate upon health cannot be more forcibly illustrated than by the statement that the *Monthly Weather Review* for August, 1896, contains no allusion to the fact that nearly one thousand persons died in the United States in that month from the direct effects of a prolonged heated term.

While the ability of man to withstand the vicissitudes of climate over the whole earth is unquestioned, yet it is realized that there is a practical limit of environment within which he is competent to perform that quality and quantity of work and to live out that span which is evidently the birthright of the normal man.

It is interesting to note that the only extended and satisfactory investigation of the geographic distribution of life in North America has been made by Dr. C. Hart Merriam, of the United States department of agriculture, and this study, excluding man, has reference only to forms of animal and plant life.

While the medical profession awaits investigations that shall outline in like manner the areas in which human life can best thrive and develop, yet no doubt obtains that the principles which dominate in the case of lower animals and plant life must to some extent be important factors in determining the congenial habitat of mankind.

In this connection the calculations and experiences of the great life-insurance associations of the United States harmonize with Dr. Merriam's formulated discoveries. He says:

"While it is not for a moment supposed that the subject has been disposed of in all its details, it is confidently believed that the principles controlling the geographic distribution of terrestrial animals and plants have been discovered, and that they may be expressed as follows: In northward distribution terrestrial animals and plants are restricted by the sum of the positive temperatures, *i.e.*, above 43° F., for the entire season of growth and reproduction. In southward distribution they are restricted by the mean temperature of a brief period during the hottest part of the year. It is believed that these two principles cover the fundamental fact of distribution."

He elsewhere points out that humidity modifies to a considerable extent the temperature conditions, but is all-subordinate to them. An important point in the distribution of plant life lies in the fact that each of the three great transcontinental faunal areas—boreal, austral, and tropical—furnish forms of animal and plant life that are in strict harmony throughout; that is to say, the mammals, insects, or flowering plants of each zone are peculiar to their climatic zones and cannot thrive in either of the other zones. The more important life region, the austral, is practically coexistent with the limits of the United States, the tropical region projecting northward only into southern Florida and the valleys of the lower Colorado River and lower Rio Grande, while the boreal region includes only the extreme northwestern Pacific coast and the mountain peaks of this country. Favored as the United States is in being within the austral zone of life, yet it presents climatic conditions that are at times and in places most detrimental to human health.

In an article of this brevity it is possible to treat only the most important factors, those of temperature and humidity respectively. It may be appropriately added that the only systematic and continuous investigations upon this subject are those which have been prosecuted under many disadvantages by Dr. Henry B. Baker, alluded to later, of the Michigan State board of health.

The hot wave of 1896, from August 4th to 14th, is fresh in the minds of all. During this period it was reported that no less than 1,000 deaths were directly or indirectly caused by the heat alone. At Chicago the ordinary death roll was greatly increased by the heat, there being 125 deaths reported on one day. Of direct fatalities, the following are the most important: In New York there were 231 deaths; in Chicago, 91; in Philadelphia, 30; in Baltimore, 25; in Owensboro, Ky., 16; and in Washington, 14. In St. Louis, of 200 prostrations, 40 were immediately fatal.

It is significant that death from sunstroke and exposure to heat is practically unknown over regions where the highest temperatures have not exceeded 100° F., that is, on the immediate Pacific coast, the region of the Great Lakes, over the Blue Ridge, Alleghany, Catskill, Adirondacks, and other mountains in the eastern part of the United States, and also the higher altitudes of the Rocky Mountain region, as well as at

certain places on the New England and New Jersey coasts.

It should be understood that the heated term of August, 1896, was unprecedently fatal to human life, yet it was only a maximum instance of frequently recurring heated terms within the limits of the United States.

Among the most remarkable of these in recent years may be mentioned:

July, 1876, the heat caused an increase in the death rate of many of the largest cities to the then highest reported percentages.

July, 1878, the direct fatalities from heat were very numerous, there being 163 deaths in St. Louis; in Memphis, 45; in Chicago, 30; and in Milwaukee, 12.

The Ohio valley suffered particularly, the temperature rising for fifteen consecutive days above 86° F., but New England was not entirely exempt, as shown by the death of 6 persons in Boston.

July, 1879, while the Ohio and Missouri valleys experienced some fatalities, yet the peculiar feature was 30 deaths at Charleston, S. C., where the temperature rose to 111° F.

In many respects the most deleterious effects upon the public health through climatic conditions occurred during the months of July and August, 1881. While as usual the most numerous fatalities occurred in the Ohio, lower Missouri, and upper Mississippi valleys, yet the Atlantic States suffered excessively. July 14th, the Cincinnati health officer reported 549 deaths in the previous week, of which 363 were caused by heat. In St. Louis 31 died from sunstroke, and in the valleys before mentioned 700 deaths were directly due to the intense heat. In August, while the fatalities were perhaps fewer, the heat conditions were more widespread, extending from the lower Missouri valley eastward to New England. The weekly mortality report of Chicago of August 8th showed a rate of 52 per 1,000, as against the normal rate of 18. These data are striking evidences of the injurious effects of high temperatures upon the public health.

Passing from the injurious effects of high temperature upon human health, a brief allusion may be made to a factor of secondary importance, that of the humidity of the air. Low humidity permits great ranges of temperature, so that very high temperatures of the summer month or of the middle of the day are followed by corresponding low temperatures both in midwinter and in early morning hours, thus aggravating certain forms of ailments or disease incident to humanity. Very low humidities with accompanying temperature changes are most noted over the Rocky Mountains and plateau regions of the United States; and at many points in Arizona the average daily temperature ranges run from 35° to 43° F., and on some occasions the temperature has changed from fifty to sixty-five degrees in a single day.

An important characteristic of the very low absolute humidity in the upper Missouri valley is the extreme absolute dryness of the air, there being in some of the winter months only about 0.3 grains of water to each cubic foot of air, as against 8 or more grains in southern Florida. The effect of such contrasting humidity conditions in the air necessarily inhaled is a question for medical experts on respiratory diseases.

Recurring to Dr. Baker's investigations, he shows that in Michigan the average amount of vapor inhaled from the air daily is but 0.74 Troy ounces in January, as against 4.06 in July. The differences are even greater in Minnesota and in the Dakotas.

Among Dr. Baker's papers on the health and meteorology of Michigan, the following are worthy of the attention of students of climate and health: "The Causation of Influenza and Allied Diseases," "The Causation of Pneumonia," "The Causation of Cold-Weather Diseases," "Relation of Certain Meteorological Conditions to Diseases of the Lungs and Air Passages." These and other similar studies are to be found in the reports of the State board of health of Michigan.

The climatic conditions which during the heated term are so injurious to health are evidently of a complex character and cannot be set forth until such time as a special study of the subject has been made. It has been claimed that deaths arising from heat are in inverse order to the humidity, but this rule does not hold good, as shown by the data herewith. The area over which very excessive death rates obtain during the heated periods extends from New York City westward through the Ohio and lower Missouri Valley. In these latter two regions the air is comparatively dry, and as we go southward t the Gulf, with increasing humidity and higher mean temperature, we find them marked by a diminished death rate, at least so far as is directly traceable to extreme heat. One, therefore, seems to be warranted in the belief that the temperature dangerous to mankind is that in excess of the temperature of the human blood, and that when the air temperature runs for a considerable number of hours above 98° F. the fatal effects of the great heat necessarily follow. It is obvious that casualties from the intense heat are greatly increased by the unsanitary conditions of life in the great cities, so that it is hardly possible to assign a suitable weight to unfavorable temperature conditions and to insanitation. It is evident, however, as has been shown elsewhere, that injury to public health comes rather with the summer heat than with the winter cold.

In *résumé*, it appears that the extreme heat of summer is injurious to human health in the United States, except along the immediate ocean coasts, in northern New England, in the lake regions, and on the elevated lands, say, from five hundred to two thousand feet; the elevation necessarily decreasing with the latitude and increasing with the distance from the sea.

Temperature conditions are ameliorated or aggravated by humidity conditions. Very dry air and great temperature changes, diurnal and annual, obtain to the westward of the Mississippi River and over the mountain peaks of the Atlantic coast. As a rule, the air increases in dryness in its distance from the oceans and great lakes, and especially with increasing latitudes. Very moist air obtains in Florida and along the Gulf coast for some distance inland, particularly in the lower Mississippi Valley and on the immediate coast line of the Pacific.

The Surgery of Pelvic Inflammations.—Dr. William Polk (*American Gynecological and Obstetrical Journal*, September, 1896) summarizes his paper as follows: 1. In acute inflammation, with implication of the cul-de-sac, incise and drain. 2. In unilateral suppuration, tuberculous inflammation excepted, treat the uterus and remove the diseased appendages by the vagina—anterior colpotomy. 3. In double suppuration, vaginal hysterectomy with enucleation and removal of the purulent appendages—the so-called pus sacs. 4. In suppurative disease, whether double or single, if the patient is too weak to stand the radical operation, evacuate the pus and drain, reserving the radical operation for the future. Choose the route (vaginal or abdominal) which the pus seems disposed to select. 5. In broad-ligament abscess—a matter to be determined by a vaginal exploratory section, if necessary—evacuate by approaching the pus through the utero-vesical region, or beneath the peritoneum along the route of the round ligament. 6. In suppurative disease do not do abdominal section, but, if you should, do not leave the uterus or the cervix.

THE COMMON ACCIDENTS OF SUMMER TOURISTS.

By JAMES E. PILCHER, M.D.,

CAPTAIN IN THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY.

The number of cases that come to the physician with symptoms exaggerated by the officious efforts of anxious bystanders, or accentuated by the inattention of negligent friends, is large enough to cause every practitioner to wish for the prevalence among the laity of sufficient information to enable them to render to the sick and injured the necessary temporary first aid, without intruding upon the province of the physician. The absence of this kind of knowledge as a matter of fact may properly enough be said to be the cause even of death in not a few cases every year. Not long ago a prominent clergyman of one of our great cities, while emerging from an elevator in a large office building, slipped and fell so as to sustain an extensive laceration of the thigh and a rupture of the popliteal artery, producing a hemorrhage, fatal before a surgeon could be obtained. When one considers that it requires five or more minutes for a man to bleed to death, even in case of section of the larger vessels, the possibilities of cases such as this can readily be perceived. Proper pressure above the laceration would in this instance have saved not only a useful life, but, by rendering possible the continuation of the victim's public services, would have vastly benefited an entire community. Such cases of course are extreme, but the fact that great numbers of them occur every year, is sufficient justification for every one to be upon his guard against their possible occurrence in his own experience.

The medical department of the great army of competitors for the favor of the summer tourist is as yet lamentably insufficient. The railways, notwithstanding the enormous number of casualties incurred upon their lines—averaging nearly forty thousand cases a year—have done but little in the way of preparing for immediate aid in the treatment of either slight or severe accidents; but little if any more has been done by the masters of water transportation, and other lines of travel are absolutely wanting in facilities of this kind, while the remaining still larger number of caterers to the tourist have made no better provision than these.

It is desirable, then, that every traveller should be instructed to a certain extent in the first-aid treatment of accidents and emergencies, in order that he may be able to give to himself the assistance denied him by those who are catering to his amusement. The family physician may with entire propriety assume the position of instructor, since he will in so doing not only contribute to the possible comfort and safety of his clients but will also conduce to a more favorable condition of his patients in case emergency should bring them under his future care. He may give them personal instruction or he may direct the reading of a good first-aid manual. A very successful practitioner of the writer's acquaintance has presented each of the principal families of his *clientèle* with a first-aid book, the use of which he believes has very materially assisted in the successful prosecution of his practice.

In any case it would be well to call the attention of those contemplating travel especially to certain common accidents to which the tourist is particularly subject.[1] In referring to these matters the physician must bear in mind the entire absence of technical knowledge upon the part of the layman, and remember that information which is but the A-B-C of his experience is an unpenetrated mystery to his client. In this paper, then, the subject is viewed from the standpoint of the patient, to which fact must be attributed its very elementary character.

Foreign Bodies.—In camping parties particularly, insects are liable to find their way into the auditory meatus and produce great annoyance and sometimes no little pain. It will do no harm to hold a bright light to the ear in the hope that the intruder may be attracted to emerge, but it is better that every person should know how readily foreign bodies can be floated out of the ear by injections of warm water.

The eye is even more subject to travel accidents of this kind than the ear, and unless the body be embedded in the cornea or conjunctiva, which is comparatively unusual, no emergency is more readily relieved. There is no reason why the laity should not understand the simple manœuvre of exposing the lining of the lower lid by looking up, while gentle pressure is made just below the eyelid. The drawing of the upper lid down over the lower is equally easy and often effective in removing the foreign body; in case of failure, the removal may be attained by drawing across the eye, under the upper lid, a little corner of a very soft linen handkerchief moistened with the patient's saliva. Sufferers from this accident should be informed that a slight conjunctival abrasion, produced by a foreign body which has been removed, will continue the sensation of the presence of the body even after it has disappeared.

Cutaneous Accidents.—The burns of the stage of rubefaction and sometimes of slight vesication, produced by the exposure to the rays of the sun, of persons unaccustomed to outdoor life, are common to summer tourists. The recognition of the fact that this accident is a genuine burn renders its treatment readily understood. The numerous cold creams and other unguents sold in the apothecary shops serve well enough, but nothing can be better for general use in these cases than the carbolated petrolatum everywhere available.

The same may be said of the lichen tropicus or "prickly heat," to which delicate skins are subject in hot weather. The intense itching of this trifling but exceedingly annoying affection is also usually readily brought within the limits of endurance by carbolated applications. The little jar of carbolated petrolatum is a most advantageous constituent of every tourist's summer outfit.

The more severe inflammation produced by contact with the various species of rhus, the "poison ivy," the "poison oak," and the "poison sumach," is often temporarily treated with advantage in the same manner. These injuries, however, pre-eminently come under the category of matters in which the "ounce of prevention" is particularly applicable, and it is well for persons going into the country for an outing to be able to distinguish them from the harmless growths which they resemble. The beautiful woodbine or Virginia creeper is distinguished from the venomous "poison vine" by the fact that the leaf of the harmless growth consists of five leaflets given off from a common stem, while that of the toxiferous plant has but three leaflets upon the main stem. The "poison oak," or rhus toxicodendron, may be detected by the same conformation of leaf. The "poison sumach," or rhus venenata, which produces a cuticular inflammation similar to those already mentioned, may be distinguished from the ordinary harmless sumach by the fact that, instead of bearing close bunches of red berries at the ends of its branches, its fruit consists of slender clusters of small white berries given off from the axils of the leaves.

Wounds.—It is difficult to realize that in this day

[1] In a brief journal article, it is of course impossible to present the subject of first aid fully, and the reader who desires further information is referred to the author's "First Aid in Illness and Injury," published in New York by Charles Scribner's Sons.

and generation any person can be so ignorant as to treat slight wounds with anything but cleanliness and gentle pressure. But the cobweb, tobacco-quid, and filthy-mud heresies all still have enthusiastic partisans, and slight wounds are exceedingly liable to be transformed into poisoned wounds of considerable extent by the employment of such agents. It is well then to impress upon the traveller the fact that in wounds of no severity simple cleanliness and gentle pressure, maintained by a clean compress held by a clean bandage, comprise all the requisite treatment. It is worth while indeed to go farther and explain that filthy agents should be eschewed in any kind of wound. Why fresh cow dung or dust-permeated cobwebs should be considered to possess healing qualities is a question that the wisest cannot answer. But, with the predilection for those dressings which possesses the bucolic mind, it is a most wise precaution to warn contemplating travellers against them and in favor of clean applications; and to explain that anything contaminated with animal secretions is dangerous, from the mucus-laden handkerchief to the sweat-saturated shirt —clean paper being better than soiled linen, the ink of the printed sheet being rather an advantage than otherwise. The removal of a barbed fish hook by thrusting the point out through the skin and then, after breaking off the barb, easily withdrawing it, is so simple a procedure that it seems hardly necessary to mention it, but experience has shown how few of the uninitiated bethink themselves of this very natural manœuvre. It should also be understood that the temporary treatment for severe wounds, after checking hemorrhage and placing the parts in a comfortable position, is identical with that for slight ones.

Bleeding.—The most alarming feature of the more severe wounds is the bleeding, which, in case of an injury to an artery, may be dangerous to life. Every person should understand the differences between arterial, venous, and capillary bleeding. The bright red hue and spurting flow of the wounded artery should be recognized as an indication of danger promptly to be treated. The fact that pressure between the wound and the heart will control such bleeding should be impressed on every mind. The simple construction of a tourniquet from a large handkerchief, a bit of a garment, a suspender, or any similar article which can be bound firmly about a limb, and the method of tightening the bandage thus created by thrusting under it a rod of any kind and twisting it until the pressure exerted checks the bleeding, should be a part of the elementary knowledge of every one. To this should be added the fact that firm pressure directly upon the wound, in other than arterial bleeding, is the proper method of restraining the hemorrhage. The laity should be cautioned, however, to immediately apply pressure with the hands directly upon the wound, even in case of an arterial injury, until the extemporized tourniquet can be put in place. Death has been known to occur from an arterial wound while the amateur surgeon was so much interested in manufacturing his tourniquet that he neglected to control the bleeding in the mean time.

Fractures.—Some points with regard to fractures may be of the greatest value to the summer tourist—the main point being aptly expressed in the Scottish motto, *noli me tangere*. Fractures and dislocations are so frequently aggravated by meddlesome handling that the dictum to do nothing more than place the injured part in the most comfortable position possible for the patient and retain it there, should be most emphatically impressed upon the lay mind. Extemporized methods of immobilizing the parts in the easiest position should be generally understood, including the utilization of canes, umbrellas, sticks, and the like as temporary splints to prevent the accentuation of the pain and the aggravation of the injury by motion at the point of fracture.

Sprains are sometimes fully as painful and disabling as fractures, and like fractures they should not be made the object of unnecessary meddling. No injury is more frequent with the summer tourist than the sprain, particularly of the ankle. The mode of vacation life, with its admixture of athletic sports and unaccustomed exercise, particularly predisposes to this accident. The laity should learn to avoid arnica, turpentine, and other abominations in favor of immediate immersion in hot water for a considerable period, followed by elevation of the extremity and gentle retention of the parts by a bandage, the material for which may well consist of elastic flannel.

Heat Stroke or heat prostration is one of the more frequent results of exposure to unexpected exercise in summer travelling. It is well for tourists to understand the danger of prolonged exposure to the sun in very hot weather. The use of alcoholic stimulants or the drinking of water in excess should be avoided before going out, and the advantage of applications of cold water to the head in these cases should be well understood.

Drowning.—As the water enters largely into the plans of summer excursionists, the list of summer casualties naturally presents a large number of cases of drowning. While the great majority of these cases are beyond recovery before the body is taken from the water, there are still many in which artificial respiration, persistently and effectively applied, may restore the pulmonary and cardiac action. The Sylvester method is the most popular, consisting—the patient lying upon his back—of alternate contraction and expansion of the chest, by alternately pressing the arms upon the chest and raising them strongly over the head, from twelve to fifteen times a minute, all this of course after the water in the air passages has been emptied by gravitation. The best authorities believe that artificial respiration is often too soon discontinued, and advise that it be persisted in for from thirty minutes to an hour. It should be remembered that the body, until the lungs become filled with water, is buoyant and will float, not high up, but still with its upper surface above the water; and the addition of the merest trifle of assistance, such as is afforded by a small board, not to speak of an oar or larger floating body, will enable the head to be kept well out of the waves. If then one can have self-possession in the very disconcerting moment of submersion, he may be able to keep himself afloat until aid can arrive, or possibly until he can reach the shore unaided.

There are many other points in first aid, easily acquired and readily remembered, the application of which may not only contribute greatly to the comfort and ease of the ill and injured, but will also materially assist the practitioner in his future treatment of the case, should the accident require the ultimate action of a physician: but those here mentioned are perhaps of the greatest importance to the summer tourist. The whole subject is an important one, however, and the question of general instruction in connection with it is coming to be recognized as of steadily increasing consequence, while the number of persons qualified to stand in the breach in emergency is constantly growing, all of which is destined to result in a great saving of suffering in future injuries and a vast diminution in the mortality of future accidents.

Bromide of Potassium should be of the best quality and entirely free from impurities, such as iodides and chlorides, when given in large dose and for a long time, in order to insure freedom from eruptive and other disagreeable and even dangerous results.

SOME PHYSICAL EFFECTS OF ARCTIC COLD, DARKNESS, AND LIGHT.

By FREDERICK A. COOK, M.D.,

SURGEON OF THE FIRST PEARY NORTH-GREENLAND EXPEDITION.

GENTLEMEN: At the request of your worthy president and secretary I am here to-night to tell you something of the effects of Arctic cold, darkness, and light upon animal organisms. In this endeavor I find before me a series of problems surrounded by a mysterious halo —a fascinating mystery, as is everything Arctic from which it is difficult to extricate scientific facts. Nearly all previous Arctic expeditions, although nominally scientific in their aims, have proven to be popular ventures of rescue or bold efforts to discover a commercial highway to the Orient, and lastly, the determined strifes for the farthest north. In nearly every one of these expeditions the collections of pure scientific data were minor considerations. Even on the expeditions well prepared for scientific work hopes were shattered by unavoidable accidents. Hence I prefer to narrow the scope of my paper to personal observations, experiences, and deductions.

As we enter the frosty realm of the hyperborean regions we are first impressed by the simple and the primitive forms which all nature arrogates. On closer approach, however, we find it marked by the most stupendous features. The weird fantastic attitudes assumed by land and water and life differ as radically from warmer landscapes as if they belonged to another planet. The scenery is always strangely awful and dreary, and the frequent snow storms even in midsummer serve to enhance this impression. But during clear days there is always a bewildering panorama of bewitching scenes to which one is irresistibly attracted by the glimmer of mystery and the fascination of strange probabilities which surround all unknown lands.

There is such a perverted impression in the popular mind about the actual Arctic conditions that I always find it difficult to impress my listeners with a real knowledge of polar phenomena. The surroundings are of course wild enough to satisfy the most savage longings, but it must not be inferred that the temperature of the air is always below zero, nor that the land is completely buried by perennial snow, nor that the sea is always covered by paleocrystic ice floes or mountainous ice masses. During the long Arctic night such conditions are fairly constant, but for much of the year the genial rays of the sun are felt.

Our headquarters in 1891 were pitched on the northwest coast of Greenland, near the seventy-eighth parallel of latitude, which is about midway between the North Pole and the Arctic Circle. In this latitude the seasons are briefly as follows: A long nightless summer day of nearly four months and an extended dayless winter night of nearly four months. These periods are separated from each other by a season of advancing night during the autumn, when the sun gradually recedes but reappears for a shorter period every succeeding day, until it finally remains below the horizon on October 25th. In the spring there is a similar period, but it is the dawn of the coming day. The sun reappears on February 14th. It first remains only a few minutes, but each succeeding day it rises higher and sweeps more of the southern sky, until about May 1st it remains above the horizon and then the long Arctic day with its silvery glory begins.

The atmospheric temperatures during the winter range from zero Fahrenheit to 60° below; during the summer from zero to 60° above. The intervening periods have a temperature fluctuating from about 20° below to 20° above.

[1] Read before the Brooklyn Medical Society, September 18, 1896.

There are many elements which combine to make Arctic air the purest and in every way the most tonic of any known atmosphere. Those of us who have studied the conditions here know that the bed of atmosphere surrounding temperate and tropical zones is always a perceptible obstacle to vision. It seems at all times more or less opaque, and this is due to the presence in it of large quantities of floating dust and gases. The bustle, haste, and mechanism of civilization increase this atmospheric pollution. The ever-changing brilliant shades of sunrise, sunset, and rainbows are caused by the prismatic effect of this impurity. Rain and snow precipitate it. In the Arctic conditions are different. The insignificant particles of matter from bared cliffs are brought down by the frequent rains and snow. Dust and smoke are very rare, and except for the frequent fogs of summer the atmosphere is remarkably clear.

This is magnificently illustrated as one watches the polar sky as well as the cold earth beneath when it is painted by atmospheric reflections in primal colors of virgin purity. In a similar way this air fills life with primitive joy; for, while it arouses savage ambitions, it infuses men with a wine of action that permits great physical labor with little exhaustion.

The ice formation of the polar glacial bed is an all-important regulator of temperature and a forcible eliminator of air pollution. The great clouds of watery vapors which arise from the southern oceans are carried north by winds. As they pass over the polar basin the change in temperature quickly condenses the mass and it falls crystallized to the surface below. This phenomenon is constant. It snows through all seasons of the year. In the interior of Greenland there is a never-ceasing accumulation. The precipitations of atmospheric moisture for many centuries are there piled in successive sheets. This prodigious mass of snow, in some way with which we are not yet entirely familiar, is transformed into ice. The ice again finds its way slowly into the sea by the glacial streams. As it emerges from this glacial bed in disrupted masses, which we call icebergs, it floats slowly southward, only to be lost in the warm embrace of the heated southern seas from which it arose perhaps centuries ago.

In this complicated series of water transformation we have a beautiful illustration of the grand provisions of nature, a method by which it mitigates the excessive inequality of polar temperature which is caused by the prolonged withdrawal of the sun's heat: for if moisture was absent and only dry land exposed to the sun, it would be scorched by the incessant rays of the summer sun and pinched in the heatless darkness of winter by the most intense and unimaginable cold —a condition which would be fatal to all organisms.

We are in the habit of looking upon this snow and ice of the polar regions as the greatest enemy to life and to animal comfort. A mere thought of the endless seas of ice or the limitless Arctic snows is apt to arouse within us a protest to nature for permitting such an apparently hopeless condition of things. But it is a kindly provision, for neither animal nor vegetable life would be possible without the influence of the glacial phenomena in the constant equalization of extreme temperatures. Without this the prolonged and incessant heat of the summer sun would not be endurable. Certainly life through the winter darkness and cold would be impossible. None of the present animal or vegetable forms could endure such awful extremes. So long, however, as ice remains to thaw or water to freeze, the temperature of the atmosphere cannot vary beyond certain limits. Hence the gloomy snow fields and awe-inspiring ice masses are often a kindly protection to all Arctic organisms. Life under such conditions has to me a peculiar interest, but the

scope of this paper, the time at my command, and your patience, I fear, will not permit me to enter into a lengthy discussion of Arctic life.

The specific effects of cold and darkness and light are difficult of analysis, more so among the members of our party than among the native people and animals. The effect of isolation, of change of food, clothing, and habits of life are so potent that any physical or mental peculiarities must necessarily include these elements.

The withdrawal of heat is so gradual that the animal organisms have an opportunity to protect themselves. During the summer (the only time when the extreme north is accessible) the temperature and some of the meteorological conditions are much like our March and April weather. Incredible myriads of birds in summer plumage, fresh from the temperate zone, now congregate on the off-lying islands and moss-covered rocky cliffs. But with the first warning of the polar night, as the sun drops below the southern sky they quickly emigrate to a more congenial land, leaving apparently lifeless the cold shores which have been animated by their wild shrills of love and joy. Their powers and instincts are such that they have only to seek the lands which are best adapted to their manner of living. Many of the forms of sea life are able to do the same. But men and all other land animals must remain and become adapted to the changing conditions.

The polar bear changes his fur during the summer to protect him from the expected cold next winter, but life is to him an awful struggle during the long night. Nevertheless he early develops an ability to fast for prolonged periods, which is a faculty possessed by all other Arctic land life. The nearly complete covering of the sea by the winter ice deprives him of his accustomed source of food. Hence he must either hibernate or find his way far out over a lifeless sea of ice to the open water, where varying fortunes may put him in possession of an unwary seal. But with all bruin's ingenuity and hard-earned adaptability long periods of famine are always before him.

The superb adaptability of Arctic life to the ever-changing conditions is beautifully illustrated by the reindeer. No other animal is so well prepared to meet the changing vicissitudes which prevail at all times in the far north. It feeds upon the dwarfed grasses, the hardy mosses, and lichens which are abundant along the coastal fringe of land during the summer, but during eight months of the year the vegetation is very largely buried by the ever-present snow. Hence to maintain bodily heat and muscular strength to search for food makes life a fierce struggle against awful odds.

I studied the deer very carefully because I was convinced that here we had a most wonderful example of the peculiar transformation of organic life to surrounding conditions.

Its fur is the most perfect non-conductor of heat that I have ever seen. In summer it is short and dark, in color like the surrounding rocks. In winter it is long and nearly white, like the beds of snow under which it digs for food. It is thus protected even in color from its natural enemies.

When the deer is well fed, every part of the body is uniformly developed, and if prosperity continues there is a plentiful storage of fat for future use. But this fat is not diffused all over the body, as is the case with an overfed man; it is placed over the dorsal and lumbar regions, where it affords least resistance to locomotion. As winter advances and food becomes scarce or more difficult of access, the fat is used first, then the muscular tissue begin to atrophy, and finally every vascular part of the body is partly used. Indeed, when the sun returned, every deer which we killed was reduced about one-half its weight. Even the skin was wasted to a mere film, but the fur which protected the body was more effective than ever.

The physical adaptation of the deer, including as it does the many organic transformations to meet the hard necessities of Arctic inclemency, bespeaks the laws of all northern life. It is imperative for man and beast to roam about and constantly hunt for new sources of food and new places of shelter.

The native people, like the animals, have evolved a system of life and adaptation to their habitat which could not be much improved by civilized aid. They are able to withstand long periods of famine like the deer and bear with no apparent injury except a loss of bodily weight. Their cutaneous circulation is always profuse. The muscular outlines are largely obliterated by an envelopment of fibro-fatty tissue like that of the seal and walrus. The intestinal capacity is greatly increased to afford greater surface for the absorption of nitrogenous and fatty foods.

These are perhaps the most important physical changes. The increased peripheral circulation and the blanket of fat protect them from the harsh and changing temperatures, while the abdominal enlargement affords the increased intestinal surface which we know is necessary to digest an absolute diet of meat.

The light of the Arctic summer is in itself an interesting study. The sun, always low on the sky, sends rays over snow, ice, and water at such angles as to reflect and bend the beams which fairly burn the skin even in low temperatures. It is to this mirrored reflection of polar sunbeams that we must ascribe the intense bronzing of the exposed skin of explorers and natives. This luminous glow is also an efficient tonic to the mind and body; but before the night begins the stimulation is replaced by a progressive depression. The darkness, cold, and isolation then drive the mental faculties on to melancholy.

The resistance of the body to low temperature depends upon several important elements. First there must be a system of healthy elastic arteries, a sound heart, and normal kidneys; second, a liberal allowance of food and non-stimulating warm drinks, preferably tea; third, a total abstinence from all alcoholic drinks, for no man can long retain elastic arteries or a well-balanced vasomotor system who consumes alcohol in even moderate quantities. The first effect of low temperature is to augment the internal production of heat, which goes to supply the increasing loss without.

Then follow a sense of warmth and increased vigor, a ravenous appetite, and an irresistible desire for muscular exercise. If the body is well clothed and a cheery sunlight prevails, a feeling of pleasure and general well being is extended over a period of weeks or months. Darkness and the gloom of stormy days, however, always induce a temporary depression of vital forces.

Our animal temperatures during the summer season were always normal, even though we were exposed to an atmospheric temperature of -50° F., but long continued darkness almost invariably induced a subnormal temperature.

Next to darkness the greatest enemies to polar life are humidity and wind. The disagreeable effects of low temperature depend as much upon these as upon the absence of heat. To judge the temperature by its effects upon our feelings was always deceptive. We frequently went out for a stroll in a temperature of -50° F., when the air was calm and dry, and found ourselves as comfortable as in New York with the thermometer above zero. At other times, with an air charged with moisture and driven by winds, we were unable to travel in a temperature of -30° F. When we felt the effects of extreme cold, one of the first sensations was that of piercing needles in our appendages,

particularly the hands and feet. Then our arteries felt as though vichy was poured through them from siphon bottles. Next ideas followed slowly and our minds became blunt, while the general cutaneous sensation was diminished.

I am not prepared to state what influence, if any, the Arctic conditions have upon the functions of the organs of generation in Caucasians. Among the natives, however, I observed many significant facts. Their genital sense is not particularly affected by low temperatures. Certainly a northern buck will not miss a good opportunity, nor will a female object because there is no shelter or because it is cold and stormy. If it has been mutually agreed, copulation takes place usually with only the canopy of heaven above them and an unmeasured depth of snow beneath. Indeed they delight in telling stories of how they stripped in the face of a driving snow storm.

The genital sense of these people is decidedly periodical. They seek gratification to some extent throughout the year, but during the night the sexes are more or less indifferent to each other. There is a grand annual outburst of sexual rage soon after the return of the sun. It comes with such force and overtakes them with such suddenness that they frequently quiver for days with passions. This culminates during the first summer days with what might be called an epidemic of venery, when wives and husbands are frequently exchanged with becoming grace and good intentions. For the rest of the year life resolves itself into a hard matter-of-fact existence—a continuous series of fierce struggles for food, clothing, and shelter, during which they have little time or ambition to nurse or gratify amorous instincts.

The reproductive organs of the primitive Eskimo mature rather late. The men do not as a rule copulate until after twenty. They rarely marry before twenty-two, but the sexual appetite seems to be acute in the aged long after the reproductive functions cease.

Girls marry at ages ranging from thirteen to sixteen and sexual congress begins at once; but they do not as a rule menstruate until after sixteen. The sexual appetite is probably not developed until after menstruation is established, which occurs between the ages of sixteen and twenty. Occasionally impregnation takes place before menstruation, but that is rare.

The menstrual function as a whole is strikingly peculiar to this far northern tribe—a people which by the way is the most northern on the globe. The first discharge usually begins during the annual period of sexual excitement. It is rather profuse in quantity and highly colored with blood. At the same time there are other hemorrhages from the mucous membranes of the mouth or nose. It continues about five days. Every succeeding monthly flow becomes paler and less profuse, until the advancing night checks the discharges almost entirely. During the very cold and dark periods of the year there is rarely more than an unusual serous moistening of the vagina for a few days every month. This is the usual history of the menstrual functions of most women until they are thirty-five years old; then the discharge becomes ever less bloody and less in quantity until about forty years, when it usually ceases.

Ideas seem to melt and flow like the fresh glacial streams in the mellow sunshine of the Arctic day; but as we were submerged under the darkness and gloom of the long night, the mind was depressed and all animal functions became less active. Our temperatures were usually subnormal, 97°–98° F.; pulse from 60 to 70; respiration, 14 to 20. All the secretions were scant and there was usually a gastro-intestinal stasis. Vague muscular pains, vertigo, cerebral congestion, and anæmia indicated the sluggish circulation or the lack of vasomotor stimulation. At about Christmas, which is the polar midnight, matters reached a climax. Although laboring under a superficial and false exuberance which suppressed real outbursts of anger, we soon found ourselves lethargic and more or less overcome by spells of melancholy. As the light returned we found our skins jaundiced and pale. We were incapable of prolonged exercise without great prostration. Although we had not lost weight during the night, we did lose vigor and ambition and interest in our surroundings. Our condition was a mixture of the vague elements of chlorosis and the profound debility of anæmia. With the return of the sun came a rapid transformation. The jaundice, the pallor, and muscular debility quickly disappeared. Periods of profound vasomotor disturbance and of mental and nervous excitement followed each other like eddies in a spring freshet. Before the sun had reached its summer altitude our bodies were quivering with the renewed buddings of animal passions. Our skins, which were nearly bloodless, were now flushed. The mucous membranes were now congested and all the secretions were excessive. The eyes which were dry now sparkled; the saliva at times fairly trickled from our lips. We bled easily from nasal membranes upon active excitement. Indeed, the return of the sun started life into a renewed rivalry of bursting springs.

I shall always remember our camps while travelling over the trackless wastes of snow during this period, particularly the stormy scenes. We undressed in the open air, crept into our sleeping-bags, and with a rare delight stretched out upon the virgin fields of snow for a long sleep. There was nothing but the high blue sky above us, and often there were many hundred feet of snow and ice beneath us. At first after reclining we were nearly stiff from cold, but this was soon followed by a glowing reaction, when we were conscious of bounding streams of heated blood sent throbbing through tense arteries. We felt doubly the wild pleasures of primitive life, as we heard the roaring storms and felt the snow-charged winds blasting against our protected bodies.

Such storms always brought us to sharp consciousness of the superb animal comforts, as comforts go in the Arctic. All of this served to enhance our admiration for the wonderful mechanisms of the human body. Nothing could bring one to a keener realization of this than our experience. To feel the heart force heat and life to the surface while resting over and sometimes under a blanket of protecting snow, is to feel the electric glow which for the want of a better term we call life.

In conclusion, I wish to emphasize the fact that it is not the low temperature of the Arctic from which explorers suffer. It is the long and intense darkness and the inability to carry sufficient food and accustomed aids to personal comfort. But this is easily counterbalanced by the acute passions of life as they are brought out by the prolonged noonday splendor and rested in the lasting darkness. The white lights and dark shades entering into the soul make life a long dream—the spirit now effervescing, then smothered again, almost frozen, only to be thawed out for an ascent into an atmosphere of heavenly purity.

In my judgment, polar grandness lifts the mind's horizon, and as a whole the experience affords a wild, weird, and poetic existence long to be remembered. It fires the soul with new flames and instils the body with renewed action. The dayless nights and the nightless days and fierce storms are bewildering, but these maddening contrasts are productive of clear and forcible intellects. I am confident that many forms of nervous, gastric, and pulmonary diseases would be greatly benefited by some of these conditions, particularly the congenial summers. Those who have early exhausted the sparks of youthful enthusiasm, who seek

the elusive elixir of life, who long for the fugitive balm of perpetual youth, would find in the raw Arctic wilderness a new interest in what has become a weary life. There the strong relentless conditions incite the mind, but throw it back upon itself. They inspire the imagination without satisfying its curiosity. There the atmosphere is charged during the white splendor of summer with noble sentiments. It is also illuminated with an endless mirage of fetching perspectives. These conditions, excluding the winter darkness, are indeed a true nursery to the exhausted body and the worn brain.

687 Bushwick Ave., Brooklyn, N. Y.

TUBERCULOSIS AND CLIMATE.

By E. T. CAMPBELL, M.D.,

tabor, iowa.

Nothing within the whole range of medicine has given the physician more discouragement and heartache than tuberculosis; and nothing does he hail with more joy than a treatment which gives promise of better things—that gives promise that that dreaded disease may be stayed or modified if not cured. Not a drug listed in our pharmacopœia but has had its brief day as a champion for first place in the cure of this disease, only to be retired after a short time to the place it formerly occupied; some to appear for a second trial, with like results. All the solids, all the liquids, and all the gases have in turn been "weighed in the balances and found wanting." Many, it is true, have won permanent places as aids to alleviate certain conditions or symptoms, but one and all have been denied first place.

The discoveries of Koch mark the beginning of a new era in the battle with this prince of destroyers. Founded on this established truth, investigation and experimentation have established a more rational line of treatment. In place of the empirical administration of medicines, we now have a definite object in view, viz., the destruction of the bacilli and the repair of the damage done.

Until recently the disease-resisting power of the system has not been sufficiently considered, the germicidal properties of the white blood corpuscles have been overlooked; but now the plan of treatment is to assist nature in her battle with the countless millions of enemies which are besieging the portals of our being, and the question now is: "In what way can we most quickly and safely help nature to shake off her enemy and repair the breech?"

Our most efficient means at present are climate, hygiene, and diet. We find that in low, moist localities, with great extremes and sudden changes of temperature, great humidity, and dearth of bright sunshiny days, this disease works deadly havoc; whereas in localities of higher altitude, more sunshine, lower humidity, less variation and fewer degrees of temperature, and better drainage, the disease is arrested and often cured.

Too great an altitude is not to be advised, as it is dangerous save in incipient cases in which there is no associated heart trouble, an altitude of from fifteen hundred to two thousand feet above sea level being better in a vast majority of cases than much higher altitudes.

A uniform temperature also is to be sought for, not too cold in winter or too hot in summer, and freedom from sudden changes and a large proportion of bright sunny days.

Above all, climate must not be taken in given doses, like medicine, but continuously, *ad infinitum*. Those affected should seek a desirable climate to live in, not to get cured in, for innumerable subjects apparently cured have returned to their former homes only to have the disease return.

One essential factor in the climatic cure of tuberculosis has been touched on only slightly, and that is the presence of ozone in the atmosphere of those elevated regions. Ozone we know to be a powerful disinfectant and respiratory stimulant. In a recent paper read before the Iowa State Medical Society, Dr. Braunworth spoke of the purifying effect of the electric-arc light, attributing this effect to the light itself, whereas the purification was due undoubtedly to the ozone produced by the electric current.

Colorado and parts of California are perhaps most noted as resorts for tuberculous patients, but other parts of our country are claiming attention as possessing the necessary qualities to recommend them. The vicinity of Asheville, N. C., is becoming very well known, and not without cause. And again, on the southern slope of the Ozark Mountains in southern Missouri we find all the advantages of elevation, large number of sunny days, freedom from extremes of temperature, the thermometer seldom registering more than 90° F. in summer, or below 15° F. in winter, with always cool nights in summer, freedom from sudden changes such as occur in higher altitudes, large proportion of ozone, plenty of pure water, and good drainage. Many have come to this region while in the first and second stages of consumption, and found complete restoration.

One point in favor of this country, perhaps above all others, is that, it being a comparatively new country, lands are cheap, thus giving the man of limited means a chance to come and buy a home. It being in the lumber region also, lumber is cheap.

It is a most important factor in the treatment of any disease, and especially tuberculosis, that the patient's mind be as free as possible from all worry; and patients with limited means cannot gain the advantages of curative climates when the expense thereof is beyond their means, or so great as to be a source of worry and anxiety to them.

In a meeting of the New York State Medical Society, one member suggested that in the place of consumptive hospitals we have consumptive farms; and this will surely prove the keynote to success in the treatment of this disease. To live continuously in the pure ozone-permeated air, with good wholesome food, water, and plenty of exercise, cannot but work wonders.

And the exercise should be of a constant, not periodical character. If possible, the patient should be continuously in the fresh air, attending to work about a farm if possible; if not, then wandering at will over the hills, botanizing or geologizing, or bent upon some object. Above all, let the mind be constantly diverted from himself toward some interesting occupation.

Hygiene, in conjunction with a favorable climate, is essential. Frequent bathing and well-ventilated rooms both day and night, good wholesome food, pure water, and good drainage, combined with a suitable climate, will prove our most efficient means of combating this most dreaded disease.

Intravesicular Injection of Sterilized Air has been carried out in three cases of tuberculous cystitis by Dr. Raymond (*Jour. des Prat.*, February 13th) with some relief of symptoms, which he thinks warrants renewed trials. The urine is completely drawn off and through a soft catheter from one hundred to three hundred cubic centimetres of air, passed through sterile cotton in the end of a hydrocele syringe, are forced in and allowed to escape, at first through the catheter and afterward by forcing the sphincter. It is especially adapted to enfeebled subjects who would not bear operative procedures.

OUTLINES OF RURAL HYGIENE.

By HARVEY B. BASHORE, M.D.,
WEST FAIRVIEW, PA.

MEDICAL men in general, unless they have made a special study of the subject, have little idea how defective are the sanitary arrangements in rural districts. The text-books on hygiene tell us all about water supply and waste disposal for large cities; medical teachers, apparently forgetting that their pupils will practise for the most part in outlying districts, tell them all about municipal hygiene, but neglect the sanitary conditions of isolated houses and of ill-constructed villages. So it has come about that the rural districts, in which the greater part of our population lives, are singularly devoid of sanitary arrangements save in a few individual instances. True, the boards of health have inspectors for such places, but unsalaried positions do not lead to much advancement or development. England and continental Europe are much ahead of us in this respect. One can hardly pick up a copy of the great English journals which does not contain something about rural sanitation, but then the English are pre-eminently a "country people." Some localities, of course, are worse than others, but in general there is much defect. Cemented cellars and damp-proof walls, ground air, and ground moisture are factors unknown to the country builders. The old-fashioned privy still reigns supreme for the disposal of excreta. Not one family in a thousand uses an earth closet; indeed, most country people seem to have no knowledge or idea of any method of disposal save the privy.

In the case of water supply there is great deficiency, but the people are beginning to make some progress along this line, for many towns are procuring a public supply from neighboring springs or streams, but in the lack of watchful care, which should be exercised over such small gathering-grounds, I fear that the story of Plymouth will be repeated many times. A public supply is undoubtedly desirable, but great care must be used in procuring it.

For certain isolated places wells, it seems, must continue to be used, but advancing progress demands that they be better than they are at present. When wells are used, the ground water must not be fouled by leaking privies; consequently the question of water supply from wells resolves itself into the proper construction of the well and the elimination of leaking privies and sewers. The old well, when not already infected, might be treated as Dr. Koch has suggested, and made into a tube well containing a surrounding sand filter; or one might dig a new well and make it according to Dr. Poore's directions. In certain other places, especially along the Atlantic coastal plain, a public supply from artesian wells furnishes all that can be desired.

There is a source of water supply for rural districts which is generally overlooked, *i.e.*, the storage of rain water in cisterns; with a properly constructed cistern containing a partition and a filtering layer of sand, gravel, and polarite, we can procure as wholesome and pure a water as is available anywhere. The problem of the old well is best solved, to my thinking, by the cistern, and if we would turn to this source of supply the death rate from typhoid would be greatly lowered. Another point is the examination of wells and well water. Each physician should know especially the chlorine normal of his locality—the amount of chlorine present in the unpolluted streams and springs. Then he can readily discriminate whether this or that well might be or might not be dangerous.

Waste disposal is a second chapter in rural hygiene. In the disposal of excreta the country population has made no advancement since the days of our prehistoric ancestors, who likely left their excrement on the surface of the ground. This would be almost, if not altogether, as good a method as the filth-containing privies. The proper way and the only proper way for people who live in places cut off from water service to dispose of excrement is by some form of earth closet. This may seem very primitive, but the fact is that the earth closet is a very scientific piece of furniture. It depends for its action on facts which we have only lately learned from the biological laboratory, for adding the earth is simply adding certain nameless nitrifying bacteria which we are yet unable to isolate from their natural habitat. Schloessing, Müntz, Warrington, and Winograwdski have done much on this line, but there is yet much to be done. Personally I think that in the house the ash closet is a little more desirable, because it is more absorbent and lighter; of course it is sterile as far as nitrification goes, but if the mixture is buried or scattered over the surface of cultivated land nitrification is only a little delayed. Infected fæces should not be received into an earth closet, but a special receptacle should be used, and the contents disinfected and then buried two or three feet beneath the surface. If the contents are buried without disinfection, we run the danger of the pathogenic germs being washed away by a sudden rain, and infecting a large neighborhood, as happened lately at Bayreuth.

The matter of slop-water disposal is easily solved by the method of subsoil or surface irrigation. Surface irrigation is, I think, less likely to cause trouble, for in this sunlight and oxygen are always at work.

The construction of a surface drain is very easy. An old perforated tin roof gutter, twenty or thirty feet long, supported a foot or so above a garden bed, will dispose of all the slops of an ordinary family of four or five. The ground underneath the drain needs a little raking now and then. The gutter may be directly connected with the kitchen sink and bathroom, or a tin-lined slop bowl placed at one end of the drain may be used to receive the water. It is a good plan to have two buckets set aside for kitchen slops, one for liquid and one for solid refuse. If a perforated basin is placed on the one, the liquid can be readily separated from the solid. This method of waste-water disposal, if used with care, I know to be practically very efficient.

Professor Poore has recommended another kind of surface drain, constructed of perforated bricks arranged over a suitably prepared trench. This is highly praised by some English physicians, and if properly constructed would likely give entire satisfaction. In certain places subsoil irrigation might be the only method available, and if well made with agricultural drain tiles would probably answer all the requirements of a good drain. Solid kitchen waste can either be buried, or, if soil is available, be placed on the corner of the garden bed, covered with earth from time to time, and allowed to nitrify. Another way of disposal is by the fire of the kitchen range or a specially constructed furnace.

For the reception of broken crockery, tin cans, etc., nothing serves so well as a flour sack. When necessary to empty it it may be tied, carried away, and the contents used for filling. Sewage disposal sometimes forms an item in rural hygiene. It has been customary for isolated houses to dispose of their sewage into a cesspool. Instead of a cesspool a shallow tank should be constructed, and the contents disposed by irrigation over a neighboring field. This is the scientific way to dispose of sewage.

The proper construction of dwellings may be considered a third chapter in rural hygiene, for nowhere else are the houses so badly constructed. The foundations and the cellars are almost always damp, and the large amount of phthisis, muscular rheumatism, and catarrhal inflammations in rural districts other-

wise healthy is ample proof of the factor of dampness. Heating and ventilation are both very crude.

School hygiene, which deserves a separate chapter, is beginning to make a little progress, yet the floor and air spaces are usually much too low and the lighting is always defective. Heating and ventilation are especially bad. I doubt if there is one country school in Pennsylvania where these points are anything like the sanitary requirements. Even when hot-air furnaces are used, the misplaced outlets carry off the warm air before it has circulated around the room. A common stove, such as is used in all country schools, can be made into a very effective heating apparatus by properly constructing it into a "ventilating stove" and by having the foul-air outlets suitably placed. The old idea that the warm-air inlet should be at the lowest part of the room and the foul-air outlet at the highest point are well-known fallacies.

HOT SPRINGS, S. DAK., AS A HEALTH RESORT.

By C. W. HARGENS, M.D.,

HOT SPRINGS, S. DAK.

Climate, mineral water, and the element of change, as adjuncts to other treatment, will often bring relief to invalids afflicted with certain chronic diseases when everything else fails. As a result the general practitioner is frequently consulted concerning the merits of the different health resorts in this country, and it becomes necessary for him to have a knowledge of medical climatology.

Within the last four years Hot Springs, S. Dak., has attracted considerable attention, and the object of this paper is to set forth the climatic and sanitary conditions of this place. The climate of any locality depends largely on the latitude, altitude, local topography, precipitation, temperature, winds, nature of the soil, vegetation, watersheds, and the contiguous territory.

The ideal health resort possesses a moderate altitude, minimum rainfall, equable temperature, porous soil, swiftly moving streams, little wind, and air currents from regions uncontaminated by contact with ponds, small lakes, or a soil saturated with or encumbered by masses of decaying vegetation. Such a place we have in Hot Springs, S. Dak. Our climate at Hot Springs differs as widely from the climate generally accepted, and in fact generally true, of South Dakota, or even of the Black Hills as a whole, as the climate in the Valley of Mexico differs from that on the summit of the adjacent mountains. The local topography separates us absolutely from the surrounding country, and the reports of weather-bureau stations are not a proper index to our climate.

Hot Springs is situated on the southern border of the Black Hills, in the angle made by the plains to the south and the hills to the north, with an elevation of thirty-four hundred feet. It is the lowest point in the Black Hills; within a few miles it is protected by mountains attaining an elevation of over five thousand feet. On the north and west, twenty-five miles out, it is protected by mountains attaining an elevation of six thousand and eight thousand feet. Thus situated in a narrow canyon from two hundred feet to a mile wide, with a drainage incline of one hundred feet to the mile, sheltered from winds, free from dust, it basks in perpetual sunshine. The atmospheric currents pass over it, and heat radiation in this angle is so great that a warm current is constantly rising, and precipitation is rare, because mist and clouds are dispersed when cold currents come in contact with warm ones. During my service of four years as voluntary United States weather-bureau observer, I have found the precipitation as low as eleven and not more than seventeen inches in any one year. This alone would give us an unusually dry climate, but combined with the excellent drainage and the exceedingly porous soil it makes this element in our climate an unusually important one, as the precipitation is less than one-half of that of Iowa, Illinois, and Michigan and neighboring States, one-third of that of the Southern States, and one-fifth of that of our Arkansas competitor. The small amount of annual precipitation, the mountain protection, the medium elevation, assure us of few cloudy days, sunshine being greatly in excess. Combining the effects of minimum precipitation, mountain protection, dry air, porous soil, we have a resulting warm atmosphere and soil, a resulting temperature much above that of contiguous territory, a temperature not subject to sudden and wide ranges, a climate always regulated by cloudless skies, thus preventing the accumulation of heat with resulting sultry conditions; a dry, warm, sunshiny day, and cool, clear mountain night; air always calling for a pair of blankets at night, while the shade in summer always affords a cool and inviting spot. As an example of the dryness and purity of the atmosphere I will cite the fact that beef killed and cut into pieces convenient for handling may be hung in the open air and will cure without the aid of any of the metallic salts usually employed for that purpose. Now these climatic conditions are not accidental; they are the result of the local topography and the influences already enumerated. We have but little snow fall, and that, influenced by the warm soil, sunshine, and chinook winds, rapidly disappears. The mountains cut off all supply of moisture from the Pacific coast, while the great distance from the Gulf, the Atlantic, and the lakes exhausts the moisture from these sources before it reaches us. To sum up, we have here an ideal climate, climatic conditions that will at once appeal to the practitioner as being of inestimable value in the treatment of many chronic affections—prominent among them, tuberculous, pulmonary, and bronchial affections, subacute and chronic rheumatism.

Combined with favorable climatic conditions, this resort possesses the advantages of about seventy-five mineral springs, varying in temperature from 86° to 96° F. Among the mineral constituents in these waters we find the sulphates of sodium, potassium, magnesium, and calcium; the chloride of calcium and magnesium; the carbonates and phosphates; nitrate of magnesium; chloride and chlorate of sodium; bicarbonate of magnesium and iron. Coupling the mineral water and the various uses thereof with the climate, we have a number of valuable factors; however, this does not suffice. It is a well-recognized fact that a patient's mental attitude has a marked influence on his ultimate recovery, and this is especially true in many chronic ailments. When the weak condition of the patient prevents much outdoor exercise, we are certain to have greatly depressed mental states that need relief. Very often the simple element of change will relieve the mental depression, but my experience has been that to obtain a prolonged impression it is necessary to have at hand a large variety of attractions and pursuits that will gain and hold the attention of the invalid; this variety can be found in and within a short distance of Hot Springs. The scenery of the Black Hills is unrivalled by that of any other section in America, and this is truly the Switzerland of America. We possess all the advantages of a mountain country; great pine forests, a beautiful lake, camping, hunting, and fishing, mountain climbing, horseback and donkey riding, wind and crystal caves, marvellous freaks of nature, the great Homestake Gold Mining Company with its immense mills and smelters, Battle Mountain, Harney Peak, the Needles, the Bad Lands, and other

neighboring attractions of natural formation. Our magnificent Plunge Bath, with its crystal pool fifty by two hundred and fifty feet, and its inflow of one hundred thousand gallons per hour, with a constant temperature of 96° F., is alone ample attraction for a journey to this place, as the waters are laden with elements which cure, while the plunge entertains the patient: there are also many other magnificent bath-houses, beautiful parks, nooks, drives, etc.

To the above advantages we can add other civilized advantages of the city of Hot Springs, among them four and five story hotels, the equal of which cannot be found west of Chicago, from which it is only two nights and a day's ride. I recently took Sunday night's 10:30 train from Chicago on the "Northwestern Line" and had breakfast at home here Tuesday morning at 7:30. Travelling accommodations are now so universally good and comfortable that such a trip is a luxury rather than a hardship, and no one need be deterred from getting the benefit of this magnificent climate and other superior advantages on account of the journey.

SOME THOUGHTS UPON ALCOHOLISM.

By G. H. McMICHAEL, M.D.,

BUFFALO, N. Y.

Careful observation during the past ten years has forced me to the conclusion that every human being has a congenital predisposition toward some form of disease. Favorable conditions in many cases prevent the development of the disorder, but the special susceptibility—the diathesis—is always present. There are some brains which react toward alcohol to a marked degree. In their case the nervous system has a special affinity for intoxicating drinks, and if they are indulged in the alcoholic habit is quickly acquired. The class of brain to which I refer is one of bad quality. Want of balance and an unstable nervous system are signs of degeneration, and if the man who drinks four small glasses of whiskey, or their equivalent, every day has any grandchildren, there is likely to be an idiot or an epileptic among the number. Further, it is well recognized that the Koch bacillus has a special predilection not only for drunkards but for their descendants. What is a drunkard? it may be asked. The answer is that any person who habitually consumes one and one-half ounces of absolute ethyl-alcohol per day (Anstie's standard), in any form, is a drunkard; whether alcoholic narcosis takes place or not is quite immaterial.

Persons who possess brains specially susceptible to alcohol have usually a strong desire for cerebral stimulation; they appear to be constantly looking for some pleasurable outlet for their energy, and they generally have an aversion to ordinary routine work. While some of them never see a woman without lascivious thoughts coming into their minds, others are remarkable for the interest they take, always for a short time, in some important question, which escapes their memory before a month has passed. Obviously these characteristics are of comparatively little moment unless they are very prominent, and unless other qualities which act as a check upon the alcoholic predisposition are deficient.

To the normal child alcoholic drinks are distasteful, as they are to many men who have never been in the habit of taking them. But there are children who display a liking for alcohol and for other drugs at a very early age. Dr. Clouston, in an article upon "Diseased Cravings," has given some examples of this phenomenon which have come under his notice. One other point occurs to me, viz., some children and some adults—especially women possessing a particularly delicate nervous system—are seriously affected by extremely small doses of alcohol and other drugs. If this peculiarity is very pronounced, it may be taken as evidence of the alcoholic diathesis. As this assertion may be disputed, I wish to remind my readers that the alcoholic diathesis is merely a special susceptibility toward alcoholism. To become a drunkard one must habitually consume some intoxicating drink.

There are certain men whose nervous condition seems to compel them to "explode" without any sufficient provocation. It is manifested almost every day in the matter of drinking. I can remember quite a number of men who have indulged in prolonged sprees without any appreciable reason for so doing, having started out without any intention of getting drunk. These bouts of drunkenness are often periodic, and they are valuable as demonstrating the connection between the alcoholic and the insane diatheses. The tendency toward alcoholic excess, whether congenital or acquired, is present in many persons whose self-control is in a marked degree defective. This condition is of course due partly to some impairment of the functions of the cerebrum and partly to the absence of suitable education.

The public believes that every new function acquired by any animal produces some alteration in the reproductive elements whereby the acquisition is transmitted to the next generation. This belief, under the name of neo-Lamarckism, is supported by Professor Eimer (of Tübingen), by Mr. Spencer and Mr. Mivart. When the name of Professor Cope (of the University of Pennsylvania) has been added, all of the eminent neo-Lamarckians have been mentioned. Having done justice to my opponents, I refer my readers to the doctrine known as neo-Darwinism, which is as follows, viz.: the reproductive element of life, what Weismann calls the germ-plasm, when suitably nourished is almost independent of environment, and is virtually uninfluenced by changes produced during the lifetime of the individual. Acquired characteristics, pathological or otherwise, are very seldom transmitted—if they are at all. But the nervous organization favorable to the acquisition of a variety of disorders is passed on to the next generation, and the surroundings are responsible for the particular disease. What I desire to emphasize is that drunkenness in the parent does not, through the direct influence of heredity, make any difference in the character of the offspring. A tendency toward alcoholism in a child, however, may be the result of the blending of unsuitable paternal and maternal characteristics, though neither parent may have been addicted to drink. Indeed, the children of neurotic parents are very liable to become drunkards, just as they are liable to become tuberculous or insane. In short, if a child has inherited an unstable nervous system with its various susceptibilities from an alcoholic parent, it will probably become a drunkard, unless an environment is provided which specially guards against that form of disease. The habits of the parents are the most important factor in moulding the child's character, chiefly because they furnish the example which it consciously or unconsciously follows. Hence hereditary susceptibility is exaggerated by vicious surroundings into actual disease.

Drunkenness is not the only disorder which is apt to transmit the alcoholic dyscrasia. Any form of vicious life—and persons who lead vicious lives are really morally insane—is generally due to a neuropsychopathic constitution, which is transmitted to the next generation with great certainty. Of course the defect in the nervous system may take many forms, but alcoholism is as common a form as any other. To expect

the children of habitual criminals and of prostitutes to be sober men and women would be absurd, since these persons systematically lower their vitality by continually subjecting it to severe and prolonged unnatural strains. Further, these persons usually furnish an additional factor in the development of drunkenness in their children by surrounding them with as vicious an environment as can be imagined. I have heard of professional thieves who did not drink to excess, and I have been told of prostitutes who were total abstainers; but I have no hesitation in writing that the members of these two classes, representing, as they unquestionably do, the degenerated portion of the community, are in the majority of cases disposed to inebriety. This article is not a temperance lecture, nor is it an attempt to explain away the vice of the drunkard. It is an effort to study a nervous disorder; and let it be remembered that any man who habitually consumes spirituous liquors without food is dangerously near that disorder—call it narcomania, inebriety, alcoholism, or any other name you like.

The answer to the question: "Why do men and women drink alcohol?" cannot be anything more than approximate, because it involves so much that is unknown. At present we know only some of the most probable reasons. The desire for food is physiological and normal; the desire for alcoholic drinks is pathological and abnormal. Our knowledge of both cravings and of the processes connected with their satisfaction is still very vague. Ethyl-alcohol is an anæsthetic to the nerve centres, and it seems temporarily to quiet the warning voices of certain strains; it conceals the distress signals of fatigue and acts as a seductive narcotic, bringing for a short time what seems to be an ideal condition of rest.

Persons who are predisposed to the drinking habit usually possess a lax moral character which causes them to blame others for their bad habits rather than to place the entire blame upon themselves. The excuses given for drinking are, in the majority of cases, nothing more than subterfuges; but if one fact connected with this question is any more certain than another, it is that the lazy habit quite prevalent among physicians, of prescribing alcoholic drinks for the "tired feeling" so common in neurotics, has frequently been the first scene in the well-known every-day tragedy which, unless proper treatment be resorted to in time, ends with insanity, or paralysis and death. Dr. Norman Kerr, in the third edition of his book on "Inebriety," relates some cases which undoubtedly prove what I have written.

If alcoholism had no pathology, the treatment of it might be left to the minister of religion; but as it is a nervous disease, very closely allied to insanity and epilepsy, some general idea of treatment is necessary.

The real problem is how to reconstruct the character of persons whose indulgence in the pathological pleasure of drinking has deprived them of those qualities which constitute a useful life. All surplus energy has left these patients, and their power of ordinary attention to any given subject is small. While it is true that alcoholic indulgence impairs any man's best qualities, yet very many inebriates, under proper care, are capable of getting back their will power and of developing a new line of life.

It is on record that when cerebral disease has destroyed the basis of certain functions, new areas of nervous mechanism have taken up the functions of the lost parts, and have eventually acquired some proficiency in the performance of their new duties. Some process similar to this is what must be searched for in the case of the drunkard, and it is necessary to consider how new ideas can be suggested to his mind and how the requisite energy can be best directed, if it can be brought into existence. Of course, if the latter object cannot be accomplished, the case is most unpromising.

The opinion of alienists is that, as a rule, the way to try to cure a sufferer from delusions is neither to contradict his assertions, nor to laugh at him, but simply to ignore what he says. The same method answers with the drunkard, for the experience of the nursery is almost always confirmed when any other plan is attempted. In short, to forbid indulgence is much the same thing as suggesting it. The patient must abstain from alcoholic drinks, and a total abstinence pledge may be of some use if it binds the maker for a short time only; but there is nothing to be gained by allowing an inebriate under treatment to attend meetings at which drinking is abused and denounced. Indeed, the consequences of such attendance are likely to be detrimental. The application of external control is obviously requisite. However successful any treatment may be in arousing the patient's interest, stimulating his energy, and giving him back his will power, the result will be lost if the opportunities to drink are at hand, as they usually are. First, then, the patient should live in the physician's house. Secondly, the physician must be his patient's friend and confidant as well as the keeper of his conscience. A drunkard, being a creature of habit, has no power of origination, neither has he any judgment worthy of the name. His memory is defective, and his power of observation is quite limited. The doctor must take the initiative for him; must attempt to arouse his dormant will power, and must in everything either take him by the hand or drive him. Of course he is a liar; all drunkards are; and while he must be distrusted, it is well not to let him know that little of what he says is believed. Above all, he must not know that he is not doing the thinking and acting himself. When anything has to be decided upon, the suggestion is the most satisfactory process, for then the patient feels that the choice was his. As the treatment continues he must be taught to believe that he is growing strong and never to imagine that his personality is being lost.

The cure of drunkenness demands great attention to the requirements of each particular case, as the moral cause of each breakdown often gives some indication of the nature of the remedy that is required. One more suggestion can be made. In human life, whenever a new adaptation to environments is being evolved, the organs which fulfil the new function command for a time the resources of the organism, and may even hamper more essential functions. Whatever introduces any man—even the normal man—to a new point of contact, absorbs for a time a great deal of his attention. This fact must be seized upon by physicians who treat alcoholism, for it is necessary to start the drinker upon a new line of life, and to make it permanent if possible. The patient's enthusiasm must be aroused; and yet fanaticism of any kind must be guarded against.

Drugs alone are of little value without moral training. It is well to administer a cathartic as soon as the patient commences the treatment, for drinkers' stomachs are generally disordered. Other medicine may or may not be necessary. The prescriptions given by Dr. Norman Kerr, upon pages 269–275 of the third edition of his excellent work upon "Inebriety," are all that can be suggested. A nourishing diet and plenty of fresh fruit are an essential part of any serious attempt to cure alcoholism.

75 West Tupper Street

A New Styptic.—Antipyrin and tannin rubbed together produce a sticky compound very useful as a styptic. It may be applied with a sponge.

Progress of Medical Science.

Rupture of Healthy Œsophagus from Vomiting.—At a recent meeting of the Pathological Society of London, West and Andrews (*Lancet*, April 10, 1897, p. 1,027) exhibited the œsophagus from a man, fifty-five years old, who came under observation on account of acute pain referred to the left side of the chest, together with persistent vomiting. After death a rent three inches long was found in the posterior wall of the œsophagus near the cardiac extremity. There was dark fluid in the posterior mediastinum as high as the root of the lung and in the retroperitoneal tissue below the diaphragm as low as the pancreas. There were also collections of brown fluid between the base of each lung and the diaphragm. There was no sign of previous disease of the œsophagus, and the rupture appeared to have been caused directly by the vomiting.

Osteotomy of the Femur in the Treatment of Tuberculous Disease of the Hip in its Early Stages.—Tobin (*British Medical Journal*, April 24, 1897, p. 1,034) contends that no treatment better than rest, combined with constitutional remedies, is known for tuberculous disease of the hip. In a large proportion of cases this disease, especially in those in which flexion has occurred, goes on to suppuration, and one of the chief causes of its doing so is the difficulty of giving the joint rest. Much of this difficulty lies in the fact that the position of greatest ease for the tuberculous hip-joint is one in which it is very awkward for the patient to carry the limb, very difficult for the surgeon to fix it, and therefore one in which the joint is constantly exposed to disturbance. It is possible, and in many cases advisable, to remove this difficulty by such an osteotomy of the femur as will allow the limb to be put straight, while the upper of the fragments retains "the natural position of rest." The operation also does good in some cases by relieving tension in the bone. An osteotomy of the femur, when done in this respect, is not as formidable an undertaking as it is under ordinary circumstances, for it is not the division of the bone that is formidable in this operation, but the constrained position in splints and the long period of rest required for union. As these latter incidents are a great gain for the tuberculous joint, they must be put to the credit of the operation, thus leaving very little to be entered upon the debit side.

Strangulated Hernia in an Infant Four Months Old.—Dowd (*Archives of Pediatrics*, May, 1897, p. 321) has reported the case of an infant, four months old, whom he found suffering from strangulated right oblique inguinal hernia. The child had been carefully examined for hernia after birth, and none had been found or become evident before the day of operation. The strangulation had existed for six hours and an effort to reduce it by taxis had already been carefully made under ether. The hernia was as large as a goose egg and was very tense. Immediate operation was undertaken, the method of Bassini being followed. The outcome was successful and the little patient recovered without complication. Strangulated hernia in infants is rare, and from a study of the fourteen cases collected from the literature, in conjunction with his own, Dowd concludes that infants less than a year of age endure operations for strangulated hernia remarkably well. The mortality, according to the accessible statistics, differs little from that encountered in adults. From the histories of reported cases it would appear as if delay, while the strangulation existed, has been the chief source of danger. When strangulation has occurred, the following procedures are recommended: (*a*) Elevation of the legs, with the infant in a warm bath, accompanied by very gentle pressure upon the hernial sac. (*b*) Very gentle taxis under anæsthesia, which, if unsuccessful, should be followed immediately by operation. If strangulation has existed for a long time, taxis is more dangerous than operation. The records indicate a mortality of less than ten per cent. when the operation is done promptly.

The Treatment of Diabetes by a Diet from which all Carbohydrates have been Excluded.—As a result of careful personal observation of a typical case of diabetes, as well as from the quoted experience of others, Munson (*Journal of the American Medical Association*, May 15, 1897, p. 922) has undertaken to show that a diabetic should be placed under no different conditions of diet than are granted the healthy individual, and that a rigid exclusion of carbohydrates from the diet is productive of abnormal metabolic changes, which result not only in progressive emaciation and weakness, but also in the production of various toxic bodies, to which the severe cerebral symptoms of this disease are to be attributed. From this study the conclusion is reached that sugar is always present in the blood, and that the absence of carbohydrates from the diet does not cause a disappearance of the blood sugar. Hence, sugar must have some other source than the carbohydrates ingested. This other source of sugar is the ingested and systemic albumin, through a process of decomposition. An increased albumin decomposition, due to the rigid enforcement of a purely nitrogenous diet, means an increased metabolism and consequent loss of body weight. Hence the cutting off of carbohydrates from the diet directly produces an increased metabolism. *Vice versa*, the administration of carbohydrates retards metabolism. The diabetic has an especial predisposition toward metabolism. The diabetic has by no means lost the power of burning sugar; therefore, sugar must, even more than in health, be allowed in order to prevent loss of weight and muscular weakness, which may eventuate in one of the natural endings of diabetes, death by asthenia. The abnormal albumin metabolism, which is especially produced by a rigid proteid diet, results in the production of toxic bodies, for the action of which the depressed nervous condition of the diabetic is especially favorable. The production of toxic bodies is prevented or retarded by the administration of carbohydrates. Hence, carbohydrates should be administered to the diabetic to prevent the formation of certain toxic bodies and the severe and often fatal nervous and cerebral symptoms which they induce.

The Plague.—I. Varieties: The varieties of plague known under the names fulminant, typical, and pestis minor are allied. The cause of fulminant and typical plague is a diplobacterium in the blood and tissues. The cause of pestis minor may be an allied diplobacterium, but with a lesser toxic power. An appropriate name for the fulminant and typical plague is "malignant polyadenitis." An appropriate name for the mild variety (pestis minor) is "benign polyadenitis." II. Infection and contagion: Plague is infectious chiefly from the dust arising during the cleansing of dwelling-houses which plague patients have occupied. Plague is contagious by prolonged and intimate contact with the plague stricken, as in the case of a nurse carrying a child ill of the disease. III. Distribution: Plague is met with in a definite area of Asia, which may be termed the "plague belt." The home of plague is at the present day in Mesopotamia and the countries adjacent. From Mesopotamia as a focus the

plague may spread northward to the Caspian Sea, westward to the Red Sea, southward as far as Bombay, and eastward as far as (Formosa) the China Sea. During the present century plague has shown a western retrocession and an eastern accession of virulence. IV. The bacillus: Typical plague (malignant polyadenitis) is associated with pestis minor (benign polyadenitis). A bacillus of somewhat similar appearance microscopically is reputed to be found in both. The bacilli differ in their toxic powers only. A benign polyadenitis may run its course without being preceded or followed by the malignant variety. Malignant polyadenitis may run its course without being preceded or followed by the benign variety. The bacillus of the benign variety attains malignancy by passing through some intermediate host, possibly, but not probably, the rat.—Dr. James Cantile (*British Medical Journal*, January 9th).

Clinical Department.

A CASE OF MERYCISM.

By H. A. MINASSIAN, M.D.,

DES MOINES, IOWA.

The following history was given me by Miss G—— on December 3, 1896: Aged twenty-five years, bookkeeper. For more than ten years she had suffered from various gastric disorders, the present morbid condition being of one year's standing. Its immediate precursor was involuntary regurgitation of ingesta, which insidiously merged into rumination. The transition from one to the other was not perceived by her. She ruminates now, commencing about half an hour after meals and continuing from one to two hours, according to the amount of food taken; regurgitates her food with perfect ease and returns it to the stomach after thorough remastication. The food brought up is not sour nor unpleasant, although she derives no pleasure from the act. She can ruminate at will, but rumination occurs largely unobserved by her and without detracting her attention from her daily work. Water and fluid food in general enhance regurgitation. Nausea, pyrosis, pain, or distress referable to the stomach and all other subjective symptoms of organic disease are absent. She is a hearty but hasty eater. Family history is negative. She is not a neurasthenic.

Physical examination: Patient is a robust and well-nourished young woman. Tongue clear; size and position of stomach normal (by percussion, later confirmed by inflating the stomach). Firm pressure on the epigastrium elicits no tenderness. All thoracic and abdominal viscera normal.

Ewald's test breakfast was ordered, and on December 4th, two hours after the test meal, the patient was asked to regurgitate as much of the stomach contents as possible. After persistent effort she failed to eject any food whatever. Consequently the stomach tube was passed, and expression and aspiration were tried, also without success. The stomach was then washed with a pint of water, the latter containing a mere trace of the meal. Examination of this fluid gave: Faint acid reaction; HCl = 0; erythrodextrin and achroödextrin +.

Following the first examination, through a period of two weeks analyses of the gastric contents were made once each day with special reference to HCl and total acidity. The quantity of food found in stomach four hours after a Leube dinner or two hours after a Ewald breakfast was so small that only half the usual time was allowed before removing the same, which was easily accomplished by the patient. The variation in the results of analysis on different days was insignificant; hence the following specimen is representative: December 9th, quantity of food ejected, eight ounces; color, white; odor, none; reaction, acid, admixture of glairy mucus; total acidity = 3; HCl = 0; pepsin and rennet ferments present; dextrins present.

Two points worthy of note in the above are: (*a*) the abnormally rapid passage of food through the stomach, and (*b*) the uniform absence of HCl. Hyperprochoresis and not pyloric insufficiency was believed to account in this case for the former, since there was no evidence of regurgitation of intestinal secretions and bile into the stomach. Was not this increased motor function compensatory to (*b*)? And does it not sustain causal relation to rumination? There being practically no gastric proteolysis in the absence of HCl, on the one hand the food is returned to the mouth in small portions for remastication and more thorough ptyalization, and on the other it is forced on more rapidly than normal into the intestines.

It would be taking too much for granted to claim that during the entire period of one year through which she ruminated hydrochloric acid was uniformly absent from the gastric secretion; nevertheless it is true that positive achlorhydria existed from December 4th to 19th inclusive. This in itself is sufficiently striking and furnishes the key to the cause of rumination in this patient. The achlorhydria itself was doubtless a neurosis, since carcinoma and advanced chronic gastritis were inadmissible. The results obtained by treatment fully confirmed this.

Considering the condition as a neurosis, the following schema is offered indicating the relative positions as well as order of the development of the three principal elements of the disease in this case:

1. Achlorhydria, primary neurosis.
2. Hyperprochoresis, consequent to (1); compensatory.
3. Merycism, dependent on (2); compensatory.

Treatment was commenced on December 20th, and consisted of the administration of six minims of strong muriatic acid (largely diluted) after each meal in three divided doses at intervals of fifteen minutes. Patient was advised to suppress rumination as far as possible, to masticate her food thoroughly, and take but little fluid with her meals. No special diet was thought necessary. Intragastric galvanization was recommended, but patient begged to have this postponed until it was found absolutely necessary.

January 9, 1897: Patient reports improvement. She had been instructed not to use hydrochloric acid during the past two days. She voluntarily ejected a portion of the stomach contents, which upon examination gave the following results: Reaction, acid; HCl present; acidity = 11.

January 27th: No muriatic acid taken past two days, as before. Gastric contents removed with the stomach tube to avoid ruminating. HCl present; total acidity = 20.

February 8th: HCl +; acidity 35. Rumination has practically disappeared.

She left the city shortly, and was advised to continue the use of the acid in smaller doses as long as necessary.

The successful stimulation of HCl secretion by the administration of hydrochloric acid in the above case is certainly of great interest.

Tuberculosis of the Peritoneum with Effusion.—Dr. Senn says: "Diffused tuberculosis of the whole peritoneum begins practically always in females in the pelvis, as a distinct tuberculous salpingitis. The usual history is one of tuberculous metritis followed by tuberculous salpingitis, the latter in turn by tuberculous peritonitis."

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 12, 1897.

THE SEMICENTENNIAL OF THE AMERICAN MEDICAL ASSOCIATION.

THE fiftieth anniversary of the foundation of this great medical society was fittingly celebrated in Philadelphia last week by one of the most successful meetings recorded in the annals of the organization. The attendance was unusually large, the number of registered members being over two thousand, but so efficient was the management of the committee of arrangements that there was no confusion whatever, and the exercises were carried out according to programme without a hitch. In addition to this being the largest it was also one of the most harmonious meetings that the present generation of members has ever had the good fortune to see, and it was most gratifying to find that the protests of the MEDICAL RECORD against the quarrels which had become so frequent at the general sessions, which protests were rendered yet more effective by the earnest words of the president in his address at the opening meeting, had borne fruit so abundantly.

The addresses of the president and of Drs. Flint and Keen, full abstracts of which were presented to our readers last week, were worthy of the occasion as well as of the authors. That of Dr. Senn, as is the custom in the presidential address, contained a number of suggestions for reforms and improvements in the manner of conducting the meetings. Had his genius risen to prescience, he undoubtedly would have uttered a word of protest against the publication of all the addresses in full in the daily papers, along with the portraits—dreadful caricatures—of the authors and others. The publication committee of the *Journal* would seem to have had a very loose hold upon the original copies of these addresses, for we cannot believe that the authors themselves would give them out to the press in direct violation of a rule of the association.

The committee on nominations could not have made a better choice for president than that of Surgeon-General Sternberg, who is honored throughout the medical world, apart from his rank, for the vast amount of original work he has accomplished in many lines. The other officers and orators were also well chosen. The selection of Denver as the place of meeting in 1898 was well made. That city is nearly as accessible from points in the middle West and South as is Philadelphia, and it contains so many physicians who began their medical life in the East, after forming friendships which they have always kept up, that it will draw many men to the meeting who might not be tempted to go so far to any other city.

Dr. N. S. Davis was rightly the central figure of the jubilee exercises, and any man might well be proud to occupy such a position as his, at a moment when two thousand physicians were present in person, and many thousands more in spirit, to do honor to the founder of the association. Not only does the body owe to him in a measure its very existence in the form it now has, but his wise counsels have carried the organization through many periods of stress and danger. To few men is it given to watch their work for fifty years, and to see it grow and spread and finally become established firmly as a monument to his zeal more lasting than one of stone or brass. We trust the father of the American Medical Association will be spared yet many years to watch over and guide his fifty-year-old offspring.

The meeting, finally, will be memorable as the one at which the labors of Dr. Gihon, the indefatigable chairman of the Rush monument committee, were crowned with at least the promise of success. In a few moments pledges were given by men whom he had moved by his eloquent appeal for an amount many times greater than the total that had so far been obtained by years of toil and entreaty. Few men would have persevered in the face of apparent defeat, as Dr. Gihon has done, and when the monument is finally erected as a result of his untiring efforts justice will demand that his name be graved with that of Rush on the granite pedestal.

THE DANGERS OF CONTAMINATED WATER.

THE coming of summer brings with it the important question: Where shall we go for a holiday? The rate at which we live in these days makes a rest from toil and the worry of business a necessity rather than a luxury. A change of scene and in the mode of living is essential to every one. The facilities, too, of locomotion enable those who are not rich to travel farther from home than was possible years ago and to view "fresh fields and pastures new." Yet, although a holiday is both necessary and pleasant, a certain amount of discretion should be observed in the choice of locality; reliable information as far as is possible should be obtained as to the sanitary arrangements of the selected place, and particularly in regard to the water supply. The remark that "water is sometimes the most deadly drink you can take" is unfortunately true; and that disease can be conveyed by drinking-water has been undeniably proved, so that even the lay mind has now grasped that fact. In these days the bacteriologist has to some extent superseded the chemist. At one time the judgment of the chemist on any water was considered final. This, however, is not the case now. Bearing on this point there has lately been held a discussion among the bacteriologists of

New York State "On the Relation of Impure Water to Disease," an account of which has been published in the *Albany Medical Annals*. Many important facts in connection with water-borne diseases that have been investigated and established were set forth in a brief and practical manner. The relation of impure water to typhoid fever was the main subject of discussion. Statistics of the comparative death rate of the large cities of the world from typhoid were given as one of the means of proving the connection between that disease and contaminated water, and it was pointed out that the large towns of the United States were far behind those of the European continent in respect to their water supply. But, as is well known and as was demonstrated in the paper on "The Dangers of the Domestic Use Other than by Drinking of Contaminated Water," it is not only from the use of water for drinking purposes that danger of infection is to be feared; water containing pathogenic bacteria may cause disease in many other ways than by being used for drinking-purposes. Various articles of food will carry bacteria from contaminated water, as, for example, milk, oysters, ice, cream, which are also themselves good media for the growth of bacteria. That oysters by the agency of contaminated water will convey pathogenic bacteria to the human body has been conclusively proved, and it is probable that other shellfish share a like property. Thus it will be seen that in eating and drinking, care should be observed both by those who travel and in a lesser degree by those who stay at home. Those who require their bodily health improved by pure and invigorating air should be on their guard lest they fall into a death trap. Often the change of air, regarded as a necessity, is fraught with danger, and the majority of people would be safer in their healthy homes, so long as they have no means of insuring a sanitary residence at the place of their selection.

SOME UNUSUAL CAUSES OF COUGH.

That the origin of a cough cannot in many instances be traced to any pulmonary complication or to any affection of the respiratory tract is well known. These unusual kinds of cough are often a source of much trouble to both the patient and the medical man. Thomson classifies coughs as expectorants or as non-expectorants, useful or useless, and puts the number of useless coughs at fourteen. In a paper read before the New York State Medical Society at Albany in February last, Dr. Emil Mayer touches upon some unusual causes of cough, and presents an account of cases occurring in his own experience. He says: "The literature on reflex coughs is abundant, and there are those among the more recent writers who still maintain a purely neurotic theory, despite all that has been said to the contrary." Various authorities are then quoted who hold views at variance with these, and numerous cases are cited in support of the antineurotic theory. Perhaps the most interesting is the one reported by Kurtz, in which a woman who was pregnant four months suffered from a terrible cough, and was found to have two polypi in the uterine canal. These were removed without the patient's knowledge, and on the following day the cough had disappeared. In this paper it is also demonstrated that the paroxysmal hacking cough of children may be due to an unbalanced central nerve action; that umbilical hernia, cutting of a tooth, a foreign body in the ear, swallowing a peach stone, worms, etc., will cause cough. The reports of seven cases treated by Dr. Mayer himself are given, in which the coughs were caused by adenoids with hypertrophied tonsil, follicular pharyngitis, hypertrophied lingual tonsils, leptothrix pharyngealis, and foreign body in the ear. In all these cases, when the cause had been diagnosed and removed the cough ceased The view that these unusual coughs are all neuroses is strongly combated, and the signs are given for arriving at the conclusion that the cough is of reflex origin: 1st, When it is spasmodic, practically constant, without expectoration and temperature; 2d, when the physical signs of pulmonary disease are absent; 3d, when it persistently resists all medication, 4th, when the general health remains comparatively undisturbed; and 5th, when upon removal of cause it promptly ceases.

In addition to the unusual causes of cough referred to in this paper may be mentioned the two given by Rice: 1st, hypertrophied glossal papillæ, overlapping an epiglottis which is bent far forward but otherwise normal; and 2d, a congenitally asymmetrical epiglottis, which has been made still longer by inflammation caused by constant friction with the tongue. "The hacking cough of puberty," so named by Sir Andrew Clark, is also worthy of notice.

THE USE AND ABUSE OF TOBACCO.

A leading English review of this month treats of "Tobacco in Relation to Character and Temperament." The extraordinary increase in the consumption of tobacco in the British Isles is the *raison d'être* of this article. Statistics are given of the consumption of tobacco in various countries. Holland is at the top of the list, with a trifle over 7 pounds a head of her population; United States, 4.5 pounds; Austria, 3.8 pounds; Denmark, 3.7 pounds; Switzerland, 3.3 pounds; Belgium, 3.2 pounds, Germany, 3 pounds; Sweden and Norway, each 2.3 pounds; France, 2.1 pounds; England, a little under 2 pounds, Italy, Russia, Spain, 1.25 pounds. It is estimated that 2,000,000,000 pounds weight are used annually, of a money value of more than $2,500,000,000.

These stupendous figures are calculated to excite curiosity, and the question that naturally occurs to one is: What effect does this consumption have upon the general health? Of course opinions vary as to the harmfulness of the use of tobacco, but the highest authorities on the matter have come to the conclusion that the pathological action of tobacco is not nearly so pernicious as its opponents claim it to be. Sir Benjamin Richardson, who studied closely the effect of tobacco on the human system, said that "smoking increases pulse rate and decreases arterial pressure;

that it acts as an irritant on the motor parts of the nervous system, not as a narcotic on the sensational; that it does not decrease the amount of urine eliminated, but rather increases it; and that it does retard waste of tissue." In regard to the action of excessive smoking on the heart, Richardson says that it does not produce organic disease, although it has a tendency to produce debility, and he denies that cancer can be caused by smoking. In a broad way, it may be said that the effect of the use of tobacco varies with different temperaments and under different conditions. A man of phlegmatic, easy-going disposition can smoke heavily without receiving harm, while a highly nervous person who smokes to the same extent will probably injure his health considerably. Again, a man who is much in the open air and takes sufficient exercise will experience no ill-effects from smoking, while a man who leads a sedentary life may suffer much. Tobacco would appear, after tolerance has been established, to be a cardiac stimulant (objectively) and a nervous sedative (psychologically and subjectively). The smoker imagines he is only being soothed. It will be found in most cases that he is being vascularly stimulated.

Of the various forms of using tobacco, cigarette smoking and chewing are the most harmful, and doubtless are the cause of many functional derangements. Laryngitis, pharyngitis, and nervous irritability may also often be laid at the door of the soothing weed. In phthisis, although it does not set up the disease, it aggravates it. Thus it may be laid down as a rule that smoking to excess is always more or less harmful, and that smoking by the young is in every case to be reprobated. It is more than likely that an excessive use of tobacco does occasionally deteriorate the moral character—in the same way as chloral or bromide of potassium may deprave the mind—by lowering the tone of certain of the nerve centres by narcotizing them and impairing their nutrition. Tobacco is not of much therapeutic value, on account of the difficulty in obtaining it in uniform strength, although its antiseptic qualities are lauded by many.

THE CHARITABLE INSTITUTIONS OF NEW YORK.

The report made annually by the "Department of Public Charities of the State's Charities' Aid Association of New York City" is always worthy of serious attention, and, in view of the discussion in regard to the abuses of medical charities, the last report is more interesting than usual. It is reassuring in a high degree to take a retrospective survey of the former condition of these charities, and to compare it with its present one Not many years ago the mode of management of the charitable institutions of this city was a scandal to a rich and civilized community. Politics held the sway, and the state of affairs existing then seems incredible in these days. The institutions one and all were conducted in a careless, almost inhuman manner, the public was callously indifferent, and the sole object of those in authority was to spend as little as possible upon the unfortunate inmates, and to publish a satisfactory report. Up to the year 1850, hospitals, penitentiary, almshouse, workhouse, and lunatic asylums were all huddled together, while prisoners from the penitentiary and workhouse were utilized to perform various duties in the almshouse, hospital, and insane asylums. Abandoned women were employed as nurses in the hospitals, and prisoners as attendants in the insane asylums. In 1850 the attention of the public was drawn to these methods of conducting charitable institutions, pressure was brought to bear upon the authorities, and gradually, but very gradually, reforms were introduced. In 1896 a sweeping and radical reform was effected when by a State law prison and charitable administration were placed in separate departments, and at the same time it was enacted that prisoners should not be employed in any capacity in the wards of any hospital. There is still, however, room for considerable improvement; though much has been done, much has been left undone; prisoners are still employed in the wards of the hospitals, and in several of the institutions the amounts appropriated to substitute paid help for prison help has been expended in other ways. Many structural repairs and additions are required, some of the buildings being in a state bordering on dilapidation. The equipment of the almshouse is deficient in all that goes to produce comfort and decency, the overcrowding is excessive, not to mention the unsanitary side of the question. There is no need that these institutions should be made too easy, and so become pauperizing, but at any rate they should be decent and in a good sanitary condition.

Perhaps the most gratifying feature in connection with these reforms is the great change for the better in the care and treatment of the insane. The truth that insanity is simply a disease, subject to a large extent to the same physical conditions as other diseases, is recognized more and more every day, and although this fact has been grasped and great progress made in the curative treatment, yet the places in which the insane are received are still too much of the asylum and too little of the hospital type. The State has a distinct duty to perform to its insane, and at last seems to have arrived at a proper appreciation of that duty. To Dr. Weir Mitchell's scathing indictment of the fossilized methods in use up to 1894, much of the credit for the improvement in lunatic treatment is due. The progress made since the State hospitals were removed from the domain of politics and vested in the State board of charities is most encouraging. The New York system of treating and housing the insane, which at one time was a byword, is fast becoming an example to other countries.

THE "MEDICAL RECORD" AND PUBLIC BATHS.

It is gratifying to note that the suggestions offered in a recent issue of the Medical Record concerning the means to the end of carrying out the law on the public-bath question have borne substantial fruit. The New York *Herald* with its powerful influence sec-

onded our endeavors and brought the matter still more directly to the attention of the powers that be. His honor the mayor was thus prepared to listen to the appeal of the committee of the Academy of Medicine and gave it his assurance of substantial assistance. The consequence is that one or more of these baths will be erected at once upon property belonging to the city and located in the crowded tenement districts. There are plenty of available places for the purpose named which can be fitted up at comparatively small cost, and the large buildings originally proposed are entirely unnecessary.

News of the Week.

Address on State Medicine before the American Medical Association.—Dr. J. B. Hamilton, of Elgin, Ill., delivered an address on the prevention of tuberculosis, at the closing session. This disease causes about one death in every seven reported in the United States; about one death in eight is caused by tuberculosis of the lungs alone. Excluding injuries by mechanical violence, it is safe to say that localized tuberculosis causes nearly one-third of the surgical diseases for which operation is required, and is responsible for seven-eighths of the crippling spinal and joint diseases. It is now the province of State medicine to point out the methods by which this plague may be gradually extinguished. This cannot be accomplished in a day, but its ravages may be made less by such prompt measures on the part of our boards of health as can easily be taken, provided the laity is taken into confidence. The public must be fully educated to an understanding of the causes and methods of propagation. The public must be made to understand, he said, that since the discovery of the bacillus tuberculosis the disease has been added to the list of preventable diseases. The public schoolmaster must be taught that he may render his healthy boys and girls immune by gymnastics and calisthenics which increase their vital resistance, for it is known that the healthy cell has a power of resistance which may be increased so as to form a nearly impenetrable barrier against bacillary invasion. The consumptive must understand fully that he has no right to allow himself to become a centre of infection by carelessness, or to marry. There is no longer any question of the possibility of infecting the lower animals by the injection of tuberculous milk, but direct evidence of transmission of tuberculosis to man by the ingestion of milk is yet wanting, except in cases of udder tuberculosis. Tubercle bacilli have been found in the flesh of horses, cattle, and swine. Birds and fowls also become infected. The careful cooking of meat and boiling of milk before eating and drinking these articles will prevent them from doing positive harm, but few would relish food if it were known to be tuberculous, however much it were cooked. The danger from animals, however, is not great in comparison with the dangers which confront us in daily contact with consumptives. The great danger is from the dried sputum, and other existing causes are of much less importance. The local infections found in the bones and in the internal viscera are produced by invasion through the circulation, while the infection of lymphatic glands is caused by direct absorption through lymph channels. After the methods of infection are known, the means of prevention of the spread of tuberculosis are sufficiently apparent. The factors in successful prophylaxis are (1) a guarding against infectious food and drink being issued to the people anywhere; (2) the prompt destruction of cattle proved to be tuberculous; (3) proper notification to the sanitary officer of the occurrence of cases of tuberculosis, especially walking cases of pulmonary consumption, in order that the officer may, in conjunction with the attending physician, make sure that proper precautions shall be taken to secure thorough disinfection of sputum and bedding. An early diagnosis is important as a curative procedure as well as a means of prevention. Physical signs are not always pronounced and the bacilli may escape observation. The tuberculin test is therefore not less valuable in man than in animals, but the dose should be carefully graduated.

"Pediatrics," for June, is devoted to the children's side of the Congress of American Physicians and Surgeons. In addition to complete reports of the American Pædiatric Society and of the American Orthopædic Association, it contains abstracts of all papers on pædiatric subjects read at the meetings of the other component societies of the congress. This is an evidence of enterprise which it is unusual to find in a journal devoted to a single specialty, and it shows that the large measure of success to which our contemporary has attained is well merited.

The Society of the Alumni of the Newark City Hospital elected the following officers at its annual meeting (May 10th): *President*, Dr. Gilbert Van Vrancken, of Passaic, N. J.; *Vice-President*, Dr. Maurice Asher, of Newark, N. J.; *Secretary and Treasurer*, Dr. F. C. Jacobson, of Newark, N. J. The paper of the evening was by Dr. Peet, of New York City, and was entitled "Gonorrhœa in the Female."

The American Electro-Therapeutic Association.—The next meeting of this association will take place on Tuesday, Wednesday, and Thursday, September 21, 22, and 23, 1897, at Harrisburg, Pa. The Harrisburg Academy of Medicine has offered the use of its building, and the Dauphin County Medical Society has appointed a special committee of arrangements to act for the association. The president of the association is Dr. William T. Bishop; the secretary, Dr. Max Einhorn, of New York.

Dr. G. La Breche-Smith has been appointed to the medical staff of the New Amsterdam Eye and Ear Hospital.

The Late Dr. Benjamin F. Sherman.—At a special meeting of the Ogdensburg Medical Association, held Monday evening, May 31, 1897, at the office of Dr. G. C. Madill, the following resolutions were adopted as a mark of respect to the memory of Dr. Benjamin F. Sherman, who had for many years been the president of this society:

"*Resolved*, That in the death of Dr. Sherman this association has lost a member who was endeared to all by his attractive personal qualities, and who added honor to the association by his scientific work and his distinguished professional attainments.

"*Resolved*, That the Ogdensburg Medical Association extend to the family of the deceased its earnest sympathy for them in their bereavement, and assure them that the members share in the deep sense of personal loss which Dr. Sherman's death has occasioned.

"E. H. BRIDGES, M.D.,
"J. H. BROWNLOW, M.D.,
"WILLIAM MABON, M.D.,
"*Committee.*

"It was also resolved that a copy of the above resolutions be transmitted to the press of the city, the MEDICAL RECORD, and the *New York Medical Journal*, and that an engrossed copy be sent to the family of the late president.

"It was resolved that the members of the association attend the funeral in a body.

"W. N. BELL, M.D., *Secretary.*
"G. C. MADILL, M.D., *Vice-President.*"

The Craig Colony.—Governor Black has signed the bill passed by the last legislature, making an appropriation of $126,600 for the Craig Colony. There are at present two hundred and four patients at the colony, and no more can be received until new buildings, to be constructed under the above appropriation, have been completed.

The Medical Society of New Jersey.—The one hundred and thirty-first annual meeting of this society will be held in the United States Hotel, Atlantic City, on Tuesday and Wednesday, June 22 and 23, 1897.

Obituary Notes.—DR. FRANCIS LEMUEL DICKINSON, one of the oldest physicians in Connecticut, died at Rockville on June 2d, at the age of eighty years. He was born in Chatham, Conn., in 1817, and was graduated from Yale Medical School in 1840. He retired from active practice a number of years ago.—DR. ASA F. PATTEE died a few days ago in Boston. He was a native of New Hampshire, and was descended from a long line of physicians extending back to William Pattee, who was said to have been physician to Oliver Cromwell and Charles II. He was graduated in medicine from Dartmouth College, and in 1859 began practising in Amesbury, Mass. He was professor of materia medica and therapeutics at the College of Physicians and Surgeons, Boston, was a member of the Massachusetts Medical Society and the American Medical Association, and for several years president of the Boston Therapeutical Society. He was an honorary member of the Botanical Society of Italy.—DR. GEORGE THOMAS, professor of laryngology and physical diagnosis at the College of Physicians and Surgeons, Baltimore, died in that city on June 3d, of pneumonia. He was thirty-eight years old, and a native of Maryland.—DR. CHARLES O'LEARY died in Providence, R. I., on May 31st. He was born in Ireland in May, 1832. He came to America in May, 1850. He had practised medicine in Providence for thirty years. He was a brigade surgeon during the civil war, serving through the Peninsula and Maryland campaigns.—DR. W. H. STRANGE, of Toronto, deputy surgeon-general of the militia force of the Dominion of Canada, died suddenly on June 5th.—DR. WILLIAM D. ALDRICH, of Warrensburg, N. Y., died suddenly on June 4th. He had complained of feeling ill and had retired. A few hours later he was found dead in his bed.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending June 7, 1897. Medical Director T. N. Penrose retired from June 6th.

A Mosquito Bite is an Accident.—The court of appeals, sitting in Louisville, Ky., recently decided a suit against an accident insurance company brought by a woman for $30,000 for the death of her husband, which resulted indirectly from a mosquito bite. The lower court held that the bite was not an accident in the meaning of the word as used by insurance companies, but upon appeal the plaintiff got peremptory instructions in her favor.

Father Kneipp, of water-cure fame, was reported recently to have died in Woerishofen, Bavaria, where he has his church and his dispensary. He is very ill, but the report of his death was premature.

The Metric System in Great Britain.—A bill has been introduced into the House of Commons to legalize the metric system of weights and measures.

Baltimore Eye, Ear, and Throat Hospital.—The directors of the Baltimore Eye, Ear, and Throat Hospital intend to tear down the present building used by the hospital, and erect a new and handsome structure.

Registration in Connecticut.—A dispatch to the *Evening Post* from New Haven says that with the prospect that the "medical-practice bill" will become law, establishing examinations by a State board, there has lately been a rush of practitioners from outside the State, many of them irregular, for registration under the present loose statute. Twenty have recently been registered in Greenwich, the Connecticut town nearest New York City.

Systematization of Fresh-Air Charities.—Representatives of twenty-one fresh-air and summer charities have organized a "Council of Fresh-air Charities," the object of which is, as stated in the constitution, "to bring the fresh-air charities of New York City into closer relations with one another, in order that the benefits afforded by such agencies may be systematically and fairly distributed among those who need such aid, so that 'overlooking' as well as 'overlapping' may be reduced to a minimum." A central bureau of registration is to be established, to which the fresh-air charities are to be asked to send lists of their beneficiaries, and from which each agency may ascertain the number of outings which any child has already had.

Summer Health Resorts.

It has become the custom of the American people to take a summer vacation for health and recreation, but too often without sufficient discrimination with reference to the main object. Our purpose is to aid discrimination in this regard. But so numerous are "health resorts" that it is alike impracticable and inconsistent with our purpose to do more than present such as offer the best advantages in their natural relations, leaving the detail with regard to local conditions as the legitimate and always important subject of inquiry by the would-be health seeker or sojourner at any place.

In presenting the readers of the Medical Record with a list of summer resorts for 1897 it will not be so much our aim to go into details as it will be to mention such as will be safe, that the physician desiring to advise his patient may find some practical suggestions which will commend themselves to him. More particularly will this be proper as applying to those who must consider the expense, not only of the journey but also of maintenance at the resort selected. It often happens that a very short journey and very inexpensive entertainment will afford the greatest amount of pleasure and the most marked benefit to a patient.

The United States and the Canadian provinces afford an almost limitless number of seacoast summer resorts. The North Pacific coast is dotted with resorts where the summer heat is tempered to an enjoyable degree, affording comfort and health to the inhabitants of the heated valleys and the desert regions of the interior.

Atlantic Coast Resorts.

Beginning with the seacoast resorts of the eastern Canadian provinces, we find, first:

Cape Breton, usually spoken of as an island but consisting really of a number of them, while there is also a large number of peninsulas which are with relation to the ocean practically islands, and whose climate is essentially insular. Though they are surrounded by salt water, nature has dealt lavishly with these islands in the abundance of sweet fresh water too, and it is to this that Cape Breton owes much of its charm for the summer tourist.

The primitive simplicity of former days is still to be found in many portions, but the advent of the railroad, opening up the interior to easy access, has brought with it many of the modern conveniences for the comfort and entertainment of the tourist, or of such invalids as may encounter a high humidity of the atmosphere without injury, or even find it favorable in some conditions; for example, some classes of neurasthenics and overworked business men. The average temperature during the summer months is about 65° F., and there is sunshine during about forty-five per cent. of the time possible for the sun to shine.

Prince Edward Island, called the "Garden of the Gulf," lies to the northeast of Cape Breton Island, and is reached by the Intercolonial Railway or by steamer. Charlottetown is the capital and principal city of the island, and affords good hotel accommodations. The climate is essentially the same as that of Cape Breton. The weary tourist who has been used to the confusion of the conventional summer resort will find here the cool ocean breezes that charm the mind and soothe the nerves, and while it is a place of rest it is also a paradise for the fisherman and sportsman.

Nova Scotia, a peninsula, in climatic conditions possesses the characteristics of an island, while it has the advantage of accessibility by rail. Fogs are prevalent during the summer and the atmospheric humidity is very high. The mean temperature during July and August is about 66.5° F. Warm clothing should be plentifully provided. No part of the provinces can be recommended for the genuine invalid.

Halifax, with its magnificent harbor, its strong citadel garrisoned by British troops, and its essentially English environment, might lead the tourist who had not kept good account of himself to suspect that he had left America behind him. It is strongly British in its manners, customs, and sympathies. The citadel commands a view of land and water for many miles, and from its towers the visitor may enjoy a view of the harbor with its islands, the sea with its ships, the city with its busy streets, and the distant hills and forests, that are seldom equalled for beauty and variety. Halifax affords good hotel accommodations and a journey thither is a very good substitute for a "trip to England" for those who dread the water. Hay-fever sufferers are free from their trouble in its climate.

New Glasgow is as essentially Scotch in its characteristics as Halifax is English, and the country around, with its fertile fields and its little villages of Maxwelltown and Arrisaig, are strongly suggestive of the Caledonian origin of its early settlers. New Glasgow is the largest town on the north coast, and a convenient point from which to reach the uplands and fine farming-sections of Nova Scotia. From here too are seen and easily reached the Antigonish Mountains, which serve to remind the tourist from the west that America is still within reach.

St. John is the principal gateway to all points in New Brunswick reached by the Intercolonial Railway. It is accessible either by all rail from Boston and all other points, or by steamer. The city is handsomely laid out, with wide streets and avenues at right angles, and the location is admirable in every respect as a seaside resort. Besides almost unlimited variety in the way of sailing-trips, the surrounding country affords many attractive drives. The River St. John, which has been called "the Hudson of New Brunswick," offers many very attractive features, and the trip to Fredericton, the capital of the province, is one which tourists should not fail to take.

Moncton is the junction point from which departure is taken for Prince Edward Island, Cape Breton, Nova Scotia, or westward to the western provinces. Moncton has not so much of attraction to offer as other points, but the tourist may well stop here a few hours to see that great natural curiosity, the "bore" from the Bay of Fundy, or the rising tide. The town is essentially a railroad town and of modern growth, while most New Brunswick towns remind one of old-world origin and association.

Dalhousie is the fairest of many fair spots on the Gulf of St. Lawrence. It is situated at the head of the Baie des Chaleurs, one of the most beautiful bays in America. The sheltered position of the place gives it a freedom from the raw winds and fogs which are characteristic of the more exposed points on this coast and the terror of so many invalids. Baie-des-Chaleurs is ninety miles long and twenty-five wide, and affords safe passage to the largest ships. Fine beaches and water of moderate temperature tempt the bather. There is no finer yachting locality on the Atlantic coast.

Campbeltown is a pretty village with great possibilities as a resort, and every facility for salt-water bathing, salt-water fishing, and boating. Campbeltown lies at the junction of a broad and beautiful river with Baie-des-Chaleurs.

The Gaspe Peninsula is out of the route of general travel, and consequently but little known even to the professional tourist. It has not a promising look on the map, and unless something has been learned of it in advance the tourist is likely to pass by a region

that affords more of the quaint and curious in a small space than almost any other part of the American continent. This peninsula is formed by the Bay Chaleur, Gulf of St. Lawrence, and River St. Lawrence, and is almost a *terra incognita* to the average American. From Crown Point to Port Daniel extends one long street or highway, settled from one end to the other. On the one hand is the sea with its ever changing panorama, on the other rise the mountains, one overlapping another to a height of four thousand feet, clad in primeval forest growth.

Perce, on the eastern end of the Gaspé Peninsula, gives the most adequate idea of the beauty of the scenery. This is one of the places of the beauties of which language fails to convey a correct idea. It must be seen to be appreciated. The walks and drives are delightful, and immediately back of the town lies "La Table à Rolland," the summit of Mt. Anne, at a height of thirteen hundred feet above the sea.

The town of Gaspé is situated on the heights overlooking the Gaspé Basin, and is so securely protected by the hills that it seems an ideal place of shelter. There are good hotel accommodations in the town, and its variety of pleasure excursions need be limited only by the inclinations of the visitor. For the weary man or woman, weary in mind or body, who desires to get "sixteen miles from a lemon," where no care of conventionalities need worry and where a mixture of sea and mountain can be enjoyed at the same time, it is doubtful if a more ideal spot can be found on the Atlantic coast of America, and but few comparable to it along the Pacific coast.

Quebec, Lake St. John, and the Jaws of the Wonderful Saguenay are the points of a triangle which marks the route covering the grandest of Canadian summer resorts. Tourists may now cross by rail from Quebec to Lake St. John and half-way down the eastern side of the triangle to Chicoutimi, thus avoiding the tedious portages or dangerous rapids of the old route.

Quebec, the starting-point, has been called "the sentinel city that keeps the gates of the St. Lawrence," and for grandeur of situation, romantic associations, and picturesqueness in details has no equal on the American continent. There is scarcely a foot of ground which is not historic or which has not been consecrated by the blood of those who fought either to gain or to save the half of a continent to their respective countries. While enjoying these and other attractions, the tourist may make his home at one of the most elegant hotels of the continent, the Château Frontenac. Built upon the famous Dufferin Terrace, overlooking the St. Lawrence and surrounding country for miles, it occupies probably the finest hotel site in the country. Quebec has also other good and much-frequented hotels, and ample accommodations for all classes.

From Quebec to Lake St. John the tourist passes through many picturesque and interesting villages, with French names, French customs, and French language, over the Laurentian Mountains, which geologists claim to be the oldest mountain chain upon the crust of the globe.

Lake Edward, the largest body of water between Quebec and Lake St. John, is also the most beautiful; with its numerous small and wooded islands, which rise often to a considerable height from the water, a more picturesque combination than this it would be difficult to find. The water is so clear that often it is possible to see handsome red-bellied specimens of the salmo fontinalis, weighing from four to six pounds each, lingering in refreshing indolence twenty feet below the surface in a quiet pool. There are excellent hotel facilities, as also good camping-facilities for those preferring this free-and-easy mode of life.

Lake St. John is almost an inland sea, as from the Hotel Roberval, even in the clearest weather, the opposite shore can scarcely be seen. It is fed by a number of very large rivers, most of them bearing musical Indian names, while all of them are swarming with fish. The Hotel Roberval is a first-class hotel, with accommodations for over three hundred guests. Steamers make excursions up all of the rivers for some distance, and are then supplemented with bark canoes and guides as far as time and purse will allow.

Cacouna, which is called the Newport of Canada, lies on the south shore of the St. Lawrence, and is the resort of the wealth and fashion of Canada. There are many handsome cottages, and one of the most popular hotels of any on the St. Lawrence is here.

Riviere-du-Loup is also an important watering-place, with several good hotels and many elegant private cottages. The half-hour's drive between Rivière-du-Loup and Cacouna is one of the most picturesque in the country.

The Seacoast of Maine boasts of several delightful summer resorts. All the varieties of fish that frequent the New England coast are to be caught in abundance in season in the vicinity of these resorts, affording sport and healthful exercise to all piscatorially inclined.

Portland may properly be considered the distributing point, as from it many well-known resorts are easily accessible, either in a few minutes or at most in a few hours. Among those best known and in the closest proximity are Old Orchard Beach, Scarborough Beach, Pine Point, Isles of Shoals, Kennebunk Port, Biddeford, Bath, Popham Beach, Bar Harbor, Mt. Desert, Rockland, and Boothbay—all points where tourists will find entertainment and facilities for enjoying the coast advantages to their full desire.

Mount Desert Island, with its Bar Harbor, wears the crown of all the scenery of this unrivalled coast. Forty years ago a few summer wanderers discovered the beauties of the region, though it had been explored by Hendrik Hudson's Dutch mariners early in the seventeenth century. At Bar Harbor there are to-day a score of immense hotels, innumerable boarding-houses, and cottages for rent, while for miles along the shore are the beautiful summer homes of millionaires from nearly every city of the land. To the eastward between Mt. Desert and Portland extends a reach of wild coast, abounding in unusual and beautiful scenery, and containing the towns of Gouldsborough, Milbridge, Harrington, Jonesport, Machias, Cutler, Trescott, and Lubec, "and there are others," reachable only by stage coach or small steamer, but containing many charming resorts for the summer tourist and invalid.

The Isles of Shoals, off the coast of New Hampshire, are an available summer resort, where the benefits of an ocean atmosphere may be had on solid rock. Appledore Island, the chief of the group, has a good hotel and several cottages, where invalids are supplied with every comfort.

Portsmouth, the only large town on the New Hampshire coast, though not particularly noted as a resort, possesses the advantages common to the seacoast, has good accommodations and many attractive features. The summer atmosphere is a little warmer, about seven degrees, as compared with that of Eastport, Me., and the percentage of sunshine is a little larger, being fifty-two per cent. against forty-five per cent. at Eastport.

Nantasket Beach, twelve miles from Boston, is to the "Hub" what Atlantic City is to the "City of Brotherly Love," and has become celebrated as one of the finest ocean shores on the Atlantic coast. It affords a variety of lowland and high bluff but seldom found in close juxtaposition, and in the midst of the

clustering highlands and headlands are its noted hotels and cottages dotting the hillsides. Owing to the almost direct east-and-west trend of the beach, it escapes much of the effects of a hard blow direct from the bosom of old ocean. Its climate is essentially that of Boston, having fifty-two per cent. of sunshine for the summer months.

Martha's Vineyard, off the south coast of Massachusetts, has been for many years a favorite seacoast resort. Its shores in many places consist of bold bluffs and cliffs, picturesque in the extreme, while its accommodations in the way of hotels and cottages have grown to the extent of a "Cottage City." The weather statistics of Block Island Station, R. I., probably come as near to covering the condition of Martha's Vineyard as any obtainable. These show for the summer months sixty per cent. of sunshine; mean relative humidity, eighty-four per cent.; and mean seasonal temperature, 67° F. While this temperature and humidity would not indicate to the votaries of high altitudes a favorable condition for pulmonary troubles; still the equability, large percentage of sunshine, and pure sea air ought to render it a favorable place for palliation in advanced cases, and for all nervous conditions.

Nantucket.—What has been said regarding Martha's Vineyard may at least be said of Nantucket, also an island, lying some twenty-eight miles farther out. Being farther out in the Alantic, it probably enjoys a more equable temperature than that quoted for Martha's Vineyard. No exact data are at hand.

Newport, R. I., is so well known as a summer resort that it needs only mention. It offers but little of attractiveness to those seeking rest or health only, but much to those seeking or sharing the pleasure of wealthy display, and the city itself is laid out in excellent taste, with broad avenues, bordered by the grounds surrounding the most magnificent villas in the country. The climatic conditions are essentially those of Block Island.

Block Island lies fifteen miles off the coast of Rhode Island. In area it is about seven miles by three, and it contains in its centre a salt-water pond or lake, which nearly bisects the island. Small as is its area, it has a diversity of hill and valley that is quite remarkable, and lends additional charm to the many attractions of a strictly marine resort. Block Island is a regular station of the United States weather bureau, and its climate is probably a fair specimen of that of other islands similarly situated. Temperature for summer, 67° F.; for autumn, 53° F.; for winter, 32° F.; for spring, 43° F.; annual mean, 50° F. Mean annual rainfall, 53 inches. The relative humidity for summer is 84 per cent.; for autumn, 79 per cent.; for winter, 75 per cent.; for spring, 74 per cent.; annual mean, 77 per cent. Sunshine, for summer, 63 per cent.; for autumn, 43 per cent.; for winter, 51 per cent.: for spring, 48 per cent.; annual mean, 53 per cent.

Long Island, N. Y., has gained a high place in the public estimation as a resort. There is an endless variety of attractions, and its contiguity to America's centre of greatest population renders it accessible to more people for local patronage than almost any other resort region. There are beaches and surf bathing on the south shore, and bluffs and quiet water on the north, and in the central portion pine groves, lakelets, and trout streams. The sea breezes sweep across from the ocean to the Sound, and the summer temperature is generally several degrees lower than in the same degree of latitude on the mainland. Taken altogether, it is difficult to find any other region that furnishes a greater diversity in style of entertainment for from six dollars a week to six or more dollars day, and a climate that leaves little to be desired. Manhattan Beach, Rockaway, Ocean Park, Wave Crest, Bayswater, Far Rockaway, and Lawrence are fair samples of beach resorts for transient visit. The whole south shore of the island is dotted with ancient villages, which have become nuclei of innumerable summer cottages. Eastward as far as Eastport these are situated upon Great South Bay; beyond they are close to the ocean beach. There are few hotels at any of these places, but good boarding-houses with reasonable charges abound. The heat of summer is tempered by prevailing "on-shore" breezes. Fogs sometimes blow up, usually in June. The Long Island Railroad Company issues a guide book.

New Jersey.—Of all the States on the Atlantic coast, New Jersey presents the most superb, best appointed, and most elegantly equipped surf-bathing beach. All the way from Cape May to the foot of the Highlands of Sandy Hook is the cleanest of sandy beaches, and with scarcely a break a continuous line of admirably policed accommodations, suited to every taste and every purse.

Cape May, the model of seaside cities, comprises all of the most delightful features of a seaside resort. For safe and enjoyable surf bathing Cape May is unexcelled, if indeed equalled, by any other ocean resort. For healthfulness and the very best of all the elements one expects to find in a seaside resort, there is no other point on the Atlantic coast more promising.

Atlantic City approximates, even if it does not quite equal, Cape May in all that is most desirable and enjoyable. The recently completed sewerage works and an abundant supply of pure artesian-well water have greatly added to its attractiveness.

Long Branch has long been noted as the resort of the wealth and fashion of New York and Philadelphia, and its palatial hotels, built upon the main avenue upon the crest of the bluff overlooking the sea, are filled with people attracted by the excitements afforded rather than by the quiet offered. Long Branch is the seat of the Monmouth Park race course, one of the most celebrated racing tracks in America, the great iron grand stand of which will seat ten thousand people.

Asbury Park is a relatively new and admirably planned resort. The ocean bathing is excellent, its beach being among the best, while three fresh-water lakes furnish unlimited amusement in the way of boating and fishing. Asbury Park is the centre of a number of resorts more or less famous for special attractions, such as Seagirt, the camping-place of the New Jersey National Guard; Avon, the home of the Seaside Assembly and Summer School of Philosophy; Elberon, made historic as the place where President Garfield suffered and died; and near by are the famous Highlands of Navesink, Atlantic Highlands, Monmouth Park, and Loch Arbor—all places of more or less note and favorite resorts.

Spring Lake deserves mention as a rare combination on the New Jersey coast of pastoral scenes with the ordinary beach sands and waves of the seashore. Against the bluff beat the waves of old ocean, while back of it rest green fields, blooming orchards, and shaded groves, which, together with the beautiful fresh-water lake, affording safe boating, render it a most desirable family resort and one which has rapidly grown in favor during the last few years.

Ocean City, Md.—While Maryland has but a limited ocean coastline, known as Sinepuxent Beach, what it has affords one of the most attractive resorts for the health seeker and sportsman to be found anywhere on the Atlantic coast. Ocean City is about midway between Atlantic City, N. J., and Old Point Comfort, Va. The Gulf Stream comes nearer the shore at Ocean City than at any other point of the coast, except at Cape Hatteras. The air is exceptionally clear, fogs and dampness being very rare. The

natural beauties of the place have made it a centre of gayety for many summers.

Old Point Comfort, Va., is among the oldest and most fashionable resorts at all seasons. Surrounded by the waters of Chesapeake Bay and Hampton Roads, but within the influence of the Atlantic as well, and in a latitude which insures an evenness of temperature, it enjoys the double advantage of being not only a summer resort but a most desirable winter one as well. The Point is a government reservation, containing among its attractions Fortress Monroe, the largest fortification in America. The presence of the large garrison adds much to the social features of the place, while the surrounding waters provide ample sailing and fishing, and in the summer fine bathing. Its great hotels furnish ample accommodations suited to all classes. Old Point can be reached by railway, but those caring for travel by sea can leave New York in beautifully appointed ocean-going steamers, arriving at Old Point within eighteen hours. The new Hotel Chamberlin is an attractive feature here.

Virginia Beach, Va., fifteen miles seaward from Norfolk, with nothing beyond but the broad Atlantic, and on its shore the Princess Anne, one of the finest of hotels, comprises all the most recent improvements adapting it to an attractive seaside resort. Surf bathing in all its unalloyed glory can be most thoroughly enjoyed here. While delightful in summer, it is none the less an all-the-year-round resort for both health and pleasure. Excellent shooting can be had here at all seasons, and good fishing from May to October. Back of the hotel is a dense forest of pine trees, much of which is laid out in a park. Under the Vanderbilt management success is assured.

Pacific Coast Resorts.

San Diego, though essentially a winter resort, is also possessed of many characteristics of a summer resort. It has an exceptionally equable climate, is never cold and never excessively hot; and with its Coronado Beach it affords comfort and health in summer as well as in winter.

Santa Catalina Island.—One of the most typical summer resorts of the Pacific coast is Avalon, on Santa Catalina Island, twenty-eight miles from the mainland. The island affords a variety of conditions, from sea level to a number of thousand feet of altitude in the interior, which is easily accessible by good roads. Avalon is situated upon a small bay, completely shut in on three sides by high mountains, and is consequently free from the heavy winds or storms of the Pacific. The humidity is considerable, though the town is not often enveloped in fog, which is a common factor of the climate just outside the bay. Avalon is a place where every taste can be suited, with hotel accommodations at from three to four dollars a day, or with a cottage or tent corresponding with the length of the purse. Its hotels are good, though not elegant. The ocean trip from San Pedro is a delightful one if the tourist is a fair sailor.

Long Beach is a popular resort for families and is provided with many cottages and tents. This is the seat of a Chautauqua association and attracts many of literary tastes. While not a fashionable resort, it is frequently crowded. It has fine bathing and boating facilities and an agreeable climate.

Santa Monica is the more popular resort for Los Angeles people, and attracts many tourists from the interior regions. It has a large tourist hotel and many of more modest pretensions, and many boarding-houses. The bathing-facilities are good, as in addition to its beach there is a very large natatorium, where the sea water is warmed and can be enjoyed at all seasons. It is connected with Los Angeles, twenty miles distant, by electric as well as steam roads.

Santa Barbara is a popular summer as well as winter resort, being a favorite place with many of the inhabitants of the interior towns and with tourists who have spent their winters in Arizona and New Mexico. There are few spots in California around which clusters so much of romance as around Santa Barbara, "the City of Roses." The Santa Barbara Mission is one of the most interesting of the old landmarks connecting the present with the past century. There are some twenty hot springs, varying in temperature from 60° to 130° F., and of varying chemical composition, but all strong in sulphur. These are reached by one of the finest drives in the State. The hotels at Santa Barbara are noted for their excellence, and invalids who go to California for its winter climate will find Santa Barbara fully as delightful in summer.

Monterey lies on the southern shore of Monterey Bay and forms the centre of one of the most popular summer as well as winter sections of the Pacific coast. The quadrangular peninsula between the Bay of Monterey on the north and Carmelo Bay on the south embraces a number of very popular features, among them the famous Hotel del Monte and its park reservation of seven thousand acres; Pacific Grove, one of the most popular of family resorts; and the world-famous seventeen-mile drive. The climate of this peninsula is unsurpassed anywhere for either summer or winter. Monterey has many attractions aside from its famous hotels.

San Francisco offers about as many essentials for a summer resort as any of the more celebrated places. So far as a cool and invigorating summer climate can make it, San Francisco has all the requisites. Besides this there are many attractions to be enjoyed that are found nowhere else. With her beautiful Golden Gate Park, her wonderful Cliff House and its accessories, the Sutro Baths, and the magnificent drives through the Presidio, or army reservation, magnificent hotels, and unrivalled street-car service, by which all her attractions can be reached quickly and cheaply, San Francisco certainly stands in the front rank of Pacific coast summer resorts. The objections to the climate are the prevalence of fogs and that the nights are so cool that good warm wraps are always needed after nightfall, but these are healthful conditions when properly provided for. There are many delightful summer points upon the coast north of San Francisco, as yet accessible only by steamer, but which furnish many attractive excursions for the tourist making San Francisco his base of departure. The sun shines fifty-seven per cent. of the time; summer temperature is 59° F., and relative humidity eighty per cent.

Portland, Ore., though not situated exactly upon the seacoast, is a seaport so near the mouth of the Willamette River that while avoiding some of the severities of a coast resort it yet enjoys most of its advantages. The city is bounded on the west by a chain of hills about one mile distant, and the view from any of the hundred elevations is very beautiful. Long rows of fine mansions skirt the foothills, while below lie the well-built business portion of the city and the broad river, literally dotted with palatial steamboats and large ocean-going steamships and other vessels. No city on the Pacific coast is better equipped with fine hotels than is Portland, and the tourist will find many attractions. Portland shows sixty per cent. of sunshine for the summer months, a temperature of 68° F., and relative humidity of sixty-nine per cent.

Tacoma, Wash., is built upon a peninsular promontory of triangular form, jutting out into Puget Sound some five miles and with a base of about five miles. From the water the land slopes gradually up to the highest point of the promontory, which is in the centre. No better natural location for a city could be

conceived. The residence portion is situated upon the higher ground, and is thus lifted above the stir and noise of the city. As the streets rise one above the other like the rows of chairs in a theatre, the windows of nearly every house enjoy an unobstructed view of the magnificent scenery of the sound spread out before it. Tacoma has the best of accommodations and endless scenic attractions for the tourist. The bay with its quiet waters is given a spirit of life by a multitude of water craft, from the tiny canoe to the full-rigged ocean ship. Above this scene rises the imposing majesty of great Tacoma, as it lifts its head far into the clouds. There are higher mountains than Tacoma, but no other known peak that rises so grandly and alone from the level of the sea to such a height. It is covered with a complete robe of snow from the line of green foothills to the top, where the steam of a slumbering volcano hovers over its crown, forming what is called the "liberty cap."

Seattle is built upon a hilly strip of land from two and one half to five miles in width, between Puget Sound and Lake Washington, twenty-five miles long and five miles wide, lying parallel with the sound. The sight on approach by the sound is of a city set upon a hillside, the large buildings standing out by themselves, affording a fine view of the city. Seattle has been a marvellous instance of western enterprise and push, growing from almost nothing to fifty thousand population in twenty years, and having been nearly wiped out once by fire. With her fine hotels, good natural sanitary advantages, and pleasing variety of topography, Seattle is well worthy of the consideration of the summer tourist or of the invalid to whom this pleasant climate is suitable. The percentage of sunshine for the summer months is forty-nine; relative humidity, sixty-one per cent.; and seasonal temperature mean 61° F.—a very favorable combination.

Victoria is beautifully situated on the southeast extremity of Vancouver Island. Fort Victoria was a depot of the Hudson Bay Company established in 1843. Gradually Fort Victoria was merged into the city of Victoria, with its government buildings and varied interests, and Victoria is now one of the most interesting of the Pacific coast cities. A thorough system of macadamized roads radiates from the city, furnishing over one hundred miles of beautiful drives, many of which are lined with handsome suburban residences surrounded by lawns and parks. The topography is varied, the view from the upper streets or from the summits of Beacon or Church hills being very fine, commanding as it does a large expanse of water, the Olympic range of mountains, and the imposing form of Mt. Baker in the east. The climate of Victoria is more distinctively marine, since it gets the full benefit of the air from the broad Pacific unmodified and unbroken, rendering the summer climate cool and delightful.

Alaska.—A summer trip to Alaska is one of the luxuries of travel that should be indulged in by the tourist. The best time to visit Alaska is from June to September. The latter month usually is beautiful and the sea smooth and calm, but the days begin to grow short. As there are no "palace" hotels in Alaska, the temptation will not be strong to remain over a trip, so that the time required will be only from twelve to twenty days. The rainfall is usually very large and provision of umbrellas and rain coats should be made. Warm and comfortable clothing should be provided, as the air is cool enough even in July to render heavy wraps a necessity during much of the trip. Alaska is the largest and most northerly domain owned by any country on the North American continent. Its glaciers, its mountains, its archipelagoes of islands, and its mighty rivers are typical in their grandeur and beauty. Among these dwells a primitive race, whose history is lost in the shadows of antiquity. Its members live as did their ancestors; they make the same basket and blanket work, build the same canoes, use the same household utensils, and the same primitive methods of catching and preparing their food (fish) as were habitual to their early progenitors. Great misapprehension exists regarding the climate of Alaska. The Yukon district, including all that part of the territory north of the Alaskan range of mountains, has severely cold and long winters and short hot summers. Southeastern Alaska, including a narrow strip of mainland and the large group of islands known as the Alexander Archipelago, is warm and moist, the thermometer seldom going above 85° F. in summer or below zero in winter, the mean annual temperature being about 45° F.

Lake and Mountain Regions of New England.

The Rangeley Lakes.—The chain of lakes known as the Rangeley Lakes lies near the boundary between the States of Maine and New Hampshire. These are sometimes called the Androscoggin Lakes, because their final outlet forms the river of that name. They are six in number, and with but few exceptions they lie in unbroken wilderness. They vary in altitude from twelve hundred and fifty-six feet to fifteen hundred and eleven feet above the sea, thus being among the highest lakes of any extent in the country. They are easily accessible from many directions, and they have become renowned as summer resorts for all lovers of nature. The combination of lake, pond, and river scenery, coupled with pure air and water, a most delightful summer climate, and the conveniences of hotels, clubhouses, camps, and private dwellings for the entertainment of visitors, have made Rangeley Lakes a favorite resort.

Moosehead Lake, Me., is the largest of the New England lakes, being thirty-eight miles in length by fifteen in width. It is about one thousand feet above the sea and of very great depth. Promontories, headlands, and islands almost innumerable mark its contour, while the characteristic scenery is that of the most primitive wilderness. It is one hundred miles from the ocean, and has many hotels and community establishments where the tourist can be accommodated in almost any way his fancy may dictate.

Gorham, N. H.—Space will permit of but very brief mention of a few of the many attractions. For river scenery in connection with impressive mountain forms Gorham can hardly be surpassed. The Androscoggin sweeps through the village, while the nearness of the great peaks of Washington, Madison, Jefferson, and Adams gives a grandeur to the environs seldom equalled. The village is eight hundred and twelve feet above sea level and the air is dry, invigorating, and healthful. Added to these many attractions is a first-class homelike hotel. Gorham is the nearest village to Mt. Washington and also to the great northern peaks. It is in fact, as in name, "the gateway to the White Mountains."

Lake Winnipiseogee, N. H., lies at the base of the White Mountain region in central New Hampshire. The lake is four hundred and seventy-two feet above the level of the sea, is twenty-five miles long, and from one to seven miles in width. Scattered over its area are islands, large and small, to the number of nearly three hundred, many large enough for habitation, but the larger part being simply islets forming most attractive scenic features on all sides. These islands constitute most desirable excursion points. The shores of this lake present a series of summer resorts, as Alton Bay, Wolfborough, Centre Harbor, and Weirs, which are chiefly centres for summer visitors, being indeed little more than such, while all the towns and villages in the neighborhood partake largely of the

same characteristics. The mountain scenery about Winnipiseogee is very fine. Long Island, one of the larger of the islands mentioned, has two summer hotels and is about eight miles from Centre Harbor.

Laconia, N. H.—Just to the south of Lake Winnipiseogee, on the shores of Lake Winnesquam, is the thriving city of Laconia, with its adjunct, Lakeport, occupying almost the entire eastern border of the lake. Lake Winnesquam is about nine miles by two, and is a most picturesque place, its surroundings and scenery being exceedingly primitive and attractive. Laconia and Lakeport afford excellent accommodations and invite many summer visitors.

Newfound Lake, N. H., situated among the highlands of southern New Hampshire, at an altitude of five hundred and ninety-seven feet above the sea, affords many attractions. It is beautifully situated among wooded hills which present many attractions for campers; the farmers of the neighborhood open their houses to summer boarders, and the most quiet and unconventional life possible can be enjoyed. The fishing is unexcelled.

Lake Sunapee, N. H., is about nine miles long by three in width and is eleven hundred feet above the sea, amid hills and mountains which greatly diversify the scenery. All about this lake are the establishments that mark the section as a favorite summer resort for people of wealth and refinement. The water of Lake Sunapee is so exceedingly transparent that the rocks and sands along the bottom may be clearly seen even to the depth of thirty feet or more. The air is cool and delightful, and the mosquito is almost unknown on its shores.

Groveton, N. H., has some remarkable scenery in its vicinity. The village itself is surrounded by mountains. The Perry Peaks on the north will attract the most indifferent observer on account of their wonderful symmetry of form and color. Cape Horn, three miles distant and twenty-seven hundred and thirty-five feet high, can be easily ascended.

The White Mountains are situated mainly in Coos and Grafton counties in the northern portion of New Hampshire, and consist of a number of peaks from four thousand to six thousand feet in height, the highest being Mt. Washington, sixty-two hundred and forty-three feet above the level of the sea. Mt. Washington is the centre of many attractions for tourists, each having some peculiar charm. "The Notch" is a narrow gorge, the entrance being but twenty feet wide, between two enormous cliffs, and extending two miles, abounding in cascades and precipices. "Franconia Notch" contains several natural curiosities, among which is "the Flume," a waterfall of two hundred and fifty feet. "The Old Man of the Mountains" is a profile of the human face delineated by a peculiar combination of the surfaces and angles of five massive granite blocks at the height of one thousand feet, on the surface of a bold jutting cliff. "Tuckerman's Ravine," the "Gulf of Mexico," and "Oakes' Gulf" are deep ravines in which snow and ice remain till late in summer. The "Devils' Den," "Gibbs' Falls," and many other well-known places are accessible to visitors from excellent hotels which are situated in the immediate vicinity of the attractions mentioned.

Besides the places we have already mentioned in some detail, contiguous to the White Mountains are others of as much prominence as points of departure for the mountains, and very popular as summer resorts. Among these are Fabyans, North Conway, Lancaster, Scotts, St. Johnsbury, Wells River, Woodstock, and Bethlehem. This whole region is noted as a favorable resort for hay-fever sufferers. The seasonal data of Mt. Washington for summer are: sunshine, sixty per cent.; mean relative humidity, ninety-one per cent.; mean temperature, 46° F.; but these of course must not be taken as the standard of the region in general, as the data are for the summit of Mt. Washington, where the humidity would be very high and the temperature very low. As the towns mentioned are all about fifteen hundred feet above sea level, the temperature average would probably be very near to 60° F.

Profile House, N. H.—The nearest the tourist can get to hotel accommodations at two thousand feet of altitude in the White Mountains is at the Profile House in Franconia Notch and on Profile Lake, nineteen hundred and seventy-four feet above sea level, and aside from its high altitude it offers many other attractions to the invalid and tourist.

The Green Mountains. Lying east of Lake Champlain and extending from the northern boundary of Vermont almost to the southern line of Massachusetts, are the Green Mountains and their continuing hills, which form the watershed between the Connecticut Valley and the valley of the Hudson River in New York. These mountains are not so high or so abrupt as those of the White Mountain region, nor is the scenery quite so much of the type found in the greater mountains of the West, but the Vermont hills and the Green Mountain region are noted for their great pastoral beauty and a fine climate, and together constitute one of the favorite summer-resort regions of America.

Northfield, Vt., is ten miles south of Montpelier, in the very heart of the Green Mountains. The scenery is varied and picturesque, presenting an attractive place for such as wish to escape the dust and excitement of the city. Within three or four miles of the village in all directions are eminences from which most extensive views of Green Mountain scenery are obtainable. To one seeking a quiet home for the summer, among intelligent and progressive people, with quiet but excellent accommodations in hotel or boarding-house, it would be difficult to point out a more satisfactory location than Northfield.

Montpelier, the capital of Vermont, has in recent years attracted many summer tourists to its quiet precincts. In all that pertains to a city, good hotels, large business blocks, numerous churches, schools, and well-stocked stores, Montpelier is a city. In all its surroundings, throughout its length and breadth, it is a natural and artificial park, having wooded hills, green lawns, and pleasant groves. As a summer home Montpelier offers superior attractions to city residents and is a most excellent place for a family outing for several weeks. Within easy reach is Mirror Lake, a clear and lovely sheet of water, two and one-half miles long by one-half mile in width, surrounded by cedar groves where tent life may be enjoyed to the utmost, and fine farms in the highest state of cultivation.

Burlington, on the scale of beauty of scenery and location, is scarcely second to any New England town. Its unique beauty consists in a rare grouping of water, mountain, and pastoral scenery. Its Crescent Bay with headlands at either horn, its gentle slope to the college-crowned summit, its fringe of mountains with bold peaks, and nestling in the midst of these a well-kept city, complete a combination seldom equalled. Burlington offers many attractions and a welcome entertainment to the summer tourist, and is a healthful resort for the invalid.

The Berkshire Hills, Mass.,

are celebrated for scenery of great beauty and are highly esteemed as a summer-resort region. There are many towns in this region, each having its peculiar attractions and natural advantages, and it is difficult to say which would be most pleasing. Pittsfield is about midway between the north and south limits of the hills, with perhaps all possible Berkshire attractions, but other places of note are Sheffield, Great Barrington, Dalton, Lanesborough, Lee, New

Lebanon, Stockbridge, Lenox, and Williamstown—all of which have their own attractions and admirers.

The Catskill Mountains, N. Y.

In a region of such historical and well-established fame, it would be hard to single out any particular place or places for commendation. Many points in the region have well-established reputations as summer resorts.

The Adirondacks and North Woods, N. Y.

Occupying a large area of the northeast portion of the great State of New York, are the Adirondack Mountains and the North Woods, a section of country as yet but little known by the average tourist, and in places hardly explored by even the adventurous woodsman. It is doubtful if any other section of country in America affords such a mixture of mountains, valleys, and lakes as does this region, there being literally hundreds of each in a region comprising some two thousand square miles of territory. While much of the region is yet practically inaccessible, there are numerous points from which the interior is reached or which offer enough of the wild and untamed wilderness to satisfy the average traveller, and it is these accessible points only with which we shall deal in this article, leaving the minutiæ of the region to those who have made its study a specialty.

Remsen might properly be called the gateway to the Adirondacks, as it is the point of departure of the Mohawk & Malone Railroad (under lease to the New York Central), which goes directly through the mountains. From Remsen many parties start with guides and horses for the numerous lakes of the interior, notably for the Fulton chain, one of the fairest specimens of the attractions of the Adirondacks.

Old Forge, with its large and commodious Forge House, stands on an elevation above the Moose River, upon which boating can be enjoyed for a dozen miles in either direction without encountering any troublesome rapids. Steam yachts make daily trips through the numerous lakes connected by the river. This is a particularly favorable resort for ladies, as it combines many of the elements of wildness with facilities for easy enjoyment of them.

Lake Brantingham lies on the border of the Great Forest, about three hundred and fifty feet above Black River Valley and fourteen hundred feet above sea level. Its banks rise in gentle slopes to a moderate height, are richly wooded, and present a scene charmingly wild and picturesque. "Round" and "Dark" islands are popular camping-grounds. There is a good hotel of homelike character, where comfortable and reasonable entertainment can be had. Half a mile from the lake is a mineral spring, strongly impregnated with iron, magnesia, and sulphur, affording a special attraction to invalids.

Houseville, N. Y., is a pleasant hamlet high up on the forest-clad western slope of the Black River, eighteen hundred feet above the sea, and one of the highest points in New York State except the mountain peaks of the Adirondacks. Houseville has, as to purity of air and freedom from malarial influences, the characteristics of the Adirondack region. The main attractions are its pastoral beauty and homelike hotel, where perfect freedom and quiet can be enjoyed, along with the fresh cream, eggs, and berries which only such a region can furnish.

Lake Kushaqua lies among the hills, in the very heart of the wilderness. On a bluff commanding a view of the entire lake stands Kushaqua Lodge, a family hotel built for comfort rather than style. From the distant mountains comes an abundant supply of pure spring water, which, with the perfect sanitary conditions and balsamic odors of the evergreen forest in which it is located, renders it an ideal spot for health.

The Thousand Islands.

Scattered along the St. Lawrence River from Cape Vincent and Clayton to Alexandria Bay and beyond, filling a channel in some places twelve miles broad, are more than eighteen hundred islands, collectively known as the Thousand Islands. Varying in size from a small mass of rocks to picturesque islands miles in extent, nearly every island, large or small, is the pleasant summer home of its fortunate owner, while many of the larger ones have been developed into most charming and prosperous summer-tourist and invalid resorts. During the summer season the islands teem with life and gayety. Sporting in all its variety is unsurpassed, both gun and rod yielding to the sportsman unexcelled pleasure and satisfaction. For those afflicted with hay fever, or for the invalid needing change of scene, rest, or recreation, the pure and invigorating atmosphere renders this place of resort a delightful sanatorium. The hotels at Cape Vincent, Clayton, Round Island, Thousand Island Park, Westminster Park, Grinnell Island, Alexandria Bay, and Edgewood Park are modern and equal in accommodations to the resort hotels of other popular regions. As it is not within the province of this article especially to mention hotels, and as specific mention of the various islands of this group without a mention of the peculiar attractiveness of their hotels would be like "Hamlet with Hamlet left out," we will pass this region with only a general mention, calling attention to its wonderful beauty and variety as a summer resort, and refer the reader to the voluminous literature of the railroads and hotels, which is beautifully illustrated, for more detailed information.

The Lake Region of Central New York.

The chain of lakes extending through the central portion of New York is unsurpassed for beauty, and many charming resorts are located upon their banks, all of which are accessible by steamers which make regular trips from one end to the other.

Oneida Lake is the most easterly and most northerly, a handsome sheet of water, some twenty miles long by four or five in width, with numerous towns along its banks, and affording a variety of scenery and resort attractions.

Skaneateles Lake is the next in the series as one goes westward, and is about twenty miles long by one mile in width, with the village of Skaneateles at its northern extremity, the principal town on the lake.

Owasco Lake is a small sheet of water between Skaneateles and Cayuga Lake.

Cayuga Lake has at its head the beautiful university town of Ithaca, where not only superb summer-resort features but many attractions of a literary character are to be found. Cayuga is the largest of this chain of lakes, being about thirty-five miles in length and from one mile to three miles in width. Steamboats of quite palatial character ply upon its waters.

Seneca Lake, with Watkins Glen, one of the most noted of New York's resorts, at its head or south end, and Geneva, one of New York's most beautiful villages, at its foot, is second to Cayuga only in size and commercial importance, but for beauty its full equal. Both Geneva and Watkins have fine hotels and Geneva has medicinal springs of wide reputation and recognized value.

Kuka or Crooked Lake lies a few miles west of Seneca Lake, and is only about half its length. As one goes westward these lakes become smaller but more

pronounced in scenic beauties. Lake Kuka has two arms. At the north or foot end is Penn Yan, a pretty village of some thousands of population, while at the south or head of the lake is Hammondsport, noted as the centre of the great wine industry of western New York. At the confluence of the two arms of this lake is Bluff Point, a high promontory rising abruptly from the water to hundreds of feet above the lake. The abrupt shores of this lake are covered from end to end with vineyards.

Canandaigua Lake is one of the most beautiful of the chain, sixteen miles in length, and averaging about one mile in width. It has many projecting points, which with the corresponding bays give a variety both pleasing and unique. This lake is of great depth and of wonderful purity. Canandaigua, one of the prettiest villages of western New York, is at its foot, while Naples is near its head.

Between all of these lakes are high divides, rising in many places to fifteen hundred feet above sea level, the lakes themselves averaging between four and five hundred feet above sea level. All of these lakes have many summer campers and cottagers along their shores.

Chautauqua Lake.—In the extreme southwest part of the State lies Lake Chautauqua—world famous as the home of the original Chautauqua Literary Circle and annual meeting-place of the National Sunday-School Assembly. Chautauqua Lake is seven hundred feet above Lake Erie, or thirteen hundred feet above the sea. The shores of the lake afford many attractive resorts, and are very popular as camping-grounds for summer parties. There are numerous large and small hotels, and many private accommodations for tourists, and the exceptionally high altitude of the lake renders it particularly favorable as a summer resort. The water throughout this lake region of New York is impregnated more or less with lime—is, in fact, hard water if taken from ordinary wells or streams, but in many sections there are flowing wells of soft water from lower water-bearing strata.

Sullivan County as a Health Resort.

Those seeking a cool, healthful, attractive retreat during the summer months may be interested in learning that within three and a half hours' ride from New York, nestling high up among the Delaware Mountains where they join the Catskills, may be found the towns of Sullivan County, which are becoming better known each successive year as favorite resorts for those in search of health and pleasure. There are many spots in this county where pleasant vacations may be spent, but, as Liberty is the largest and best known of any of them, a description of its surroundings will be illustrative of the county as a whole.

Situated at an elevation of from eighteen to twenty-four hundred feet above the sea, and surrounded by a region of matchless scenery, sylvan dells, clear running streams, and undulating hills; blessed with an invigorating climate, cool days, and pleasant nights, during which the most wakeful of invalids can sleep as sweetly and soundly as children, it is not strange that the first few days of sojourn are always followed by increased appetite and restored health. Then among the environments of Liberty are found all the essentials to a summer's outing for pleasure. The fisherman may angle successfully in cool and shaded streams; the wheelman can roam over miles of country roads in an atmosphere so cool and bracing as to forbid fatigue. Those of more staid habits can spend many a delightful hour in driving to Liberty Falls, Monticello, White Sulphur Springs, and many other points of interest too numerous to mention. And finally the pedestrian can wander at will through woods and along shady trails, while many another idle hour may be spent swinging in hammocks under trees, in orchards unsurpassed for luxuriance and beauty.

Although known for a long time as a health resort, Liberty has come more prominently to the front during the past year, owing to the establishment in its suburbs of what promises to become the largest and most perfect sanatorium in the United States for the treatment of pulmonary tuberculosis. The late Prof. A. L. Loomis, M.D., after careful study of the various localities, chose Liberty as the one best adapted by its physical and climatic conditions, immediate surroundings, and accessibility to New York, for the establishment of the sanatorium now bearing his name.

From the sanatorium grounds the eye can reach southward forty miles to the Delaware; to the west is a succession of rolling mountains, reminding the traveller of the wild tropical mountains in the Cordilleras. To the eastward the Catskills and Mongaup Mountains lift their frowning heads. No swamps or lowlands are seen, and therefore no fogs, stagnant waters, or poisonous vapors are encountered; but on cool summer evenings the clouds, instead of fogs, may be seen scudding past with great velocity.

The Loomis Sanatorium was opened on June 1, 1896, and has been growing in size ever since, until its present capacity is eighty patients. It is built on the cottage plan.

The town of Liberty has one of the best water systems in the State. Its streets and houses are lighted by electricity. It contains numerous large hotels and boarding-houses, with accommodations for every class of people. The results that have been observed among patients sent to various points in Sullivan County, but more especially to Liberty, during the last decade, have shown remarkable evidence of the salubrity of the climate. Many years ago the old country physicians noted that persons arriving in apparently very serious if not hopeless condition, after a few months' sojourn returned to their homes greatly improved, and in many instances apparently cured. No especial note was made of these facts until the attention of Dr. Loomis was turned in this direction. From that time on the throng of health seekers has been annually augmented. Almost immediately after arrival patients begin to gain in weight and improve in general appearance, their appetites and, better still, their digestive powers show marked improvement. Those who in the city have been unable to walk more than a few blocks are, ere the lapse of many weeks, wandering at will over country roads and through the woods for nearly the whole day. Cough and expectoration diminish rapidly in the majority of instances.

Among the numerous towns of Sullivan County that may be mentioned more especially as places of health resort are Liberty Falls, elevation, 1,100 feet; Fallsburg, 1,224 feet; Woodburne, 1,400 feet; Neversink, 1,450 feet; Monticello, 1,500 feet; Hurleyville, 1,320 feet; Loch Sheldrake, three miles from Liberty; Youngsville, eight miles from Liberty; White Sulphur Springs, three miles from Liberty; Stevensville, three miles from Liberty, and White Lake. All these places are situated on the line of the Ontario and Western Railway, which runs during the summer months a number of accommodation and express trains both ways, with extra trains on Saturday running to accommodate business men who have their families located in this section for the summer.

Pennsylvania.

Delaware Water Gap, Pa.—Where the Delaware River breaks through the Kittatinny Mountain is one of nature's beauty spots, and man, not slow to appreciate what nature has done, has improved his oppor-

tunity by making a summer resort which is very popular with the inhabitants of the many cities within a few hours' ride. The gap or gorge is about two miles long, and the celebrated gorges of the Rocky Mountains are hardly more wild or attractive. A large and popular hotel accommodates the summer visitors.

Mauch Chunk, Pa., with its famous Mt. Pisgah and "switch-back" railroad, is a popular summer resort for the people of the Eastern cities. Of all the numerous American "Switzerlands," Mauch Chunk can perhaps come as near to "filling the bill" as any other spot in the country.

Michigan, Wisconsin, Etc.

Michigan lake resorts present charms peculiar and unexcelled. There are hunting-grounds abounding in game and fishing-grounds where can be found the famous grayling, trout, bass, and muskalonge. One of the resorts nearest to Chicago is

Benton Harbor, which offers strong inducements, particularly to those who at little expenditure of time or money would seek retirement from the crowded city. Lying at the junction of the St. Joe and Paw-Paw Rivers near their entrance into Lake Michigan, there are many attractions of land and water skirted by extensive fruit farms and productive fields. The Eastman Springs, twenty in number, possess valuable medicinal qualities.

St. Joseph is more directly on Lake Michigan and has an extensive sand beach, overlooked by a high bluff, along the edge of which extend a charming boulevard and shaded park.

Petoskey is a leading resort of this section, and has a reputation for favorable conditions for hay-fever patients. Petoskey is built upon tablelands which rise in successive terraces from the sandy beach of Little Traverse Bay. The location is on the south side of the bay, and, as the prevailing winds are from the north, it is always cool and laden with health-giving freshness.

Mackinaw Island possesses charms peculiarly its own. The surprise of the new visitor is not that it is a popular resort, but that it has not always been one, or that its out-at-sea character has not always been known and appreciated. It is essentially and wholly a summer resort, having no other interests. The average sunshine for the summer season at Mackinaw City is fifty-three per cent.; mean relative humidity, seventy four per cent.; seasonal temperature 61° F. Mackinaw is one of the most prominent hay-fever resorts in the country, and is bountifully supplied with hotels and tourist accommodations.

Marquette.—The south shore of Lake Superior has long been recognized by those familiar with its peculiarities as one of the best all-round summer-resort sections of our country. Much of it is wild and undeveloped, but rich in those natural elements of a health resort, viz., a healthful and delightfully cool summer climate, abundant and pure water, and an endless variety of out-door recreations such as boating, fishing, and hunting. Of all these attractive features Marquette is a most available centre. It is a substantial city of twelve thousand permanent population, and contains all the elements of a successful health resort, with fine hotels, beautiful parks, and a summer climate one degree cooler and three per cent. dryer than those of any other station on the chain of lakes. It is the centre of a large section lying along the south shore that is destined to develop rapidly into a favorite summer resort. It is particularly well adapted to hay fever, catarrhal, malarial, and general nervous diseases. Mosquitoes and insects are practically unknown in the city, owing to the almost constant lake breeze and entire absence of low or moist lands or standing water. The water supply is unsurpassed for purity.

Superior, Wis., lies at the head of Lake Superior and has many attractions for the tourist and invalid, excellent hotels, and unrivalled facilities for boating on the inland bays and river thoroughly protected from the high winds of the lake. From Superior fine lake, bay, or brook fishing is accessible in all directions. The rapid and metropolitan growth of Superior is one of the wonders of the last decade, and with this growth have come many of the advantages sought in a resort. With a more rigid regard for sanitation, Superior ought to be a favorable summer resort for all classes of invalids.

Madison, Wis., is noted far and wide for its beauty of location, being built upon rolling hills between a series of four lakes, which nearly surround the city and which afford a "lake breeze" from whatever direction it may come. Madison is the State capital and site of the State university, and thus insures a high grade of society. It has good hotels and boarding-houses, and though, like most State capitals, "a little slow," yet is a popular summer resort.

Duluth, Minn., with its beautiful boulevard skirting the crest of a hill for several miles, eight hundred feet above the Lake Superior, and affording one of the finest views of lake, bay, river, forest, and urban scenery that can be imagined; with its beautiful drives along the lake shore and back into the rolling hill country; with its large and small hotels, and with its fine summer climate, has many attractions for the summer tourist and invalid. Duluth has been for many years a favorite resort for hay fever, and but few are disappointed in the effects of a sojourn there during the summer and autumn. Minnesota Point, a strip of dry sand nine miles long by a few rods wide, stretching across the head of Lake Superior, separating the bay from the lake, is an ideal camping-ground and is utilized as such by thousands every summer.

Virginia Springs Region.

The most notable resort region of the medium-altitude class is that of the Virginia Hot Springs, which includes a great number of springs and a great variety of waters. The altitude of the valleys in which these springs are located varies from two thousand to twenty-five hundred feet, while the mountains surrounding them often rise to as great a height above. There are three distinct regions. First are the Hot Springs of Virginia, with waters at a temperature of 108° F. These springs have every facility for the effective use of the waters, and hotel accommodations which leave little to be desired in that direction. The bathhouse at these springs cost over $150,000 and all bathing is done under the strict supervision of a medical superintendent.

The Healing Springs are two and one-half miles south of the Hot Springs. The temperature of these springs is from 85 to 88° F., the supply of water being abundant, coming from four springs of essentially the same character. A modern hotel and bathhouse are here provided for the accommodation of guests.

The Warm Springs, situated in a valley, are in the midst of a grand old grove five miles north of the Hot Springs. The temperature of these springs is 96° F., and they have long been a favorite resort for health and pleasure seekers.

Millboro Springs are situated in a quiet, charming retreat in the mountains, two thousand feet above sea level and one hundred feet above the headwaters of the James River. From the eminence upon which the fine hotel stands, the view of valleys, mountains, and towering peaks is one of remarkable beauty.

Rockbridge Alum Springs also occupy an ele-

vated position over two thousand feet above the sea. The springs are nine miles from Goshen and are reached by a narrow-gauge railroad. The springs give forth alum, chalybeate, and freestone waters and are highly valued. There are accommodations for six hundred guests.

Sweet Chalybeate Springs are nine miles from Alleghany Station, which is the summit of the Alleghany Mountains, thirty-one hundred feet above sea level. These springs are strongly impregnated with iron, from which fact they have derived the name of Red Springs.

White Sulphur Springs, W. Va.—These springs have been a popular health resort for over one hundred years, the medicinal virtues of the waters having been recorded as far back as 1788. They have an established reputation in relieving dyspepsia, jaundice, malaria, hay fever, and liver diseases, and the sulphur baths for gout, rheumatism, and skin affections give almost immediate relief. While there is a large and fine hotel, the cottage system predominates, there being one hundred cottages as a part of the resort, all with complete sanitary arrangements.

Red Sulphur Springs are twelve miles from the railroad, but are reached by a fine turnpike. The buildings are spacious and filled with every convenience for the entertainment of guests. These springs have long been a favorite resort for the aristocracy of Virginia.

Salt Sulphur Springs are fourteen miles from the railroad. Here also are an iodine spring, a sweet sulphur spring, and a chalybeate spring, thus affording a great range of treatments. The buildings at these springs are of stone; they have the appearance of antiquity and solidity, and are set in the midst of a lawn of nine hundred acres.

Sweet Springs, W. Va., "Old Sweet," as they are called, are ten miles south of Alleghany Station. These are among the oldest of the Virginia springs resorts. The waters are highly tonic in effect, with mild cathartic action The scenery and accommodations at these springs are not surpassed, and the latest sanitary and hygienic improvements have been introduced.

Tennessee.

Lookout Mountain, Tenn.—At an altitude of twenty-five hundred feet is Lookout Inn, one of the best hotels in America and a favorite summer as well as winter resort. Lookout Inn is located on a level tableland overlooking Chattanooga and covered for miles with pine and oak forests.

Sewanee, Tenn.—On the upper plateau of the Cumberland Mountains, at an elevation of two thousand feet, is a university town with schools of science, literature, theology, and medicine. A good hotel and many boarding-houses entertain summer visitors from the lowlands and the far South during the hot season.

High-Altitude Resorts.

All resorts above four thousand feet in altitude will come within this classification, and necessarily are confined to a limited area of the Rocky Mountain region. The first effect of a high altitude is to cause a deeper expansion of the lungs, to compensate for the decreased amount of oxygen in a cubic foot of air, this difference at four thousand feet being about twenty per cent., or, in other words, one-fifth more air must be breathed to supply the same amount of oxygen as at sea level. This deeper breathing also requires a corresponding quickening of the heart's action, and herein lies the danger of a sudden transition when the lung capacity is to any extent lessened by disease, for in order properly to oxygenate the blood with a decreased lung capacity and a decreased supply of oxygen requires a largely increased action of the heart or a more rapid circulation of the blood to convey the required amount of oxygen to the tissues. This increased action cannot be safely imposed upon a heart crippled by organic defects or too much weakened by merely functional disease, though in the latter case a gradual approach to a high altitude is nearly always beneficial. With this general statement of the effects of high altitude the physician should be able to apply its therapeutic properties to each case as it comes up, bearing in mind always that a high altitude also necessarily carries with it an increased diurnal change, or more marked difference between sun and shade temperatures, or between day and night, than is experienced at a low altitude at the same latitude.

Denver, Col., is perhaps the distributing point for the high-altitude summer resorts, not only of Colorado but also of the middle Rocky Mountain region. Denver is too well known to need more than a mention in this connection. The altitude of Denver is fifty-one hundred and ninety-six feet. The water from its artesian wells is almost chemically pure. The sanitary conditions are good and hotels unexcelled.

Castle Rock is a small hamlet thirty-three miles south of Denver; elevation, sixty-two hundred and twenty feet. It is an attractive spot.

Palmer Lake, at an elevation of seventy-two hundred and thirty-eight feet, is about midway between Denver and Pueblo, and probably the highest point accessible to tourists beside the mountain proper. Glen Park, the Colorado Chautauqua, is within half a mile of Palmer Lake.

Colorado Springs is perhaps the typical high-altitude health resort of America. With an elevation of six thousand feet, it represents the full standard of a high altitude, while within sight of the city almost the highest altitude accessible to man is also available, with all gradations between. The characteristics of the climate are a very large percentage of sunshine, hot days in the sun but always cool in the shade, cool nights, little rain, considerable wind, and some dust, but a climate allowing out-door life nearly all the time, especially during the summer and autumn.

Manitou Springs, Col., is strictly a summer resort, its principal hotels being open only during the summer months, though its sheltered position and fine winter climate are favorable for winter as well. The special features of Manitou are the wonderful soda springs and other mineral waters, which have a wide reputation. From Manitou are accessible many of the attractions of this wonderful region. The altitude of Manitou is sixty-three hundred and eighteen feet.

Cheyenne, Wyo., is six thousand and fifty feet above the sea and the metropolis of Wyoming, possessing all the modern improvements in city building, which make it available as a summer resort with many attractive features.

Sherman, Wyo., is a small town, eighty-two hundred and forty-seven feet above the sea, amid wild and rugged scenery, Pike's Peak, one hundred and sixty-five miles distant to the south, being plainly visible on a clear day.

Laramie is called the "Gem City of the Rockies," and lies seventy-one hundred and forty nine feet above the sea. From Laramie a stage line runs during the summer months to North Park, Col.

Yellowstone National Park occupies the northwestern corner of Wyoming, extending short distances into Idaho and Montana. When this park was set aside to be forever the grand tourist resort of the people and their common property, but few had any idea of the endless variety and grandeur of this tract of country, fifty-five by sixty-five miles in area. The park embraces three

thousand square miles, has an average elevation of about eight thousand feet above sea level, and is encircled by magnificent mountain ranges. To attempt even detailed mention, let alone description, of the wonderful and varied features of this park, would require all the space allotted to this article; therefore it is only to call attention to it as one of the great summer resorts that it is referred to. All of the hotel and other facilities are under direct government supervision, so that the public is assured of the best service possible.

Soda Springs, in Bingham County, Idaho, are situated within a stone's throw of the main line of the Union Pacific Railroad, fifty-seven hundred and eighty feet above sea level, with snow-capped mountains on every side; yet the climate is said to be as "wonderful for a summer resort" as are the springs for their virtues, reputed to do away with the appetite for spirituous liquor. Good hotel accommodations are to be had, and the country affords unlimited means of recreation.

Helena, Mont., thirty-nine hundred and thirty feet above sea level, is beautifully situated, and is well provided with fine hotels. There are many attractions for the tourist, consisting of excursions to the contiguous mountains, pleasant drives, and bathing in the waters of a hot spring of high repute. Prickly Pear Canon, "the Gate of the Mountains," where the Missouri River bursts through, is said to surpass anything on the Hudson, and for one hundred miles there is a succession of scenery rarely equalled.

Salt Lake City, Utah, has most of the requisite features of a popular summer resort. It is situated forty-three hundred and eighty-four feet above sea level, and has an immense salt sea at its door, which, with the cool air and bright sunshine, makes a rare combination of healthful conditions. It combines a large percentage of sunshine with a low humidity. Salt Lake City has many other attractions which are of interest to the tourist and beneficial to the invalid.

Yosemite Valley, Cal., like the Yellowstone National Park, is a national public park, dedicated to the use of the people as a resort. But here their similarity ceases, and no comparison can be drawn between them. Having seen the one, to appreciate the diversity of wondrous nature the tourist should see the other. With all that has been written about them, they are still undescribed—because they are indescribable. The Yosemite is the tourist's paradise and the invalid's cheer; and fortunate, indeed, are the invalids who find it convenient to resort thither and enjoy its benefits. Hotel accommodations are abundant and reasonable as to cost.

Mt. Lowe, Cal.—Within three hours' ride from the surf bathing at Santa Monica, by electric cars and the famous Mt. Lowe inclined railroad, the tourist can be taken to the comfortable and unique "tavern" at the top of Mt. Lowe, three thousand feet above the sea and the beautiful San Gabriel Valley. Echo Mountain House is thirty-five hundred feet above sea level, and "Ye Alpine Tavern" five thousand feet, with the top of Mt. Lowe one thousand feet farther up among the clouds. In the great pine woods surrounding this resort are all the facilities for camping and tent life, with the city of Los Angeles within one and one-half hours' ride.

Lake Tahoe, Cal., is fourteen miles west of Carson City, Nev., the lake lying half-and-half in the two States. This beautiful lake is thirty-five miles long, fifteen miles wide, fifteen hundred feet deep, and sixty-seven hundred feet above sea level. Though surrounded by mountains whose summits are white with snow nearly the entire year, it never freezes. A fine hotel and facilities for camping render this resort one of the finest for summer to be found in California.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

(Continued from page 826.)

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Second Day—Wednesday, May 5th.

A Brief Consideration of Some Points in the Management of Consumption.—DR. R. H. BABCOCK in a paper with this title agreed with Finlayson and others that the consumptive's temperature is not febrile until it reaches 101.3° F., and only then requires treatment. He first advises rest in the open air and regulation of the diet. If this does not reduce the temperature, he advises careful sponging or the use of small doses, one and a half to three grains, of antifebrin, or some other non-depressing antipyretic, an hour before meals, as suggested by Detweiler, for the purpose of promoting the secretion of free hydrochloric acid during digestion, it being absent during fever. Sweating he combats with picrotoxin and camphoric acid. Diarrhœa is due less often than is generally supposed to intestinal ulceration; he considers it due to intestinal fermentation, and treats it with intestinal antiseptics rather than with opium and astringents. He inquired if laryngeal tuberculosis does not contradict high altitudes, and wished to learn from Colorado members why patients are often retained at that high altitude after having developed laryngeal symptoms. It is his belief that patients having recovered in high altitudes should not return to reside at their former homes in the East, although he has known individuals to do so without apparent harm. He wished to learn if the members did not consider such return unsafe and likely to bring on a fresh outbreak of the disease.

The Clinical Value of the Culture Products of the Bacillus of Tuberculosis.—DR. KARL VON RUCK, of Asheville, N. C., read a paper in which he said that the tubercle bacillus produces substances in the culture which are antagonistic to its life and growth, and that the germs cease to grow and die because of the presence of such peculiar substances. The bodies of the germs contain fats which can be extracted with ether or alcohol, and when the fat is removed they lose their properties of retaining the aniline stains. After removing the fats the author has extracted them further and practically reduced them to a small residue, consisting of cellulose. The extractive substances produce immunity in guinea-pigs, and act curatively also. The degree of such action appears to stand in relation to the amount administered. The purified products of the culture, especially such as Klebs has produced, have given the best clinical results, and several cases are reported illustrative of their action and limitations. In suitable cases, especially the earlier stages, the percussion dulness disappears in newly involved area, and the respiration becomes again vesicular, with corresponding general improvement. Their use is not attended by any danger or discomfort to the patient. It was not contended that these remedies should be used to the exclusion of all other valuable means. On the contrary, the author stated that in the treatment of phthisis we

are necessarily confronted with complex pathological changes, the results of tuberculous disease, all of which it could not be hoped directly to influence by remedies which were directed against the tubercle bacillus itself. Other factors, such as climate, had to be considered in the question of treatment. The author has also produced a serum from goats, after the method of Maragliano. In a comparative experiment both his and Maragliano's serums acted alike in effect and degree, protecting the guinea-pigs from the usually fatal dose of toxins. Some of these goats are now being further immunized with the extract of the tubercle bacillus, but neither serum nor extract has been used in the systematic treatment of human tuberculosis as yet, and they are still under experimental investigation.

Digestion versus Drugs.—Dr. Samuel A. Fisk, of Denver, Col., in a paper with this title, gave prominence to the use of "food and fresh air" in the treatment of the two most serious troubles which affect mankind, insanity and pulmonary tuberculosis, and in contrast called attention to the mass of drugs vaunted in medical publications and out of them for the cure of all diseases. He questioned whether we had advanced at all on the simplicity of "food and fresh air." He admitted that the profession was somewhat to blame for this, and cited the case of a patient who was getting by actual count eighteen different remedies in the course of twenty-four hours; also of another patient who was receiving hypodermic injections and other treatment addressed to the bacilli. Both patients had brown and furred tongue, loss of appetite, constipation, scanty and high-colored urine; both were improved by the administration of a little calomel and attention to the details of ingestion, assimilation, egestion, food, and fresh air.

Dr. Fisk remarked that the bacillus had assumed such monstrous proportions in our eyes that it must be hunted and killed at any cost. He said it had been remarked that more patients had been killed with antipyrin than had died from the grippe, and that he sometimes wondered whether the same thing could not be said of creosote and tuberculosis. His own experience has not been favorable to the use of creosote, and it is his custom to substitute calomel and potash. The speaker said that he had seen patients with consolidation, night-sweats, constant cough, and profuse expectoration, accompanied by loss of strength and flesh, and it might be with hemorrhages, do admirably because they could eat, digest, and sleep, whereas he had seen others similarly affected go down rapidly because they could not eat, or digest what they had eaten, or sleep. He cited two cases representing this difference: one subject could neither eat nor sleep and ran down rapidly; the other had an excellent appetite and made such an improvement that in a month's time he gained five pounds, the pulse had fallen from 122 to 106, and the temperature from 103° to 100.4° F., with cough and expectoration decidedly diminished, his chest drier, and his strength greatly improved. He had been given no creosote or other drug to destroy the bacillus, but his digestion had been fostered. The speaker also called attention to the care which must be taken not to tax too severely the digestive powers. He spoke of such affections as chronic bronchitis, asthma, fibroid conditions, and emphysema, in which the patient was apt to become bilious and in which the digestion had to be carefully watched, and advised a good dose of calomel. In cases of hemorrhage accompanied by constipation and scanty and high-colored urine, he had used catharsis and diuresis with good effect. The point which Dr. Fisk made was that the digestion is the *pièce de résistance* in the treatment of pulmonary disease, to be fostered and protected at all hazards, and not to be sacrificed for any desire to destroy that arch enemy, the bacillus.

Aerotherapeutics and Hydrotherapeutics in the Prevention and Treatment of Pulmonary Tuberculosis.—Dr. S. A. Knopf read a paper with this title, in which he spoke of aerotherapeutics and hydrotherapeutics in the treatment and prevention of pulmonary tuberculosis. Preventive medicine was the medicine of the present, and, while he hoped that preventive inoculation and orrhotherapy would be the ultimate treatment for all acute diseases, he expressed doubts as to the discovery of a serum or toxin that would cure pulmonary tuberculosis when it had already worked its destructive process. Continued research to combat the association of microbes, manifested by acute exacerbation, was recommended, his own work in that direction with antistreptococcic serum having been encouraging. In describing the anatomical, physiological, and pathological peculiarities of the individual predisposed to pulmonary tuberculosis, the remedies to overcome the insufficient air supply to the respiratory organs, and the abnormally increased sensibility of the general and especially the cutaneous system to the slightest changes of temperature, were pointed out. It was shown that the preventive treatment of consumption should begin with the child in utero and be kept up throughout life. A description of a thorough system of aerotherapeutics and hydrotherapeutics, comprising instructions for breathing exercises, rest cure, graduated walks, application of cold water as a tonic, antipyretic, analgesic, etc., as indicated in the various stages of the disease, completed the paper.

The Treatment of Tuberculosis by the Antitubercle Serum.—Dr. Guy Hinsdale in a paper with this title described the use of the antitubercle serum, in the preparation of which a donkey was first injected with mallein to exclude the presence of glanders, and then received an injection of one cubic centimetre of tuberculin, which dose was doubled every five or six days until two hundred cubic centimetres were received at a dose. Little reaction followed: the temperature rose only one degree or one and a half degrees, with some slight local œdema. After the maximum dose the animal was allowed to rest three weeks for the elimination of tuberculin. It was then bled and the blood allowed to stand in a refrigerator five or six days, when the serum was collected and one-half per cent. of tricresol added to act as a preservative; it was then kept sealed in a cool place. While Dr. Hinsdale considered it too early to make any complete report of the clinical tests of the agent, he described one case in which he had employed the serum in the hope that others would try it. The patient was a married woman, aged twenty-seven years, who had a cough in February, 1896, and began to lose flesh and strength. His notes taken in March of that year were: Left lung normal; right lung, increased vocal fremitus, but not marked; bronchial breathing posteriorly; slight impairment of the percussion note posteriorly; some râles at the apex. In April she weighed one hundred and twenty pounds and was losing flesh, coughed, and had night sweats; consolidation of upper lobe; bronchial breathing on both sides, especially the right; increased vocal resonance. In May there was amphoric breathing on the right side; she coughed badly and had fever at night. She was in bed one week and had a hemorrhage. She was then pregnant. She was confined January 1, 1897. The physical signs all pointed to well-established phthisis. The case was chosen as being a test of the efficacy of any treatment. The sputum was examined, with the discovery of a large quantity of tubercle bacilli. An injection of five minims of the serum was made on January 16th, and again at intervals of two or three days until forty minims were injected March 2d. On March 25th her weight was one hundred and twenty-seven pounds. There was some soreness below the left apex in the

back. There was no elevation of temperature, and no unpleasant effects of any kind were noted. The injections were made in the left arm near the insertion of the deltoid, after carefully cleansing the part. There had been general improvement in all respects, and bacteriological examinations on March 9th and 15th showed absence of tubercle bacilli. On May 2, 1897, the percussion note was clear all over the chest, front, and back, and the only abnormal sign was a slightly increased vocal resonance over right apex. Dr. Hinsdale stated that the patient was steadily gaining weight and strength, had little expectoration, and that the progress of the case would be reported next year.

Observations upon Pulmonary Tuberculosis in Colorado.—Dr. S. G. Bonney read a paper with this title, giving an analysis of two hundred recorded cases occurring in private practice, during a period of two years. He selected his cases upon a basis of supposed adaptability to the climate, and classified them with reference to the probable prognosis at the time of arrival. In stating the results the classification was made according to the physical signs and general condition. The extent and character of the tuberculous involvement and its method of onset were considered, and also the relation of climate to hemorrhage, functional nervous disturbance, and bronchial irritation. The paper concluded with a discussion of complications, with general observations as to management.

Some Personal Observation upon the Effects of Changes of Climate upon Men and Animals.—Dr. Richard Cole Newton, in a paper with this title, remarked that "ability to meet the environment" had been defined as "the condition of leadership," and said without doubt it was also the condition of health. He doubted whether the full comprehensiveness of these terms was fully appreciated, and considered that climate, from a therapeutic standpoint at least, should be defined to mean a man's environment. He considered the great need at the present moment in the study of climatology to be the study of individual cases, and more ascertained and established facts in relation to the action of climatic changes upon people or animals. From a surgical aspect he considered the virtues of the aseptic climate of the Rocky Mountains and their foothills too well known to require any detailed testimony, wounds always doing well. He had seen a knee-joint opened and a floating cartilage fished out without aseptic precautions or antiseptic treatment, and the man was entirely well in two or three days. He referred to the beneficial action of the climate of New Mexico on consumption and on wounds alike. He cited the instance of a young Indian returning from the Carlisle school, dying of consumption, and thought it would appear that phthisis was not an infrequent result of the higher education among the red men as well as among the palefaces, and that we too often lost sight of the fact that phthisis was especially the disease which cut off those who had given up a roving or outdoor life for a stationary or confined existence, and stated that the moving about, even to less salubrious climates, appeared to prevent the onset of this malady. He said that it had been pointed out that the animals in a travelling menagerie were much healthier than those in a zoological garden, and that reference had been made to the remarkable healthiness of gypsy children. He also referred to the fact that man had been so long a wanderer on the face of the earth, shifting his quarters to hunt for food, escape from or pursue his enemies, and was so stamped with this nomadic tendency, that it showed itself at times in this craving for change of air, and said that now, like the caged animals in the museum, the Indians were beginning to die of tuberculosis. The paper gave the following conclusions:

1. That the change of climate from the Rocky Mountains to the seaboard is more severe and dangerous than the reverse, especially to young children and horses.

2. That a medium or even a high altitude is beneficial rather than otherwise to nervous diseases and the diseases of women, as well as to phthisis, and is not unfavorable to rheumatism.

3. That in the climate of northern Texas and New Mexico nephritis in all forms is exceedingly rare, while aneurism is somewhat common in the latter territory.

4. That wounds do remarkably well in all parts of the Southwest.

5. That the ideally wholesome and satisfactory life is a nomadic one.

6. That change of climate does not bring change of disposition, or, for that matter, of predisposition. Precious and even invaluable as change of climate often is in a number of diseased conditions, it is not always what is most needed.

He suggested contentment with smaller doses of climate, and that they be supplemented with larger doses of hygiene, both moral and physical.

Dangers of Tuberculous Infection and Their Partial Arrest by Climatic Influences.—Dr. C. F. Gardiner, in a paper with this title, said that in reviewing the evidence of partial arrest of tuberculous infection by climatic influence, all data of a general character had to be taken with great caution. The impression, due to the complaint being so rarely seen there, that in the arid or elevated regions of the world consumption was not communicated from the sick to the well was not at all proved from such unreliable and imperfect statistics as had generally been brought forward. He said that the immunity apparently due to a climate might be really due to manner of life, such as isolation and a life day and night in the open air; or to selected lives, such as the early settlers of any country live, who, to cope with its hardships, had of necessity to be the strongest; and that therefore it was only after a country had been settled for a considerable time that reliable data concerning climatic arrest of infection could with accuracy be computed. He said that although it was a well-established law that consumption among all races and in all climates diminished in progressive ratio as we ascended from the sea level, there was no absolute safety or non-phthisical line to be drawn at a certain elevation, and that a few cases did occur at any elevation. He mentioned three cases he had seen of death from acute tuberculosis in Ute Indians who had never been out of Colorado or Utah.

Institution Treatment of Pulmonary Tuberculosis.—Dr. C. P. Ambler, of Asheville, N. C., read a paper with this title, the conclusion of which was that closed institutions for phthisical patients offer the greatest certainty for their cure, inasmuch as better results appear to be a necessary consequence of the superior advantages which well-conducted institutions afford, and that *a priori* consideration of these advantages would lead us to the conclusion which statistics and experience have both demonstrated and confirmed.

At the business meeting of the association which followed the scientific meeting of the second day it was

"*Resolved*, That the association learns with much regret that the weather bureau has been obliged to discontinue the publication of and work exemplified in its recent periodical, *Climate and Health*.

"*Resolved*, That this association would urge upon the secretary of agriculture and the chief of the weather bureau the desirability of resuming the said publication; and that the members of this association

urge upon the members of Congress from their States to furnish an appropriation for this purpose."

Dr. J. B. Walker, of Philadelphia; Dr. S. E. Solly, of Colorado; and Dr. W. W. Johnston, of Washington, D. C., were appointed a committee to attend to the matter.

Dr. Herrman Weber, of London, and Dr. Charles Theodore Williams, also of London, were elected honorary members.

Third Day—Thursday, May 6th.

Oil of Turpentine as a Remedial Agent.—Dr. J. B. Walker, of Philadelphia, read a paper on this subject. He dwelt especially on its effects in catarrhal affections and as a hæmostatic when the lesion is in the mucous membrane. In gastric ulcer, whether for its influence on the ulcerative process or as a hæmostatic, he said it ranks *par excellence* both for efficiency and acceptability to an irritable stomach. Given in small doses, from two to ten drops in water sweetened with the olæosaccharum anisi, each dose prepared as taken, its acrimony is obscured and the most sensitive stomach will retain it. In catarrhs, subacute or chronic, whether in stomach, bowels, bronchial tubes, or urinary tract, as a stimulant-alterative, reaching every mucous membrane of the body, either in its ingestion or elimination, its virtues are invaluable, modifying secretion and influencing cell nutrition directly. In the winter coughs of the aged and infirm, its general stimulant action is an advantage additional to its local effect.

Some of the Vagaries of Croupous Pneumonia as Seen in Central New York.—Dr. Henry L. Elsner, of Syracuse, N. Y., presented a paper based upon the consideration of one hundred and fifty cases of croupous pneumonia, of which careful records had been kept. He considered only the atypical forms of the disease. After giving statistics as to the age and localization of the lesion in the lung, he considered apex pneumonia, which in the majority of cases was not associated with profound cerebral symptoms. In fourteen per cent. of the cases reported the initial chill was absent. This was usually absent in the asthenic pneumonias. He had seen the presence of large areas of a consolidated lung tissue without marked subjective symptoms, and referred to the difficulty with which central pneumonia was diagnosed during early life when associated with gastric or meningeal symptoms. Abdominal pain as an initiative symptom was considered. The writer concluded that the asthenic cases were more frequent than formerly, and believed that the increased mortality of pneumonia was due to this fact. Asthenic cases without chill gave an unfavorable prognosis. He reported three cases of afebrile pneumonia, believed that there was an antagonism between pneumococci toxins and blood surcharged with urea or effete matter. To determine this question he was at the present time making animal experimentation. Cases without fever were found with lowered vitality and nerve force. Hyperpyrexia was considered, as was also "post-pyrexial delirium." Ambulatory, malignant, traumatic, and aspiration pneumonia each received consideration. He did not believe in the existence of malarial pneumonia. Toxæmia was the most important element to be taken into consideration in prognosis and treatment. Anomalies of crisis and lysis were dwelt upon, as was also the occurrence of leucocytosis. He believed that the presence of leucocytosis in acute febrile disease favored the diagnosis of pneumonia; its absence favored the diagnosis of typhoid or a severe form of lung inflammation. He did not believe that the presence of leucocytosis was a certain prognostic sign. Fully developed physical signs were rarely present before the end of the second day of the disease.

The Treatment of Gout by Natural Mineral Waters.—Dr. C. C. Ransom, of Richfield Springs, N. Y., in a paper with this title, said that Hippocrates considered the disease due to the retention of humors in the system, and advised purging and the application of cooling lotions or cold water. If we substitute the term uric acid for humors, we have the most modern theory and the treatment of to-day. He pointed out that the aim in the treatment of this disease should be to stimulate functional activity, and thereby increase metabolism and the excretion of morbific matters, and to correct vices of living, and showed how a sojourn at a properly selected watering-place met all these requirements. He said there were many things to be considered in the selection of a watering-place for gouty patients, since as a rule such patients were nervous and irritable, and needed a pleasant environment where they could be occupied and diverted and lead an out-of-door life, while their treatment is made a pleasure rather than a drudgery. To be borne in mind also was the fact that results of treatment may be obtained from the hydrotherapic standpoint alone, irrespective of the mineral ingredients contained in the water used. The analysis of the water was therefore not alone sufficient in the selection of such a place, for, unless the facilities for administering the waters were adequate and the details of the bathing procedure were carefully carried out, the treatment, instead of doing good, might be productive of serious ills. While believing thoroughly in the internal administration of mineral waters, the most valuable mineral waters Dr. Ransom believed to be those used externally in the form of baths.

In considering the treatment of gout by natural mineral waters, he related his personal experience gained from the observation of a great many cases which had come under his care during the past ten years at Richfield Springs, and gave briefly a *résumé* of the methods which he employed in the application of these waters. The form of bath given, and the one which seems to answer best, is the immersion or tub bath, the "dose" of the bath being regulated by its temperature and duration, which will be found to vary with different subjects from 96° to 108° F. for the former, and from five to fifteen minutes for the latter The object sought in the application of the bath he said is to give such a bath as will produce to the fullest extent the physiological effect without exceeding it, for then depression will be sure to follow and harm may result. He mentioned that in determining the proper dosage much care should be exercised, for different patients vary very much in their reaction to the bath, and that it would also be observed that the same individual would vary at different times. He described the usual bath as being begun at a temperature of 98° F. with a duration of eight minutes, followed by complete rest of an hour in bed. The bath is taken three days in succession, preferably in the forenoon and two and one-half hours after a light breakfast. The effects as to exhilaration or depression are carefully noted after the third bath, and from these symptoms and physical examination is determined whether or not it is wise to increase or diminish the dosage, or to continue it as begun. When the baths are found to be depressing they should be modified by lowering the temperature and shortening the duration. A bath at 96° F. for five minutes, or even less, is usually found to accomplish everything desired. Almost all patients taking a course of baths suffer from a general systemic disturbance the first week, which is the condition described as "bath fever," and to the most skeptical Dr. Ransom thought this showed that the medicinal bath is not simply a washing process, but is

capable of producing as marked systemic effect as the ingestion of a drug. Regular and systematic exercise was also urged as of great importance. In those cases in which active exercise would entail too much fatigue, passive exercise in the form of massage or Swedish movements is given. Diet also was spoken of as another important element in the treatment.

The Salicylate Treatment of Hæmoptysis.—Dr. Thomas J. Mays, of Philadelphia, said it was well known that such drugs as gallic acid, tannin, ergot, geranium, hamamelis, digitalis, turpentine, etc., although supposed sheet anchors, are consummate failures in the treatment of many cases of hæmoptysis. This the author thought is due to the fact that they do not fill the gap which exists between what they can do and what we expect them to do. He holds that in many cases the arresting of blood from the lungs does not rest on the therapeutic agents' power to constrict the pulmonary capillaries, but on their influence in removing that toxic condition which weakens the wall of the blood-vessel and makes it permeable to its contents. Such a toxin he believes the rheumatic poison to be, which he thinks is more frequently engaged in bringing about hæmoptysis than is usually suspected; at any rate, practical experience demonstrates that many a case of blood spitting which is uninfluenced by any other internal remedy yields to the salicylates of sodium and cinchonidine very readily. Several typical cases illustrating the utility of these drugs are recorded.

Meteorological Conditions of Sunstroke.—Dr. W. R. Phillips, in a paper with this title, gave a consideration of meteorological conditions predisposing to and exciting the occurrence of sunstroke. The relative importance of high temperature, relative humidity, and wind, and the relation of sunstroke to different climatologic characteristics were discussed; also the dependence of sunstroke upon high temperature or direct insolation, not influenced more by high than by low relative humidity. The author stated that the degree of temperature precipitating sunstroke was a function of the particular climate, and not fixed or definite for all locations.

Calomel in Diphtheria.—Dr. Leonardo D. Judd, of Philadelphia, in this paper spoke of his personal experience in the specific treatment of this disease. He selected a few of the illustrative cases to demonstrate the treatment which he considered the nearest to a specific. He stated that in his experience in the treatment of this disease it had been robbed of its terrors, which conviction was based upon the curative results obtained. While admitting that the treatment of diphtheria by mercury was not new, he said there had been no well-defined application of any one form of this agent which would inspire sufficient confidence to carry it to a successful end. He mentioned Trousseau's dread of its use because of the constitutional effects in "modifying the blood, augmenting its fluidity, and so changing its state that the secretion becomes less plastic," and said that in his opinion it was the constitutional action which was to be sought after as well as the topical. He thought that if the germ theory had been as well understood in Trousseau's day as it is now he would probably have modified his opinion relative to the action of the drug. He also spoke of the experience of the late Dr. Riter, of Pittsburg, and concurred in his opinion that in handling the severest type of diphtheria, the danger was not in giving too much calomel, but rather in too little, and not having the courage to push the drug until the bowel action showed the characteristic green, copious, frothy discharge, resembling "frog spittle," such as may be seen in an old water trough.

Dr. Judd cited two cases in which the treatment had been most satisfactory—one that of a child, the other that of a woman of fifty-five years, whose finger had been scratched by the hand of a neighbor's child dying of malignant diphtheria. Believing from the severe symptoms that he had a case of inoculated diphtheria, he put her on iron and chlorate of potassium with gargle. On the next day the advance of the disease had become most rapid and severe, when, with a trained nurse rigidly to carry out instructions, in consultation with Dr. Curtin, he determined upon the calomel treatment. Beginning with a scruple at the first dose, it was continued in ten-grain doses every hour for thirty-five hours; but not until three hundred and sixty-five grains had been given was the characteristic action secured, when the calomel was stopped. During the exhibition of the drug the patient ejected from the nose and mouth, at intervals, large pieces of membrane, although no gargle or spray was used. About every three hours during the treatment a mild solution of potash was given, and calomel was dusted over the initial lesion of the finger. Her recovery was splendid, and she suffered but for a short time from partial paralysis of the muscles of deglutition and impairment of the sense of touch in her hands and feet, which symptoms disappeared rapidly under the use of faradization. There was no evidence of ptyalism or other ill-effect.

Dr. Judd also referred to three other cases, the only ones which he had seen result fatally—in two foolishly fond mothers interfered with the directions specified; in the third there was what seemed to be cerebral involvement.

In conclusion, Dr. Judd believed there was no danger of ptyalism; he had never seen a case of diphtheria salivated by calomel or hypercatharsis created. He was not unmindful of the potency of the drug, and recommended its heroic use only with proper discernment, and with good, intelligent, reliable nursing. Sleep, he said, too often meant death in these cases, and the wakefulness necessary for the frequent administration of the medicine would do only good to the patient and reward the nurse, from twenty-four to forty-eight hours generally determining the issue.

A Clinical Study of Tachycardia and Its Relation to Graves' Disease and Uræmia.—Dr. Roland G. Curtin, of Philadelphia, in a paper with this title, cited two cases of tachycardia, and mentioned in connection therewith cases of undeveloped Graves' disease, culled from a large number more prominently illustrative in that they had the symptoms of palpitation and excited heart long before the other prominent symptoms presented themselves, and were diagnosticated erroneously as simple essential tachycardia. He considered the careful study of slowly developed Graves' disease very important, and believed that much valuable time could be saved by an early diagnosis. He gave an interesting table, showing the salient points in the differential diagnosis of the tachycardia of undeveloped Graves' disease and simple irritable heart.

(*To be Continued.*)

The Camden County (N. J.) Medical Society.—At the fifty-first annual meeting of the District Medical Society of Camden County, N. J., held Tuesday, May 11th, the following officers were elected to serve the ensuing year: *President*, D. M. Stout, of Berlin; *Vice-President*, Daniel Strock, of Camden; *Secretary*, B. S. Lewis, of Camden; *Treasurer*, J. G. Doron, of Camden; *Reporter*, O. W. Braymer, of Camden; *Historian*, H. H. Sherk, of Stockton; *Censors*, (five years) H. Genet Taylor, (unexpired term) W. H. Ireland; *Trustees*, H. Genet Taylor, Alex. Mecray, E. L. B. Godfrey; *Committee of Arrangements*, F. W. Marcy, W. P. Wingender, J. F. Leavitt; *Nominating Committee*, Alex. Mecray, J. M. Ridge, Maximilian West.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

LISTER'S MAIDEN SPEECH IN THE HOUSE OF LORDS—ORATION BEFORE THE MEDICAL SOCIETY—RELATION OF MENTAL AND BODILY DEVELOPMENT OF CHILDREN — LYMPHADENOMATOSIS — DERMATITIS MALIGNA — RUPTURE OF HEART—THE PLAGUE AND THE BOMBAY GOVERNMENT.

LONDON, May 21, 1897.

LORD LISTER delivered his maiden speech in the House of Peers in the debate on contagious diseases in the army. He was received with as much cheering as that eminently decorous assembly ever indulges in. He declared that as a surgeon he knew that residence in a hospital exercised a very moral influence on many patients—so much so that an accident very often proves a blessing in disguise. He saw no objection to the contagious diseases acts, and was pleased beyond measure to hear Lord Roberts testify that measures could be taken which would enormously diminish the evil without anything that could be fairly construed as an encouragement of vice. He hoped the government would be encouraged by the house to persevere in the good and Christian course on which it had entered.

The annual oration before the Medical Society was delivered by Mr. E. Owen on Monday. He dwelt at length on two "patron saints" of the society, Fothergill and Lettsom, giving some interesting historical notes on these eminent physicians of a bygone period. He repudiated the "croak" sometimes heard that Englishmen are degenerating, and said the Crimea, Afghanistan, and Chitral must be forgotten before such a suggestion could have any weight, for they are as fit for great deeds to-day as were their ancestors. Referring to the medical-aid associations, he denounced the alliance of science and trade, and proclaimed from the chair of Lettsom the liberator the existence of abuse, and called on the Medical Council to "come over and help us."

Dr. Warner has brought before the Royal Medical and Chirurgical Society some of the conclusions at which he has arrived from the statistics he has been collecting on the mental and physical conditions of childhood. You are no doubt aware that he has for several years occupied himself with the inspection of school children with reference to their bodily development and nutrition. In some quarters he is thought to have proved important facts from the mass of statistics which he has tabulated. In other quarters the talk of inspection of a hundred thousand children causes only a smile of incredulity, or the suggestion that the first impressions produced by the inspection of classes can at the best only lead to superficial and hasty conclusions. The special point in his last paper is the relation of bodily development to brain conditions in their pathological aspect. Abnormal development, nervous signs, habitual movements, low nutrition, and mental dulness or backwardness were said to be related, just as on a former occasion postures of the hand were taken to indicate the condition of the brain. Now we are told that defects or deformities are equally indicative, as are disproportions in ratio of growth. Among the examples, outstanding ears are mentioned as one of the stigmata of degeneracy. So habitual purposeless movements are classified into four kinds, among which we find grinning, fidgetiness, and augmenting or diminishing series of movements, suggesting abnormal nervous fidgetiness. But whether the relations Dr. Warner suggests between these and incoordinated brain action and that again with mal-development exist is quite another question. The difference between tweedledum and tweedledee would, I suggest, serve Dr. Warner for a further mass of statistics.

Dr. Norman Moore, whose enormous experience in the post-mortem room gives weight to his words, expressed the general desire of pathologists to find some law of correlation between defects of different parts of the body; but he had abandoned the hope, for it was only exceptionally that abnormalities of one organ were associated with those of others. Movements of an unusual character, odd gestures, or antics may certainly be accompanied by mental qualities of a very high order—an example of which may be noted in Dr. Johnson. So again large ears are not necessary signs of mental defect, for they may be observed in individuals of great mental capacity, and the repeated series of movements on which such stress has been laid should be regarded merely as habits.

It was suggested in the discussion that the stigmata were of very unequal value—that a single sign might not be important, while the conjunction of several might justify a conclusion. This, of ourse, is obvious enough, but a nervous fidgety child, even if it has large ears and some equally important defect in bodily appearance, is by no means necessarily a dullard; but, on the contrary, some of the brightest intellects have undoubtedly been associated with anatomical defect and the habitual movements indicative of nervous restlessness.

Lymphadenomatosis is a nice little word, showing what progress we are making in nomenclature. It was applied at the Pathological Society by Dr. F. T. Weber to a general affection of the bone which has been variously described as "multiple myeloma," "medullary pseudo-leukæmia," "myelogenic leukæmia," "pernicious anæmia with associated affection of bone marrow," and "primary sarcomatous osteitis." Some cases have been recorded in which the disease had not been suspected until the occurrence of fracture of the femur shortly before death, and some in which there was nothing to suggest the disease till death had taken place.

The question of nomenclature was further illustrated by cases exhibited as dermatitis maligna, or Paget's disease of the skin, it being proposed to extend the name of Paget's disease to cases in other localities than those to which it has hitherto been applied. If this suggestion be adopted, it will certainly tend to some confusion. The term maligna was also objected to, as being ambiguous and often only meaning virulent instead of denoting new growth. The cases really seemed allied to rodent ulcer.

Dr. Kingston Fox showed a specimen of non-perforating rupture of the heart from a woman of sixty-nine, who lived forty-eight hours after the occurrence, which caused slow leakage of blood, ending in fatal syncope.

Mr. Justice Jardine, in a recent lecture at the Imperial Institute on "Present Thought and Sentiment in India," referred to the plague at Bombay, and his remarks justify many of the misgivings which have been expressed in the press. There is no doubt that the government in Bombay was duly warned at the earliest period of the outbreak as to its gravity and the danger of its spreading rapidly. The precautions which ought at once to be taken were distinctly pointed out by the responsible medical officers, and yet nothing was done until General Gatacre received full authority and at once carried out the plans of the medical officers which had months before been submitted to the government. The general, having accepted the responsibility, enforced his orders, notwithstanding native prejudices, and succeeded in bringing over some of the most influential native gentlemen to the view that strong sanitary measures were necessary to stay the plague. Why such measures were not taken at first is for the Bombay government to explain.

COLORED WOMEN PHYSICIANS.

To the Editor of the Medical Record.

Sir: Relating to the priority of medical honors for colored women, I desire to state that I note the term used by you, "medical license," while Dr. Brown, of Euclid, N. Y. (who made the correction), used the term "medical degree." With reference to the former I would state that Dr. Sarah G. Jones, of Richmond, Va., a graduate of the medical department of Howard University, passed the Virginia State board of medical examiners in 1893; Dr. Hallie Tanner Johnson (a daughter of Bishop Tanner of the A. M. E. Church), a graduate of the Woman's Medical College of Philadelphia, passed the Alabama State board of medical examiners about seven years ago; and, to use a popular slang term, "there are others."

As to colored women receiving the degree of M.D., there are quite a goodly number who hold diplomas from medical colleges both North and South; hence Dr. Wakefield, who has recently made her *début*, is in no wise the first and only.

Dr. Brown may be correct as to Dr. Logum, but there has been no Bishop Logum in the A. M. E. Church.

G. Jarvis Bowens, M.D.

Norfolk, Va.

THE SPITTING-NUISANCE AND A REMEDY.

To the Editor of the Medical Record

Sir: It seems that another one of the rights of the free American citizen is going to be trampled under foot and wrested from him—his right to expectorate and spit wherever he pleases. The medical press and the profession at large are unanimous in their verdict that unrestricted spitting in public places and conveyances is a menace to public health and must cease. And every intelligent layman will concede that from both a sanitary and æsthetic point of view there is hardly a greater nuisance we have to contend with than the one in question. So far, so good. But is it not the acme of absurdity to forbid a man to expectorate on the floor, and not to provide some other receptacle? Suppose a man rides in a car from Harlem Bridge to City Hall, or half that distance—what is he to do with his expectoration or excess of saliva? We physicians know what an immense percentage of the community suffers from some form of pharyngitis, tracheitis, or bronchitis; we know that we are richer in dyspeptics than is any other nation on earth. I ask: What is a man afflicted with any of those ailments to do with his secretion? Swallow it? And is it any wonder that the order of the board of health, conspicuously posted on the car windows, is contemptuously disregarded by everybody, the conductors included? The nuisance would vanish in an instant by the introduction of cuspidors. If I had the power I would compel the companies to provide each car with at least four cuspidors—one in each corner—the cuspidors to consist of two receptacles: an outer one, fastened to the floor, and an inner one, removable, provided with an automatic cover and filled with an antiseptic fluid or powder; the inner receptacle to be removed once in twenty-four hours, emptied in a proper place, and refilled. We all know that our companies get their valuable franchises for a song, their dividends are enormous, they enjoy more freedom of action while giving us the worst service than those of any other country, and they could very well afford the expense of a satisfactory "cuspidor system." Then the public would have no sympathy with the persistent floor spitter and cud thrower, and I am sure that no judge could then be found fool enough to let such an offender go, while delivering himself of an harangue on the "sacred, inviolable rights of the individual."

I do not know whether the board of health has the authority to compel the car companies to adopt such a system as I have outlined above or not. If it has, it should use it to its fullest extent; if it has not, why then its order—not to spit on the floors—is not worth the paper it is printed on.

HUMANIZING COW'S MILK.

To the Editor of the Medical Record.

Sir: I notice an article in the *Medical Brief*, entitled "Humanizing Cow's Milk," which says that "the happy results following the use of cow's milk which has been modified so as to conform closely to mother's milk have induced Dufour to seek out a practical method for the humanizing of cow's milk in any family." The article then goes on to tell how it is done—by filling a graduate with cow's milk, allowing it to stand for about four hours, and then withdrawing from the bottom, by uncorking, about one-third of the contents, etc. My object in writing this brief article is to call attention to the fact that this method is not new here. About ten years ago I wrote an article on "Infant Feeding," which appeared in the Medical Record at that time, in which the same method is described Whether this method had been adopted before that time or not I am unable to say. After making a series of experiments about fourteen years ago, I began using cow's milk for infants, prepared as the above-noticed article recommends. Without making any claims to priority, I wish simply to say that, if this is the first time the method has been heard of in Europe, the leaders in medicine over there are way behind the country practitioners in the land of Uncle Sam.

E. W. Bogardus, M.D.

Poplar Ridge, N. Y

AN ABUSE OF MEDICAL CHARITY.

To the Editor of the Medical Record.

Sir: Can there be any greater abuse of "medical charity," or better encouragement of "medical pauperism," than the free vaccination of the children of the well-to-do in our public schools by the board of health? Shoes and clothing are not given to the school children; they are expected to have them—not admitted unless properly clothed. Now, why should wholesale vaccination slip entirely out of the hands of the profession? Charles S. Fischer, Jr., M.D.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 5, 1897:

	Cases.	Deaths.
Tuberculosis	168	99
Typhoid fever	10	3
Scarlet fever	218	22
Cerebro-spinal meningitis	0	5
Measles	269	6
Diphtheria	262	31
Laryngeal diphtheria (croup)	11	8
Small-pox	11	4
Chicken-pox	16	0

Hope Deferred.—The President of the American Medical Association indulges in the hope that some day the journal of the association will rival the *British Medical Journal*.

A FURTHER CONTRIBUTION TO OUR KNOWLEDGE OF ISCHOCHYMIA.[1]

BY MAX EINHORN, M.D.,

NEW YORK.

IN November, 1894, I delivered before the German Medical Society of this city an address upon the recognition and treatment of stenosis of the pylorus.[2] In this paper I communicated my own experience regarding this condition, and suggested the name of ischochymia, in place of gastrectasia, or gastric insufficiency of the second degree (Boas), as descriptive of the latter. This term was meant to convey the idea that the stagnation of food in the stomach is the essential symptom of this affection, and that the abnormal size of the organ is of secondary importance. For, in the first place, cases of enormous enlargement of the stomach are met with in which there are none of the symptoms of gastrectasia; secondly, the enlargement or dilatation of the stomach is rendered entirely harmless by the removal of the stagnation of the chyme; and thirdly, cases are encountered in which there is present the picture of clinical dilatation of the stomach, although the organ is not enlarged to any considerable extent. In the above-cited paper I pointed out that in the majority of cases ischochymia is caused by a stricture of the pylorus, and that, according to the nature of the stenosis (benign or malignant), a radical cure or temporary improvement may be brought about by operation.

Since then a few new articles by well-known authors have appeared upon this subject. Boas[3] is opposed to the expression "gastric dilatation" or "ectasia ventriculi," and sets up the following postulate: "An abnormally large stomach is capable of performing its motive functions in a perfectly normal manner, and a normally sized or only slightly enlarged organ may exhibit the most pronounced signs of so-called ectasia." This author emphasizes the fact that some cases of severe ectasia, or, as he terms it, gastric insufficiency of the second degree, are susceptible of permanent cure by means of palliative measures. This important fact I am able to confirm completely as the result of my own experience.

Pepper and Stengel,[4] in their article on dilatation of the stomach, describe all possible methods which serve to determine the size and capacity of the stomach, while sufficient weight is not placed upon the most important symptom, the stagnation of food. This paper also contains an abundance of case reports, and is meritorious in this respect.

The newest contribution on this subject is by J. Schreiber.[5] This author also concedes the inapplicability of the old term, gastrectasia, and proposes instead the name "gastric stasis associated with permanent digestion." The name introduced by me, "ischochymia," which expresses the same idea and is much shorter, has apparently escaped Schreiber's notice.

In view of the importance of ischochymia, both to the clinician and to the surgeon, it appeared to me advantageous to communicate here my more recent cases which have been observed by me since the publication of the above-mentioned paper, in order to make them serve as a text for a somewhat more complete elucidation of the diagnosis and therapeutics of these conditions.

The cases of ischochymia which have been under my treatment during the last two or three years can advantageously be divided into the following groups:

I. Cases of ischochymia submitted to operation.
(*a*) Benign stenosis of the pylorus.
(*b*) Malignant stenosis of the pylorus.

II. Cases of ischochymia treated by palliative measures.
(*a*) Benign stenosis of the pylorus.
(*b*) Duodenal stenosis.
(*c*) Probably pure atony of the stomach.
(*d*) Malignant stenosis of the pylorus.

I.

Cases of Ischochymia Submitted to Operation.—The cases of ischochymia from benign pyloric stenosis which were submitted to operation comprise six, and as they all exhibited some peculiarities I have taken the liberty to describe them successively:

CASE I.—George W——, aged forty, began to suffer twenty years ago from pains in the left side, which usually appeared two hours after meals. This condition was generally rapidly improved by medicaments, and the patient then obtained relief for six or seven months. Five years ago the painful attacks became more violent; they extended over periods of three to four weeks, and were now accompanied with vomiting. The patient vomited three times each day, and this also occurred at night, the vomiting being always followed by relief. In the vomited matter and in the liquid obtained after lavage of the stomach the patient has occasionally noticed foods ingested several days before. Thus on one occasion the patient had partaken of huckleberries on a Sunday, and when he washed out the stomach six days later he found these berries in the wash water. He has also observed the same thing after eating green corn. The intervals of quiescence now became shorter, lasting only a week, although two years ago the patient had one period of rest of two months' duration. Lately he has been unable to follow his vocation. During the attacks he loses considerable in weight, but soon recovers. The patient weighed five years ago one hundred and eighty pounds, and now weighs one hundred and forty-three. Appetite always good; stools usually regular. Constant thirst and desire for salt.

January 25, 1895. Status præsens: Patient seems considerably emaciated. Palpation of the abdomen reveals sensitiveness to pressure. Splashing can be readily evoked, and by means of this symptom it is possible to trace the stomach to a point a hand's

breadth below the navel. Although the stomach of the patient had been thoroughly washed out one hour previously, it was found to contain over 600 c.c. of fluid having a biliary-green color, with the following properties: HCl +; acidity = 150. Patient is directed to take at seven o'clock in the evening a plateful of rice soup, some meat, and white bread, but not to eat anything else.

On the following day (January 26, 1895), at 10 A.M., the patient was examined in the fasting condition with the tube. There was found 700 c.c. of fluid mixed with food, the grains of rice and particles of bread being most distinctly recognized. The chemical examination showed: HCl +; acidity = 90. The examination of the stomach in the fasting state was now undertaken on several days, and a condition similar to the above was always found, namely, presence of chyme, besides a large quantity of gastric juice.

The diagnosis of stenosis of the pylorus of benign character was now made, and the patient operated upon, February 1, 1895, by Dr. F. Lange. The pylorus was found considerably thickened, narrowed, and the site of adhesions; in the stomach, close to the pylorus, an ulcer was present. A pyloroplastic operation according to Heinecke-Mikulicz was performed, but the ulcer was left intact, because it did not appear advisable further to prolong the operation.

The patient convalesced slowly. Owing to the irritation produced by the ulcer, the chymus prochoresis of the stomach was impaired and the peristaltic restlessness of the organ was noticeable for a long time. After administration of large doses of bismuth and the maintenance of the milk diet, this condition improved, and the patient was then able to undertake a journey for his health to South America. I have heard nothing further from the patient, and assume that he is healthy.

CASE II.—Mrs. Aurelia L——, about fifty years old, has suffered for fifteen years from recurrent attacks of violent gastric pain and vomiting. Each attack usually extended over several weeks and greatly exhausted the patient, although after its subsidence she recovered quite rapidly. For two years, however, the patient has scarcely ever been without pains; the vomiting appears frequently. The vomited matter, according to the statements of the patient, is quite sour, contains foods of the previous day, and occasionally amounts to from one to one and one-half litres. Marked constipation has existed for several years. The patient has lost about fifty pounds in weight, and has been confined to bed for several months. The pains in the abdomen have been so violent for one-half year that opium had to be administered every day in large quantities.

February 19, 1895. Status præsens: Patient is confined to bed and appears cachectic in a marked degree. She complains of violent tension in the abdomen and a burning feeling in the pit of the stomach. The thoracic organs are normal; the pulse is quite weak and frequent. The entire lower left side of the abdomen forms a slight spherical protrusion, which extends from the level of the umbilicus to the symphysis. On longer inspection one observes peristaltic contractions, which pass in high waves from the left toward the right side, and are especially pronounced after palpation. A splashing sound can be produced, and thus the entire lower limit of the stomach can be traced to the symphysis. The protrusion is caused by the greatly distended stomach, inasmuch as no resistance is encountered here on palpation, while splashing can be evoked. To the right of the median line, three fingers' breadth above the navel, an oval tumor, about three centimetres in length, running in a horizontal direction, can be made out; this is only slightly movable, and has a smooth surface. The urine is passed in only small quantities, and contains neither sugar nor albumin.

The patient is directed to eat nothing after 7 P.M., and on the following morning (February 20, 1895), at 11 A.M., is examined with the stomach tube. More than one litre of a greenish fluid, containing remnants of food, is withdrawn; in this fine coagula of casein, fat, and minute fragments of bread can be at once recognized. The chemical examination revealed the presence of free hydrochloric acid and very high acidity; microscopically yeast cells and sarcinæ in abundance.

This examination in the fasting condition was repeated on several occasions, and the same results were always obtained, *i.e.*, the presence of chyme in the stomach. A diagnosis of benign pyloric stenosis was therefore made, and the patient operated upon by Dr. F. Lange, on March 1, 1895. The pylorus was found markedly thickened and narrowed, and attached to the neighboring organs by numerous adhesions. A gastro-enterostomy with the Murphy button was made; the patient, however, died seven days after the operation. At the autopsy a microscopic examination of the pylorus showed the presence of a benign hypertrophy.

CASE III.—December 31, 1895. Miss Elise B——, aged thirty-five years, was afflicted with a tapeworm fourteen years ago, after the removal of which she began to suffer from dyspeptic disturbances. The pains usually appeared one-half hour after eating during a period of several weeks, and then ceased for some time. The patient had always been anæmic. Eight years ago the pains became much more violent and she vomited everything that was given her. After this condition had lasted for four weeks, a profuse hemorrhage from the stomach occurred. The patient awoke at night and vomited a large dishful of black blood, in which were thick coagula. She was confined to bed for about fourteen days, and after getting up suffered from constant pains. Later she went to Carlsbad, where her condition was considerably improved; she gained in flesh, began to have a better appearance, and the pains subsided almost completely, occurring only now and then. Up to about two years ago this condition persisted; then the pains again became more violent and vomiting ensued, so that the patient was scarcely able to partake of anything but milk. The stools at that time had a pitch-black appearance for a period of eight days, although she had taken no medicine of any kind. This melæna occurred later about once in six months. Three or four weeks ago a violent attack again supervened, with intense pains, loss of appetite, thirst, and vomiting. The patient was then referred to me through the kindness of Dr. Steffen.

Status præsens: The patient is of spare build, with a well-developed osseous framework, and appears emaciated. The thoracic organs are normal. Palpation of the abdomen reveals sensitiveness in the epigastric region, and an area of resistance in a somewhat horizontal direction, which is situated three fingers' breadth below the xyphoid process, and can be traced from the median line toward the left side over a length of about three centimetres. Splashing can be readily produced, and by means of this phenomenon the stomach can be traced downward from the above-mentioned area of resistance to a point about three fingers' breadth above the symphysis. The place of resistance, which is situated in the lesser curvature of the stomach, is regarded as a tissue thickening resulting from the cicatrices of ulcers. The urine contains neither sugar nor albumin.

January 3, 1896. Examination one hour after Ewald's test breakfast: HCl +; acidity = 120; free HCl = 100. Microscopical examination: large and small bacteria are present in abundance.

January 4th. Examination of the patient with the

tube followed by irrigation in the fasting state, after she had partaken of meat, rice, and bread on the previous evening, showed that the stomach was completely empty. For the present a considerable stenosis of the pylorus was excluded, and the existing disease referred to a gastric ulcer. The patient was therefore treated by Dr. Steffen with large doses of bismuth and milk diet. She felt better, and was soon able to take a semifluid diet. She increased in weight (about fifteen pounds), but was never free from pains.

In June, 1896, the patient again consulted me. She complained that the pains had become more violent, and that she vomited more frequently. She also stated that she had noted in the vomited matter remnants of the food of the previous day.

June 5, 1896. Examination of the stomach in the fasting condition, after the patient had partaken on the preceding evening of boiled rice and milk, meat and zwieback, revealed a considerable quantity of chyme, about 300 c.c., containing rice grains as well as bread particles. The chemical analysis of the gastric contents withdrawn by the tube showed: HCl +; acidity = 80. Microscopical examination: yeast cells few, no sarcinæ.

June 7th. Examination of the stomach in the fasting state, after the patient had taken on the previous evening milk and some white bread: stomach empty.

June 9th. Lavage in the fasting condition showed again a residue of food, as on the 5th.

This variable condition of the stomach in the fasting state (sometimes empty and sometimes indicating stagnation of food) led us to conclude that we had to deal, not with a marked stenosis of the pylorus, but either with an open ulcer close to the pylorus or an adhesion at the beginning of the duodenum. The first would give rise in a reflex manner to a spasmodic occlusion of the pylorus; the second would at times exert greater traction upon the duodenum, and thus incidentally produce ischochymia.

The patient was operated upon by Dr. Willy Meyer, on October 22, 1896. There were found several thickenings about the lesser curvature, and at the commencement of the duodenum a connective-tissue cord, which constricted the latter. Besides this, there were present a few adhesions to the liver. Gastro-enterostomy was performed, with recovery. The patient later complained of pains after ingestion of the coarser kinds of food, and still vomited now and then. Her stomach was examined one hour after a test breakfast, and there was found: HCl +; acidity = 90; free HCl = 70. The patient was given one-half teaspoonful of bicarbonate of sodium three times daily two hours after meals, and the pains were now much diminished. Since the operation she has increased in weight about fourteen pounds, and altogether she is in much better health than previously, although she is compelled always to avoid coarse foods, as otherwise gastric pains are produced.

Case IV.—November 29, 1896. Aron L——, thirty-two years old, manufacturer, has suffered more or less from pyrosis since his eighteenth year. Appetite was always poor, and the patient was regarded as a small eater; he was troubled with frequent eructations, and was always constipated. During the last two years he has complained constantly of a burning feeling in the epigastrium two hours after meals; the ingestion of food, as well as the administration of bicarbonate of sodium, alleviated this symptom for a short time. Four months ago the patient began to experience colicky pains in the upper abdominal region: these usually appeared five or six hours after eating, or later at night, and especially when he had neglected to take anything for the burning. The appetite was not much changed, sometimes somewhat slighter than previously. Vomiting only seldom occurred after gastric lavage had been undertaken. The patient stated that on one occasion after washing out the stomach a small quantity of blood was noticed.

Status præsens: Patient is fairly well nourished; color somewhat pale, tongue slightly coated. Thoracic organs intact. Palpation of the abdomen reveals no areas sensitive to pressure. Splashing sound present, and the stomach can be traced to a line one or two fingers' breadth beneath the umbilicus. Peristaltic contractions are not visible. The urine contains neither sugar nor albumin, and is secreted in sufficient quantity.

November 29, 1896. Examination of the stomach in the fasting state reveals a considerable amount of chyme (200 c.c.), consisting chiefly of bread and starchy substances. HCl +; acidity = 48.

November 30th. Examination of the stomach one hour after Ewald's test breakfast: Quantity equals

Fig. 1.—Showing the entire cross-section of the excised ulcer as it appears under the lens. The concave line forms the interior, the convex the outside of the stomach. The middle portion is deprived of the glandular layer; to the left a few glands are left. × 4.

300 c.c.; HCl +; acidity = 76; slight residue of food from previous day can be recognized.

December 1st. Examination in a fasting condition furnishes a greenish fluid, containing few fine particles of food and of strong HCl reaction.

December 3d. Contents obtained in a fasting condition consist of fluid mixed with bile and brownish masses containing only a few food particles. After lavage blackish masses finally appear. The slight stagnation of foods at once awakened the suspicion of a pyloric stenosis of moderate degree, and the brownish masses (altered blood) pointed to the existence of an ulcer in the vicinity of the pylorus. This suspicion was further confirmed by the circumstance that, on December 18th, 400 c.c. of fluid, containing numerous brownish masses, was obtained from the fasting stomach; at the same time an area of sensitiveness to pressure was present in the epigastrium, especially toward the right side. The patient was now placed in bed, and a strict cure initiated for the ulcer. From December 18th to 23d he was nourished per rectum, after which small quantities of milk were administered per os.

January 2, 1897. Lavage in the fasting state showed the presence of a slight amount of food residue (100 c.c. of chyme mixed with bile); the same condition was noted on January 8th.

The diagnosis previously made of a commencing benign pyloric stenosis, complicated with ulcer in the vicinity of the pylorus, was now assumed with the greater show of certainty, in view of the futility of the treatment, and the patient was urgently advised to undergo an operation, the more so since all therapeutic measures had proved unavailable.

The operation was performed by Dr. F. Lange, on January 13, 1897. There was found an ulcer on the anterior side of the stomach, closely adjacent to the

pylorus; the latter was markedly thickened (rigid) and its lumen narrowed. The ulcer was excised, and the pyloroplastic operation of Heinecke-Mikulicz carried out. The accompanying three drawings give the microscopical appearance of the ulcer and its immediate surroundings. The mucous membrane of the stomach was markedly swollen and hypertrophied.

Fig. 2.—The left corner of Fig. 1, as seen under the microscope with low power. Glands are visible to the left of the drawing, the rest consisting principally of a proliferation of cells and connective-tissue formation.

The patient rapidly recovered from the operation, and has since completely recuperated; he is free from all disturbances, and has gained twenty-five pounds in weight.

Case V.—January 2, 1894. Esther S——, forty-three years old, has suffered for twelve years now and then from gastric pains. About a year ago the pains became more intense and vomiting occurred, obstinate constipation being always present. The appetite was variable; sometimes there was present a ravenous hunger; usually, however, more or less anorexia. During the last year the patient has lost over thirty-six pounds in weight.

Status præsens: Thoracic organs intact; tongue thickly coated. Palpation of the abdomen reveals no sensitiveness to pressure. A splashing sound can be traced from the left border of the ribs down to a point a hand's breadth below the navel. In the left hypochondriac region, close beneath the liver, an area of resistance is found, which is about 2.5 cm. long by 1.5 cm. wide, adherent to the liver, and apparently connected with the stomach. The urine contains no sugar or albumin.

January 7, 1894. Examination of the stomach by the tube in the fasting condition: Over 500 c.c. of decomposed chyme is found in the stomach; this has an extremely disagreeable odor. HCl +; acidity = 40.

Patient was treated for some time by washing out the stomach, and, as this procedure produced no conspicuous change in her condition (the ischochymia persisted as heretofore), she was advised to have an operation performed, but refused positively.

She then disappeared from my observation, but returned about the middle of December, 1896, with the statement that she had suffered intensely during the past three years. There was present constantly a feeling of tension of the abdomen and of burning in the epigastrium and in the œsophagus. Vomiting of large, ill-smelling masses every two or three days had occurred during the entire period; marked constipation existed, and since January, 1894, the patient had lost thirty pounds in weight.

December 20, 1896. Status præsens: Inspection of the abdomen in the recumbent posture shows a considerable protuberance of the lower abdominal region; this extends from the left toward the right side, commencing a few fingers' breadth above the navel and reaching as far as the symphysis. Palpation reveals in this case no tumor or splashing sounds in the entire protruding region. After palpation peristaltic waves of the stomach from left to right were observed immediately (peristaltic restlessness). This phenomenon sometimes occurred spontaneously without preceding palpation.

December 22d. Examination of the stomach in the fasting state revealed the presence of large masses of chyme; the chemical examination showed HCl +; acidity = 50; lactic acid not present.

The diagnosis of a benign stenosis of the pylorus was made, and it was assumed that the pyloric tumor observed three years before must still be present, but had been drawn so far backward by adhesions as to be no longer accessible to palpation.

The patient was now treated by me in the Post-Graduate Hospital, and operated upon, January 5, 1897, by Dr. Willy Meyer. The pylorus was found converted into a dense tumor firmly adherent to the lower border of the liver. Gastro-enterostomy was performed, and the patient recovered.

At the commencement of this month (April) she reported that since the operation she had increased forty pounds in weight; she is now able to eat everything,

Fig. 3.—Showing one spot of a proliferation of cells lying in the centre of the specimen resembling very much a spindle-cell sarcoma. Highly magnified.

and has been completely restored to health. An examination of the stomach showed that the organ extended only to a point one finger's breadth beneath the navel (splashing sound).

Case VI.—March 22, 1897. Miss Emma L——, aged fifty-three years, had passed through a severe

attack of "stomach and liver trouble" fourteen years ago; at that time she suffered from violent pains in the right side and vomiting without hæmatemesis. A diet consisting of "hot water and meat," continued for several weeks, effected a cure. After this, rapid increase in weight from one hundred and ten to one hundred and fifty-three pounds took place.

About two years ago her trouble returned. She began to experience a feeling of fulness after meals, and the bowels became constipated. The bodily weight also commenced to decrease slowly, and for a little over two months she has vomited large masses at times; the vomiting usually occurred only once in two or three days, and the vomited matter contained frequently foods of the previous days.

Status præsens: The patient is considerably emaciated and anæmic; the skin feels dry, and the tongue has a white coating. Thoracic organs intact. Inspection of the abdomen reveals a considerable prominence of the lower half of the abdominal wall, more marked on the left than on the right side. On prolonged inspection peristaltic movements passing in the form of hillocks from left to right are observed. Palpation reveals no areas especially sensitive to pressure. The splashing sound is present, and this can be traced downward almost to the symphysis. On the right side an oval area of resistance can be made out by deep palpation in the umbilical line; this is only slightly movable, and runs in a fairly vertical direction. It appears possible that this is the thickened and perhaps adherent pylorus. The urine contains neither sugar nor albumin.

March 23, 1897. By introduction of the tube into the stomach in the fasting condition, over 500 c.c. of chyme is withdrawn, having the following characteristics: HCl = 0; lactic acid +, marked; acidity = 176; free acid = 40.

On microscopical examination very numerous thread bacilli are found, also isolated yeast cells. In the fermentation saccharometer the filtrate shows no distinct development of gases, even on addition of sugar.

Patient is placed on a fluid diet, and receives resorcin and bismuth.

March 28th. In the fasting condition over 500 c.c. of gastric contents is withdrawn with the tube, in which food particles are noticeable. HCl = 0; lactic acid +; acidity = 52.

An attempt was made completely to cleanse the stomach, but this was not successful, as the fenestræ of the sound were obstructed with thick food particles.

A marked stenosis of the pylorus of benign character was diagnosed, chiefly upon the ground of the anamnestic data, although the presence of lactic acid and thread bacilli pointed to a malignant neoplasm. The patient was sent by me to the Post-Graduate Hospital, and nourished for five days exclusively per rectum. After that she began to take small quantities of milk per os, but when examined in the fasting condition the stomach was found filled with a considerable residue of milk. The pylorus appeared to allow but little food to pass through, and therefore an operation was advised as an *ultimum refugium*.

On April 6, 1897, the patient was operated upon by Dr. Willy Meyer. The stomach was found enormously enlarged, and the pylorus adherent to the lower surface of the liver to such an extent that its separation and the performance of a pyloroplastic operation could not be considered; hence a gastro-enterostomy was established. The patient recovered from the operation, but died on the eleventh day from increase of the weakness and cardiac failure, after the occurrence for several days previously of constant vomiting (bile and intestinal contents).

An autopsy showed firm adhesion of the pylorus to the lower surface of the liver and the abdominal wall, in consequence of an old perforating ulcer; the lumen of the pylorus was impassable to the little finger. No cancer could be found.

Of the six cases of malignant stenosis of the pylorus subjected to operation, I report only two, in which no tumor could be felt and in which lactic acid was absent in the gastric contents.

Case I.—October 16, 1894. Emil K——, fifty-three years old, had suffered for about six months from frequent intense gastric pains and occasional vomiting. He had lost about forty pounds in weight.

Examination of the abdominal organs revealed no areas especially sensitive to pressure. A splashing sound could be produced in the gastric region, and traced downward to a line one finger's breadth beneath the navel.

Examination of the stomach in the fasting condition showed the presence of large food masses (rice, bread particles, spinach, etc.). Chemical examination: HCl +; lactic acid not present; acidity = 140. Microscopical examination: yeast cells, sarcinæ, and bacilli. For several successive days examination of the stomach was undertaken in the fasting state, and the same result was always obtained, namely, considerable ischochymia.

A diagnosis of pyloric stenosis, very probably due to a carcinoma, was made, and the patient referred to Dr. F. Lange for operation. At the laparotomy a considerable carcinoma occupying the entire pylorus and a portion of the lesser curvature was found. A gastro-enterostomy was established; the patient recovered and lived for six or seven months in a quite comfortable condition—that is, he no longer vomited and was able to partake of a varied diet.

Case II.—October 24, 1896, Sam. K——, thirty-two years old, had suffered since four months with gastric pains and obstinate vomiting, besides a sensation of intense burning in the pit of the stomach and in the œsophagus, with tension as well as oppression in the chest. The appetite was good, the bowels were markedly constipated. Since the beginning of his disease the patient had lost over forty pounds in weight, and had become weak and languid, so that he was no longer able to follow his occupation.

Inspection of the abdomen showed a marked peristaltic restlessness of the stomach (high waves passed slowly from left to right). By following the splashing sound it was found that the stomach extended downward to a point two fingers' breadth above the symphysis. Palpation revealed the absence of any perceptible tumor.

Examination of the stomach with the tube, after the patient had partaken only of tea on that morning, showed the presence of a large quantity of chyme (casein coagula, particles of bread); the chyme had a marked green color from admixture of bile, and formed a foam on the surface of the fluid. Chemical examination: HCl+; lactic acid not present; acidity = 100. On placing the filtrate in the fermentation saccharometer at ordinary temperature of a room, one-half of the cylinder was found filled with gas. The second examination of the stomach in the fasting condition gave the following result: presence of large masses of chyme having the above described characteristics.

A diagnosis of pyloric stenosis, very probably due to an occluding carcinoma, was made, and the performance of an operation, that is, gastro-enterostomy, urgently recommended. The operation was performed several days later by Dr. Willy Meyer in the German Hospital. A tumor of the pylorus was found, connected with the lower surface of the liver; besides this, several infiltrated mesenteric glands and two suspicious deposits in the small intestine were noted. The tumor had every appearance of cancer, but, owing

to the adhesions and the swelling of the mesenteric glands, was not resected, gastro-enterostomy being performed. The patient recovered without further disturbances and since then (five months after the operation) has increased thirty pounds in weight, is able to eat everything, and attends to his business.

II.

Cases of Ischochymia Treated by Means of Palliative Measures.—(*a*) *Ischochymia produced by benign pyloric stenosis.*

Seven cases belonging to this class have come under observation; in all of these ischochymia was strongly pronounced, while peristaltic restlessness of the stomach was at first found, but later disappeared on improvement of the condition.

For the sake of illustration I will describe in brief two of these cases.

Case I.—May 20, 1896. Robert A——, forty-six years old, had since his youth suffered occasionally from stomach trouble. Thus in 1871 he had an attack of violent pains in the gastric region, which confined him to bed for several days. Since then, up to 1880, the patient had been completely healthy. He then began to experience pains in the epigastrium, which usually appeared every day at about the same time (5 P.M.) and increased in intensity. About a month later vomiting ensued; the patient now began to suffer from violent headaches, with which he was afflicted until 1883. After that, up to 1894, he enjoyed good health, and weighed one hundred and forty-five pounds. In July, 1894, the intense pains in the gastric region recurred, appearing periodically every day at the same time during about fourteen days. The patient was then very well until December, 1894, when an attack again occurred. From December, 1894, until April, 1895, he suffered constantly and his weight was reduced to one hundred and four pounds. Gastric lavage was employed, the patient being able to practise this procedure himself. During this period he was frequently troubled with profuse vomiting. At about this time the patient entered the Presbyterian Hospital, in which he remained for two months. He was nourished for fourteen days on milk, and improved in health. When he left the hospital he weighed one hundred and twenty pounds, but still suffered from tension in the abdomen and pyrosis. Marked constipation was always present. The patient continued to suffer with his stomach, and was in the habit of washing it out whenever he had pains (every night). He weighed one hundred and twenty-three pounds in his clothes when he came under my observation, being referred to me through the kindness of Dr. J. A. Booth.

Status præsens: Thoracic organs normal; patient emaciated; skin quite dry. Inspection of the abdomen reveals a protuberance of the lower half, which is more pronounced on the left side; here and there hillocks of the size of the fist, moving from the left to right, are noted. Palpation reveals no sensitiveness to pressure; splashing can be readily produced, and by means of this symptom the stomach can be traced to a point two fingers' breadth above the symphysis; a tumor cannot be discovered.

May 20, 1896. Examination of the stomach one hour after the test breakfast: HCl +; acidity = 100; free HCl = 70; besides particles of roll, other fragments of food are found (fat, spinach, barley grains).

May 22. Patient had eaten of rice soup, meat, and white bread on the previous evening, but had since abstained from food. On examining the stomach with the tube 300 c.c. of chyme was withdrawn, in which grains of rice and particles of bread were visible. HCl +; acidity = 80.

On May 29th, as well as on June 6th and 14th, examination of the stomach in the fasting state revealed the presence of food, although the quantity had steadily become less.

June 24th. Only a small amount of contents was found in the fasting stomach, and since then it has always been empty in the morning when in this condition.

The patient first took alkalies and later resorcin with bismuth for a long time. His diet consisted at first chiefly of fluids; later he was able to partake of a varied diet, but between meals had to take milk and crackers. The patient at that time felt well, had no more pains or vomiting, and on October 4, 1896, weighed one hundred and forty-four pounds, that is, had increased twenty-one pounds in the last five months.

Case II.—December 10, 1896. Johann C. L——, aged forty-three years, had suffered from "inflammation of the bowels" nineteen years ago. About ten years ago the patient began to be troubled with periodical attacks of headaches and vomiting. These attacks occurred once a month, while during the intervals the patient usually felt completely well, had a good appetite, but was frequently constipated. About three years ago he began to experience pains in the pit of the stomach, which radiated toward the right side, and usually persisted for some time, although during this entire period he maintained a strict diet. Two years ago he vomited for the first time a large quantity of blood (coffee colored), and since then has suffered constantly with vomiting. About one and a half years ago an extremely violent attack of gastralgia occurred, necessitating several injections of morphine. A short time afterward another attack of hæmatemesis took place, which was repeated for the third time in the summer of 1896. Since the beginning of his trouble the patient has lost thirty pounds in weight. During the last two years he observed that prominences of the size of the fist formed on his abdomen, moving from the left toward the right side.

Status præsens: The patient appears emaciated and exhausted, and is markedly anæmic. Palpation of the abdomen shows a sensitiveness to pressure in the scrobiculus cordis; a splashing sound is present, which can be followed down to a point one hand's breadth beneath the navel. After palpation there are noticed high waves, which pass slowly from left to right, and extend over the entire gastric region.

Examination of the stomach two hours after ingestion of a glass of milk (patient had partaken of nothing else that morning) demonstrates the presence of about three-fourths of a litre of chyme, which contains some casein, fat, particles of bread, spinach, etc. Chemical examination: HCl +; lactic acid not present; acidity = 90; free HCl = 70.

December 12, 1896. Examination of the stomach in the fasting condition, the patient having taken some meat and a plateful of rice soup on the previous evening, reveals the presence of about 300 c.c. of chyme containing food particles (rice, fat, etc.). Chemical examination: HCl +; acidity = 80.

December 15th. Examination in the fasting condition: about 250 c.c. of fluid mixed with foods is found in the stomach, exhibiting the above described chemical properties.

Ischochymia, due to a commencing pyloric stenosis resulting from the cicatrix of an ulcer, is diagnosticated, and the patient placed upon a fluid diet consisting chiefly of milk; resorcin with bismuth is also administered, and a quiet manner of life advised.

December 29th. In a fasting condition the stomach contains only 20 c.c. of pure fluid (without admixture of foods). HCl +; acidity = 70.

The patient feels much better and no longer complains of pains and vomiting. The diet is now somewhat changed, four eggs being added daily and some meat once daily.

January 13, 1897. Examination of the stomach one hour after a test breakfast: HCl +; acidity = 100; free HCl = 68. The patient is now able to take besides the previous diet thick soups, white bread, and butter.

February 16th. The stomach in a fasting condition contains 20 c.c. of pure gastric juice; HCl +; no food. The patient feels well and vigorous, and during the two months has gained fifteen pounds in weight.

(*b*) *Ischochymia, probably due to a benign duodenal stenosis.*

A case of this kind was observed which is of interest for the reason that a chronic continuous hypersecretion resulting from a duodenal ulcer was first present, and that the ischochymia developed at a later period. An operation was refused, and the case terminated fatally in consequence of a profuse hemorrhage. The history in brief is as follows:

Adolph L——, fifty-one years old, merchant, had suffered for six years with digestive disturbances. During this time he had had four attacks of intestinal hemorrhage, that is, large quantities of pitch-black blood were evacuated by way of the intestine. After such an attack the patient is very anæmic, so that he is compelled to lie down, as otherwise he is troubled with vertigo. He also suffers frequently from pyrosis and obstinate constipation.

April 12, 1895. When the patient consulted me he appeared well nourished, and examination of the chest and abdominal organs gave negative results.

Examination of the stomach one hour after the test-breakfast: HCl +; acidity = 90; no food remnants of the previous day.

April 15th. The stomach in a fasting condition contains 140 c.c. of a clear, watery fluid, in which no food particles can be observed. Chemical examination: HCl +; acidity = 80; no erythrodextrin.

Patient was treated with the galvanic current by the intraventricular method, and felt better.

April 21st. In the fasting condition 50 c.c. of gastric juice is found, and on April 23d only 30 c.c.

The patient now discontinued treatment for nearly ten months because he felt completely well, but returned to me February 27, 1896, and complained of a feeling of burning in the gastric region, which was quite intense, especially toward two o'clock in the morning, so that he found it difficult to fall asleep again.

The patient being in a fasting condition, his stomach was examined with a tube and 200 c.c. of fluid containing large quantities of food withdrawn. HCl +; acidity = 120. Yeast cells and sarcinæ were present in large numbers, as well as numerous crystals of fatty acids.

The patient was treated for some time with gastric irrigation and a spray of nitrate of silver. His condition, however, was not materially changed, and an examination made on March 6, 1896, showed that the fasting stomach contained 400 c.c. of chyme.

A diagnosis of ischochymia, due to a cicatrix of an ulcer of the duodenum, was made, and the patient urgently advised to seek surgical interference. This, however, was positively rejected, and death occurred two months later after an attack of hemorrhage.

(*c*) *Ischochymia, probably due to a purely atonic condition of the stomach.*

Cases of persisting ischochymia which are produced by an actual relaxation of the muscular layer of the stomach are, according to my experience, extremely rare; indeed, I am sometimes in doubt whether this condition exists at all.

A case of chronic ischochymia, which appears to belong to this group, is described in my book[1] (Case H, p. 343).

[1] Max Einhorn: "Diseases of the Stomach," New York, 1896.

(*d*) *Ischochymia originating from malignant stenosis of the pylorus.*

Cases of malignant stenosis of the pylorus treated by palliative measures are extremely frequent; from four to eight cases of this kind at least come under observation in my private practice every year. These comprise far advanced cases in which an operation is contraindicated, or in which it is refused by the patient or his relatives.

A case of this kind which ran a very rapid course is worthy of mention.

December 6, 1896. John R. F——, sixty-five years old, lawyer, commenced four months ago to experience a feeling of tension and slight discomfort after eating. To these was soon added occasional vomiting and obstinate constipation occurred. The disease steadily progressed, and the patient began rapidly to lose weight and strength. For about five or six weeks he has not been able to retain anything, as the vomiting immediately appears after meals. He also suffers constantly from a feeling of extremely distressing burning in the gastric region and along the course of the œsophagus, together with frequent eructations.

Physical examination of the chest organs revealed nothing abnormal, while on examining the abdomen nothing unusual was noted. No tumor was present, no special sensitiveness to pressure in the epigastrium; a splashing sound was found, by means of which the stomach could be traced down to a point about one finger's breadth beneath the navel.

December 2d. Examination of the stomach with the tube, in the fasting condition: nearly one litre of a reddish foaming fluid, having a strongly acid smell, was withdrawn, in which food particles of the previous days were recognizable. Chemical examination: HCl +; acidity = 64; free HCl = 20; lactic acid = 0; acetic acid +. In the fermentation saccharometer the filtrate in two hours gave off three-quarters of the cylinder of gas.

Patient was nourished with small quantities of fluid diet, and confined to bed. The vomiting, however, persisted, notwithstanding the administration of opiates. A diagnosis of malignant stenosis of the pylorus was made, and in consultation with Dr. L. Rodenstein an operation was advised, but refused by the family. About one day later incessant singultus occurred; the patient became more and more comatose, and died five days later.

On reviewing the above-described cases, Group I. testifies to the fact that the diagnosis of ischochymia and of the conditions which give rise to it (pyloric stenosis, ulcers in the immediate vicinity of or in the pylorus) can be made, with a fair approximation to certainty. In all the six cases operated upon, the diagnosis was completely confirmed by the conditions revealed at the operation.

Of the six cases operated upon for benign stenosis of the pylorus, four were cured, and two (Aurelia L. and Emma L.) terminated fatally in consequence of shock and cardiac failure shortly after the operation. The latter, however, sought surgical intervention at too late a period, and there can be no doubt that this was the sole cause of the fatal termination.[1] Of the remaining four, three have been completely cured, that is, the patients are able to eat everything without any disturbances, and are completely well. One of the patients has been improved, but not completely cured; that is, she continues to suffer now and then from pains which result from cicatrices at the lesser curvature, yet she is able to partake of a more varied diet without the occurrence of a stagnation of gastric contents.

[1] In order to estimate the mortality, it is necessary to add the four cases previously reported by me; we have then ten operated cases of benign pyloric stenosis, with two deaths, that is, a mortality of twenty per cent.

The above-cited cases of malignant stenosis of the pylorus show that even in the absence of tumor and also of lactic acid in the stomach the diagnosis of malignant stricture of the pylorus can be made, and further that gastro-enterostomy exerts a favorable effect temporarily in this condition. The majority of these patients who have survived this operation gain in weight and are able to pass a much more comfortable existence than could formerly have been afforded them.

Although in the two cases reported the diagnosis was made fairly early, resection of the tumor could not be performed because of the existence of numerous adhesions.

The cases described in Group II., subdivisions (*a*) and (*c*) show that ischochymia, dependent upon a benign stenosis of the pylorus or upon a relaxation of the muscular layer of the stomach, can quite frequently be improved by palliative measures. This change for the better means that in relaxation of the gastric muscularis the latter, under appropriate treatment, recuperates and becomes more vigorous, while in stenosis of the pylorus a kind of compensation of the stomach occurs; that is, the organ acts with greater energy, so as to be able to perform its functions notwithstanding the obstruction existing at the pylorus. It can therefore be readily seen that an improvement as a result of palliative treatment can be expected only in cases in which the pyloric stenosis is not very marked; moreover, it is also clear that, in the event of improvement from palliative measures, we must always be prepared for a return of the ischochymia.

If the symptoms of ischochymia do not yield to palliative treatment, surgical intervention is urgently called for, because otherwise a fatal outcome can readily take place. This is best illustrated by the case of duodenal stenosis described under subhead (*b*), in which death occurred after a hemorrhage. Cases in which death took place from starvation have been observed by me in two instances.

Case F. (subhead *d*) shows how rapid may be the course of a probable malignant stenosis of the pylorus under certain circumstances, although no tumor could be felt and hæmatemesis had never been present.

On the ground of the cases reported by me in this paper, as well as of the cases of ischochymia previously described, I will now discuss the points relating to its diagnosis as well as therapeutics.

Diagnosis.—The diagnosis of ischochymia is based upon the presence of food residue in the stomach in the morning and in the fasting condition, the patient having taken a substantial meal on the previous evening.

If this symptom is found to persist for a long time, we have to deal, at any rate, with a serious affection, and it will now be necessary to determine whether this consists in a relaxation of the gastric muscular coat or a narrowing of the pylorus; in the latter case it is further requisite to decide whether a benign or malignant process be present.

The differential diagnostic points which here demand consideration are well known to you, and I consider it the less necessary to discuss them since they are described in detail in my book.[1]

On the other hand, it appears to me of importance to analyze the diagnostic significance of some of the symptoms which, when present, are very valuable, but whose absence does not militate against the existence of pyloric stenosis. These symptoms are:

1. The dilated or abnormally large stomach.
2. The thickened and readily palpable pylorus.
3. The peristaltic restlessness of the stomach.
4. The fermentation products.

1. The abnormal size of the stomach is pathognomonic only if the organ occupies nearly the entire lower section of the abdomen, and contains over three or four litres of fluid. Such stomachs are frequently met with in old cases of stenosis of the pylorus, and their presence at once awakens the suspicion of a narrowing of the pylorus; before this diagnosis can be made, however, the presence of ischochymia must be determined. In this country considerable weight has been placed upon this symptom, as we find in the above-cited article of Pepper-Stengel; yet the absence of this diagnostic sign should not lead us astray, for it is our aim to make the diagnosis of pyloric stenosis as early as possible, while the pronounced, at once perceptible dilatation of the stomach develops only in the course of time. Hence it is not advantageous to apply the old name of "gastrectasia" to designate the entire condition, but to employ instead the term "ischochymia," because this is the most important and at the same time the earliest symptom.

2. If it is possible by means of palpation to map out the pylorus as a smooth, oval tumor, and if ischochymia be present and the disease has lasted over one and a half or two years, we can with certainty make a diagnosis of benign pyloric stenosis. Among the above described cases of this affection, this symptom was found in only two (Aurelia L., Mrs. S.).

3. Peristaltic restlessness of the stomach was found in two of the operated cases of benign stenosis of the pylorus, and in nearly all of the non-operated cases of this disease. Inasmuch as the peristaltic restlessness of the stomach but very rarely occurs as a pure neurosis, this symptom is of great significance for the recognition of stricture of the pylorus, the more so as an examination for this purpose (simple inspection of the abdomen in the recumbent position) is not attended with any difficulty.

The presence of this symptom in connection with the existence of ischochymia speaks in favor of narrowing of the pylorus, and against simple relaxation of the gastric muscular coat; the absence of this symptom is of no consequence.

4. Fermentation products (formation of lactic acid or gases in the stomach) are observed almost constantly in all cases of ischochymia. Commonly, one or the other kind of fermentation is present, that is, either formation of lactic acid or formation of gases. The lactic acid is found in the stomach in cases in which the secretion of hydrochloric acid is considerably diminished, while the development of gas is encountered in cases in which there is an abundant secretion of gastric juice. These points, which have been especially emphasized by H. Strauss,[1] I can completely confirm on the ground of my own experience.

These fermentation products may be absent, however, notwithstanding the presence of pyloric stenosis, if the stomach has been treated in a rational manner, that is, has been washed out several times.

The constant or frequent occurrence of small quantities of bile in the stomach does not in my experience militate against the existence of a narrowing of the pylorus; on the other hand, it appears to me to point to a firm rigidity of this orifice, in consequence of which the latter is never completely closed. A thickened and rigid pylorus of this kind was found in the above-described patient, Aron L., and in Mrs. S., and in both cases a certain amount of bile was constantly in the stomach.

Among the more recent auxiliary measures which are available in arriving at a diagnosis, the gastroscope has been recently employed by Rosenheim and Kelling. In my opinion there is no doubt that this instrument has a great future, although at present it has not been generally utilized.

Treatment.—In the treatment of ischochymia it is necessary first of all to ascertain the cause of the stagnation of food in the stomach.

[1] L. c., p. 355.

[1] H. Strauss Zeitschr. f. klin. Medicin, 1895.

If this be due to a far-advanced benign stenosis of the pylorus, or to a commencing occlusion of this opening malignant in its nature, surgical interference (pyloroplastic operation, pylorectomy, or gastro-enterostomy) is indicated. If we have to deal, however, with commencing benign stenosis of the pylorus, or a genuine relaxation of the muscular coat of the stomach, palliative treatment should first be given a trial, and in the event of its failure an operation is demanded.

The palliative treatment in the milder cases consists in the employment of a fluid or semifluid diet (milk, soups, with finely ground farina, meat broths with egg, egg and milk), lavage of the stomach in fasting condition, followed by spraying with a one-per-mille solution of nitrate of silver, and in the administration of medicaments which prevent fermentation. Among these may be used benzonaphthol, salol, bismuth, and resorcin. I frequently give:

℞ Resorcin	4.0
Bismuth. subnit	20.0
Aq. dest	200.0

S. One tablespoonful in a wineglassful of water three times daily, half an hour before meals.

In severe cases (frequent vomiting, frequent pains, intense burning sensations) it is advisable to keep the patients in bed for about three weeks, and to nourish them for five days exclusively per rectum, and then slowly and gradually adopt a milk diet, as in ulcer of the stomach—in this condition, however, much more cautiously and slowly.

Thus, for example, on the sixth day I give only two tablespoonfuls of milk every hour, on the seventh day three tablespoonfuls, on the eighth day four tablespoonfuls, etc., until I have reached 100 c.c. every hour; then I give 200 c.c. every two hours, and increase to 300 c.c. On every other morning I determine by washing out the stomach in the fasting condition whether it is empty.

In this manner it is frequently possible to adapt the stomach, first to a light, and later to a heavier diet. The patients then increase gradually in weight and appear completely well. Yet they cannot be regarded as entirely healthy, because we must be constantly prepared for a recurrence of the old affection.

Moreover, in cases in which it is not possible to remove the ischochymia by palliative measures, the patient may sometimes maintain a comfortable existence under use of regular washings out of the stomach and the maintenance of a light and rather fluid diet. Such patients, however, are menaced by many dangers and can enjoy but few of the luxuries of life, and for this reason the clinician should insist that an operation is to be regarded as the only correct procedure.

In summarizing this article, the following conclusions can be formulated:

1. In the vast majority of prolonged disturbances in the transportation of chyme from the stomach into the intestine, a narrowing of the pylorus exists.

2. The earliest and at the same time most important sign of pyloric stenosis is ischochymia; the dilatation of the stomach which is met with, and which is often so considerable, does not develop until later, and besides may in exceptional cases occur in the presence of an adequate prochoresis.

3. Ischochymia produced by a malignant neoplasm at the pylorus always demands an operation (gastro-enterostomy, eventually pylorectomy).

4. In cases of ischochymia dependent upon a commencing benignant pyloric stenosis (or ulcer in the vicinity of this orifice), or a relaxation of the muscular coat of the stomach, an effort should first be made to afford relief by palliative measures: if this is not successful, then a pyloroplastic operation or gastro-enterostomy should be performed.

5. Ischochymia due to a benign markedly developed narrowing of the pylorus (in these cases the pylorus can usually be felt as a small tumor) demands early resort to an operation (pyloroplastic procedures, if the stricture is not too small and if the adhesions are not too numerous, otherwise gastro-enterostomy).

20 East Sixty-Third Street.

AN IMPROVED INTUBATOR FOR THE RELIEF OF LARYNGEAL STENOSIS.

By LOUIS FISCHER, M.D.

NEW YORK,

PROFESSOR OF PÆDIATRICS IN THE NEW YORK SCHOOL OF CLINICAL MEDICINE; ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE GERMAN POLIKLINIK, TO THE WEST SIDE GERMAN DISPENSARY, TO THE MESSIAH HOME FOR CHILDREN, ETC.

The instruments herein described are merely improvements of the noble work for which the profession is indebted to the genius of Dr. Joseph O'Dwyer. While teaching intubation I noted certain difficulties which the majority of my students encountered, and thus I have been led after a vast experience on the living and also on the cadaver to devise certain instruments which seem to overcome the apparent hardships. To be in a large city surrounded by experts is a blessing, but to be able to help one's self in a remote region with a simpler instrument is an offsetting advantage.

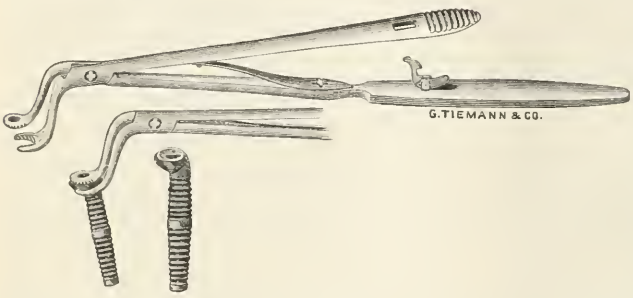
My improved tubes are constructed of vulcanized Para rubber, which is the purest and best kind of rubber. Almost all pessaries have been made for years of hard rubber; so have drainage tubes, tracheotomy tubes, and gums for artificial teeth. Adulterated rubber, which is less expensive, is brittle and should not be used.

The tube is made in various sizes, so that a No. 1 tube answers for a child of one year of age or under; No. 2 for a child two years or under; No. 3 for a child three to four years or under; No. 4 for a child five to seven years or under; No. 5 for a child over seven years and under ten years. The lumen of the tube is smooth, while the outside is corrugated.

Corrugated Tubes.—Corrugation I have found acts as a self-retaining device, and prevents the tube from being coughed out. Naturally a tube with a smooth outside surface, as the O'Dwyer tube, is much more easily expelled during a paroxysm of coughing than a tube whose surface is corrugated, especially so so when the moist mucus or other secretions act as lubricants. As to the principle involved regarding the length of the tube, I have adhered strictly to the O'Dwyer teachings. Thus, my tube fits from the false vocal cords to about one-half or three-fourths of an inch above the bifurcation of the trachea. The proportions I have verified by experiments on the cadaver. I have also made the tube bulge in the centre to give it first more weight, but chiefly to cause it by autopressure to be more self-retaining. The tube here described is not affected by acids or by secretions from the body. It will stand boiling in water and can be sterilized if necessary. I believe, inasmuch as the price of the material (rubber) is not an obstacle, that it is far preferable to use a fresh tube for each and every child. It is hardly compatible with our modern understanding of asepsis and antisepsis to introduce a tube that has been in a diphtheritic throat into a non-diphtheritic throat with a laryngeal stenosis when new tubes cost so little. I would therefore urge that each and every patient receive a new tube when required, and that the same be destroyed by burning after it is extracted. Rubber, as is well known, is pleasant, is

not cold, and will not allow secretions to adhere to its surface, as is the case with metal. I need only refer to the calcareous deposit seen on the O'Dwyer tubes after extubation, from the lime salts present in the pseudo-membranes.

Smooth Tubes—that is, tubes which were polished and were without corrugation—have proved serviceable in some cases. Thus a child of Mr. K——, three years old, was intubated by me without assistance after it had been given an injection of antitoxin, and the stenosis was immediately relieved. This was on April 29th. The case was reported to the health department, and a culture examined by it showed Klebs-Loeffler bacilli. I left a note asking that the child should not be disturbed for an examination by the inspector of the New York health department, as I have found that too frequent examination causes irritation, which excites cough and frequently causes the tube to be expelled. The case progressed favorably and the patient made a rapid recovery. I extubated after four days and the child was discharged cured. A later culture on May 20th showed bacilli to be still present. This later culture was made at the request of Dr. Benedict, owing to the question of disinfection of the apartments. With this patient I used a light-weight



smooth-surface rubber tube, and at the time of writing the voice is slowly acquiring its normal tone.

The introduction of the tube is the most important part of intubation, for when laryngeal stenosis exists the sooner it is relieved the better for the patient. In order that we may avoid apnœa (a not infrequent occurrence with incompetent operators), I have completely done away with the obturator. The tube is attached to an introducer by means of U-shaped prongs, which hold the tube but do not obliterate the opening, *i.e.*, lumen of the tube. Thus the tube permits a current of air to pass the moment it enters the larynx. This is not the case with O'Dwyer's tube until we remove the obturator, and no doubt many times it has happened with others, as it has with me, that while lifting the obturator out of the tube the tube was so tightly attached that obturator and tube came away. Unless the obturator is new, there is always more or less rotation of the tube, so that the posterior projecting portion of the flange may be inserted under the epiglottis, thus greatly interfering with swallowing. In inserting the rubber tube into the larynx, I follow the method recommended by O'Dwyer, *i.e.*, insert the left index finger as a guide, raise the epiglottis, and slip the tube into the larynx.

The tubes devised by me have an eyelet for the passage of a stout silken thread, or I have sometimes used the surgeon's ordinary thin catgut. After intubation allow the child a little time to cough and expel either mucus or pseudo-membranes, and, when all stenosis is relieved, the silk thread or catgut can be removed by pressing downward on the tube with the left index finger and drawing firmly on the thread.

O'Dwyer, in speaking of intubation, says: "Pushing down membrane before the tube is the most serious of the unavoidable accidents attending this operation." This has happened to me. I believe the fact that the lumen of my tube remains open will permit the expulsion (by the usual severe paroxysms of cough following an ordinary introduction of the tube) of any membrane which might be stripped off in the introduction of the tube. If, however, membrane should really obliterate the whole inside of the tube, then it might be necessary to remove it and reintroduce it. Competent operators report instances in which on extubation the lumen of the tube was so completely obstructed that they wondered how the child breathed, and still with the tube *in situ*, filled with this obstruction, no apparent stenosis existed.

On May 5th I was hurriedly summoned in consultation by Dr. Ruzika to a child with laryngeal stenosis, and requested to intubate. On arriving I met Dr. Lowenbein, the attending physician, who was using the usual forms of stimulation hypodermically. The patient was less than two years old. At the doctor's request I intubated the larynx, and had to use considerable force, owing to subglottic infiltration of the mucous membrane. The child had, according to Dr. Lowenbein, convalesced from a mild attack of measles and developed a broncho-pneumonia. He noticed symptoms of catarrhal croup and then sent for me. The child progressed favorably for eight days, after which the tube was removed. Stenosis was very apparent after a few respirations, and this increased in severity until a complete asphyxia was noticed. To quote Dr. Lowenbein: "Dr. Fischer had to act quickly. He used the extubator for putting the tube into the larynx. The child recovered and in four days there was a complete euphoresis, till in our absence the child coughed the tube out and died before aid arrived. Dr. Fischer used the hard-rubber tube, corrugated outer surface. I have no doubt the tube sits more firmly in the larynx than do the metal tubes, and I was surprised the tube was not coughed up before the child having had unusually strong attacks of cough."

The case, although terminating fatally, showed how rapid operating will frequently prolong, if not save life, for twice I found this child in a decidedly moribund condition, and rapid intubation was the only expedient. Once I could not wait an instant, for the child was in a condition of apnœa, and I hurriedly inserted the tube with an extubator in order to save time. Besides I used hypodermics of whiskey and artificial respiration. I was rewarded by having the child breathe first slowly, then regularly, until it was in a normal condition.

Another case in which I intubated, having been called in consultation by Dr. Ludwig Kohn, was similar to the foregoing, although not so malignant. The child is still wearing my hard-rubber tube, and Dr. Kohn has since written to me that he approves of my tube, as it gives more time for the completion of the intubation, in his opinion. Both of these cases I have already reported at the scientific meeting of the German Poliklinik, May 21, 1897.

The introducer is made of steel nickel-plated, and can be taken apart to be boiled and thus converted into an aseptic instrument. Having attached the proper-sized rubber tube, guarded by a piece of catgut or stout silken thread, the tube is grasped by the introducer and locked by a simple screw. The finger is introduced to act as a guide and to lift the epiglottis, and the tube is pushed into the larynx while the

thumb of the right hand, the latter holding the introducer, disengages the tube and allows it to remain in the larynx.

The extubation I regard for the present as the easiest part of the operation, for the child, having recovered from the stenosis and being ready for extubation, is usually stronger, and besides the factor of stenosis is wanting. I shall refer to extubation in some future paper.

In conclusion I desire to thank Dr. B. Gallaudet, of the Bellevue Hospital anatomical committee, for his kindness in granting me cadaveric material from the morgue for my investigations.

The instruments have been made for me by Messrs. Tiemann & Co., of this city. I must express my sincerest gratitude to Mr. Stohlmann and Mr. Pfarre for the faithful manner in which all my ideas were perfected, and I received from them many valuable suggestions.

Four models were made for me. I believe the one here illustrated to be the best. The four varieties of tubes were: a heavy rubber tube loaded with lead to give it proper weight, which I discarded; a light tube with a highly polished smooth outer surface, which was not satisfactory; No. 3 was an unpolished tube of rough rubber, which did not give me complete satisfaction; No. 4 is the one shown in the illustration and is my corrugated hard-rubber tube. If I have succeeded in giving the profession a slight improvement, then I shall feel amply repaid for my trouble.

189 SECOND AVENUE.

THE SKIN AS A DIAGNOSTIC FACTOR IN DISEASE.

By H. A. HARE, M.D.,

PHILADELPHIA,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA, JEFFERSON MEDICAL COLLEGE.

It is not the intention of this paper to devote any space to the consideration of the eruptions which appear on the skin in the course of the eruptive fevers, nor to discuss the changes which take place in its appearance in cases of grave diseases of the blood and of the liver. The design of this paper is rather to deal with the conditions in which the state of the skin is liable to mislead the physician as to the cause of the illness of the patient. Sometimes, too, we are too much inclined to treat the skin affection as the only lesion of importance, and fail to connect it with the underlying condition of the system which is largely responsible for its development. These underlying provoking or predisposing agents are exceedingly numerous, and are perhaps best summed up or described in a very original manner by Dr. Stephen Mackenzie as follows:

The seven stages of man could be well illustrated by diseases of the skin, though we lack a Shakespeare to do justice to the theme. In the "mewling and puking" infant we meet with sclerema and œdema neonatorum, the "red gum" or strophulus of the older writers, intertrigo, eczema, urticaria papillosa (lichen urticatus), urticaria pigmentosa, xeroderma pigmentosum, and impetigo: the "schoolboy," with his chilblains and ringworm, alopecia areata, pityriasis rosea, ecthyma, and "football disease;" and then the "lover," with his acne and sycosis, and, as a result of irregular sexual excursions, his syphilides; "and then the justice, in fair round belly," with acne rosacea, diabetic boils, and pruritus ani; the sixth stage shifts into the "lean and slippered pantaloon," with rodent ulcer and "gouty" eczema; "last scene of all, sans teeth, sans eyes, sans taste, sans everything"—except an incessant and intolerable itching of the skin which we call senile prurigo.

Aside from these dermal manifestations of systemic states, I believe that too little importance is given to the very common lesions of the skin following the use of drugs. A number of American writers have already endeavored to impress upon us these occurrences, notably White, of Boston, and Morrow, of New York, and to a lesser extent Stelwagon, of Philadelphia. Still more recently a paper by Francis Packard has drawn attention incidentally to the same subject, and in the issue of the *Archives Cliniques de Bordeaux* for January, 1897, Guirard has again dwelt upon these cutaneous drug eruptions. From his paper a very considerable amount of the present article is gathered and I desire to give him full credit for a large part of its contents.

In one of his cases a woman, aged twenty-two, who had suffered a symphyseotomy, had the wound dressed with iodoform on January 27th, and no symptom of note developed until February 3d. On this day the temperature suddenly rose sharply between three and four degrees, there was pain in the chest and bladder, and the urine had to be withdrawn by the catheter, but it was in itself normal. Quinine was given for the fever and antiseptic vaginal irrigations were resorted to. By February 10th it was noticed that the patient was marked by red lines reaching downward from the alæ of the nose. In other places they were crescent shaped. They were painless and did not itch, and rapidly changed their appearance to a reddish-violet hue. The eruption disappeared as speedily as it appeared, at the end of three and a half hours, and the skin afterward came away in furfuraceous scales. Guirard believes this to have been due to the iodoform.

Usually the eruption after operations has been more characteristic of scarlet fever. Thus Stirling[1] believes that there may be a scarlatinal rash after operations without the absorption of drugs or an infection by the poison of scarlet fever. He asserts that these skin symptoms are particularly apt to occur after operations upon the genito-urinary tract, and in this he is supported by Civiale, Spencer Wells, Verneuil, and Terrillon. A similar rash has been seen after labor by Kidd.[2] This affection is not associated with fever. Other eruptions after confinement often appear, however, accompanied by chills, fever, and sweating, and these are certainly septic even if the non-febrile eruptions are not.

The moment we leave these cases in which the eruption seems to arise without apparent cause and approach the question as to the eruptions which may be produced by drugs, we pass into an almost limitless field. Only a few of the moderately common accidental rashes can be considered in the short space that can be devoted to this paper.

As a rule, we are apt to regard iodoform as a very innocent substance, rarely producing untoward effects unless its application is exceedingly free, and then causing only general systemic symptoms of poisoning rather than skin manifestations. The observations of a considerable number of clinicians, and a large part of them Americans, have resulted in the report of numerous cases of erythematous rash from the absorption of this drug. Among these may be named Cutler, Bradley, Meunier,[3] and R. W. Taylor.[4] Usually this iodoformic rash appears when the drug is freely applied over a large surface, coming out generally within

[1] "Remarks on Skin Eruptions after Operations and Recent Injuries." St. George's Hospital Reports, 1870.

[2] Dublin Journal of Medical Sciences for 1880.

[4] "The Toxic Effects of Iodoform on the Skin and the General System." New York Medical Journal, 1887.

a few hours after the iodoform is applied (Meunier) and rarely after the twelfth day (Taylor). In two cases reported by Cathelineau[1] the rash appeared after the drug had been applied to a varicose ulcer and a soft sore, and in Wallich's case[2] when applied to a horse bite. In Trousseau's case[3] the drug was absorbed from an ulcer of the eyelid. Nearly all cases of iodoform erythema reach their acme in from one to a few days, persist for about a week after the use of the drug, and then disappear in a furfuraceous desquamation.

It is a well-known fact to many more physicians than those who know of iodoform rashes that quinine is very apt in certain persons to produce skin eruptions of all kinds and varieties. In France, articles by Grellety,[4] Dumas,[5] and theses by Bouvard de Grissac[6] and Levassor[7] have recorded many cases, and a very large number of Americans have done likewise. Guirard states that in most cases, simultaneously with the ordinary symptoms of cinchonism, we have developed a roseola, a simple erythema, or a marked scarlatinal erythema. In other cases an acute eczema or urticaria comes on. I have seen this so-called quinine rash more than once. Usually the eruption is widely diffused, but if limited it may be found only about the breastbone or groin. If the eruption appears on the face, it is usually a tumefaction or œdema. Its development is rapid and it soon reaches its greatest intensity, rarely persisting more than seven or eight days after the drug is stopped. Desquamation nearly always occurs. A differential point of value is that the eruption appears a second time if another dose is given.

Opium on the other hand is not usually suspected of causing eruptions on the skin. As a rule, the eruptions produced by it are limited to the face, but sometimes they are generalized. More commonly they are true erythemata and sometimes scarlatinal in type. In some cases there may be great redness of the skin, abundant sweating, acceleration of the pulse, heat of the skin. According to Brugisser,[8] these symptoms often ensue after small doses, such as ten drops of laudanum. In the great majority of these cases the eruption ends in desquamation, and it may be furfuraceous or in large plaques, according to Lanz,[9] and resemble in every particular the desquamation of scarlet fever. In one case seen by Guinard the desquamation lasted over a period of eight days. These opium eruptions are not only produced by the single dose but in some cases each subsequent dose so results. Thus Berenguier[10] reports the case of a patient who had an eruption three times in one week from the use of doses of opium, and Brugisser records the case of a patient who developed an eruption on one leg from the use of four grains of Dover's powder, another eruption the next day from another dose of one grain of Dover's powder, and a third eruption after five drops of laudanum. Deschamps[11] and Apolant[12] do likewise.

Finally we may discuss the skin lesions produced by turpentine. These follow both its internal and external use. As long ago as 1824 Barbière in his work on "Materia Medica," and in 1841 Galtier in a similar volume, described the onset of erythematous rashes, vesicles, and papules of very fleeting character after the ingestion of turpentine. Trousseau and Pidoux in their book on "Therapeutics" have done likewise, but all these occurred after very large amounts of the drug had been used or after its external employment. In 1879, however, Cordes[1] published an early case of true turpentine rash following its internal use. In this instance a patient of thirty-four years after the ingestion of turpentine developed an erythema over the skin of the trunk. Another case observed by the same author was that of a woman who developed a marked urticaria under similar circumstances. In both these cases the eruption was very fleeting in duration.

The conclusions reached by Guirard are as follows:

1st. That medicinal eruptions are commonly limited to the face, afterward extending to the trunk symmetrically, and usually developing suddenly, as does erysipelas.

2d. Unless they arise from very large doses they generally develop without being associated with general systemic symptoms. He thinks that the absence of these symptoms aids us in separating these cases from the infectious diseases.

3d. The eruptions due to drugs often change from one type to another, particularly those due to the balsams.

4th. The eruptions are usually sudden in onset and develop rapidly.

I have drawn attention to the facts so admirably recorded in Guirard's paper, because I believe that error in diagnosis often arises from ignorance of them and because my own experience is that drug exanthems are by no means so rare as we suppose.

THE TREATMENT OF RETRODISPLACEMENTS OF THE UTERUS.

By W. F. B. WAKEFIELD, M.D.,

OAKLAND, CAL.

PERHAPS there is no condition in the female pelvis which has occasioned more discussion than that of backward displacements of the uterus. In view of this fact I feel a certain amount of hesitation in taking the subject up. Nevertheless, as I desire to lay particular emphasis on one form of treatment which has received too little notice in this country, and one which appears to me to be particularly practical, in spite of Kelly's statement in the *American Journal of the Medical Sciences*, December, 1896, that the operation has been practically abandoned, this article may not be superfluous.

Concerning the etiology, pathology, and symptomatology of the affection I shall say nothing, but shall limit myself to a short study of its treatment.

We are told by nearly all writers that before taking into consideration any operative procedure for the cure of this affection, we should, if possible, place the organ in its normal position by bimanual manipulation and retain it there for several months by means of pessaries or tampons, until the round ligaments and other supports have had a chance to regain their natural tonicity. We are then told that should this fail we are justified in considering some operative treatment for the patient's relief, providing the symptoms are sufficiently troublesome to warrant us in subjecting her to an operation.

I cannot agree with such advice. It is true that by

means of bimanual manipulation, aided if necessary by the use of the sound or some form of uterine repositor, we can in simple cases in which no strong adhesions exist place the uterus in a fairly normal position. We can also by means of a well-fitting pessary or judiciously applied tampons, provided the pelvic floor is intact, oftentimes hold the uterus in position. It is also true that by the long-continued use of such supports, combined perhaps with pelvic massage, we can do much to improve the tone of the ligamentous supports of the uterus. The patient for the time being feels better, many of the troublesome symptoms have been relieved, and, as she is not willing to submit to tamponing or wearing a pessary *ad infinitum*, we cease the tamponing or remove the pessary, and hope that our months of patient toil have not been in vain. We request the patient to return to us in a few months, in order that we may ascertain whether the uterus has remained in its normal position or not, and we are disappointed to find that usually it has not and that the patient begins to feel some of her old symptoms returning. Then in desperation we advise the patient to have the condition cured by operation. She probably goes away from our office disgusted with us for having subjected her to months of futile treatment. Personally I think it would have been much more satisfactory if we had advised operation at the outset. We often find in our cases of retrodisplacements some injury to the pelvic floor which weakens its supporting power, and before we can hope to keep our tampons or pessary in place it must be repaired, and when the patient must be subjected to operation for this the operation for the direct relief of the malposition may just as well be undertaken at the same time. The use of pessaries, tampons, pelvic massage, etc., appears to me to be simply makeshifts, giving, it is true, much temporary relief, but rarely if ever affecting a permanent cure, unless the patient is willing to wear some such support constantly. This being the case, it does not seem fair to me to subject our patient to troublesome treatment which promises so little, when we have at our disposal an operative measure which, if carefully performed, has no more risks than the ordinary plastic operations.

Let us consider then the prominent operative procedures for the cure of retrodisplacements. We have:

1. Alexander's operation, by means of which the round ligaments of the uterus are shortened extraperitoneally.

2. Wylie's and Dudley's operations, in which the round ligaments are shortened intraperitoneally (Wylie scrapes the inner side of the round ligaments so as to make the surfaces raw, folds them external to the uterus, and passes three silk ligatures around each fold. Dudley, on the other hand, folds the ligaments in front of the uterus, and attaches each fold by two silk ligatures to the surface of the uterus).

3. Hysterorrhaphy, or ventral fixation, in which the fundus of the uterus is fastened to the anterior abdominal wall.

4. Vaginal fixation, in which the fundus of the uterus is fastened to the anterior vaginal wall.

In speaking of the Alexander operation, I desire first and foremost to mention the names of Paul F. Mundé and Edebohls, in whose hands the operation has met with such success and to whose painstaking and valuable work the operation has received a great impetus in this country. Nevertheless, with all due respect to these gentlemen and with all due appreciation for their valuable contributions to the literature on this operation, I believe we have a better operative procedure, and one which is more satisfactory in its technique and results. I would like briefly to enumerate some of the objections to the Alexander operation. In the first place the ligaments are not always easy to find, and they are oftentimes very thin and capable of giving but little support when found and shortened; besides which it is easy in such cases to break the ligaments, even under moderate traction. Mundé reports this accident as having several times occurred in his own hands, on one occasion the ligaments breaking close to the uterine attachment. Again, suppuration is a more or less common result after this operation, especially if much tearing or manipulation of the cellular tissues has been required to find and draw out the ligaments; and convalescence is oftentimes protracted on account of this suppuration. Further, in unskilled hands wounding of the femoral artery is possible, and Mundé has recited an instance in which he stopped his assistant as he was in the act of tying off the femoral artery in mistake for the round ligament. Any adhesion of either the uterus or appendages forms a positive contraindication to Alexander's operation, which fact greatly limits its field of usefulness. Then again, in this, as in all operations for the relief of retrodisplacements, any abnormal laxity of the vaginal walls, any defect in the pelvic floor, or any extensive laceration of the cervix which results in a chronically enlarged uterus must at the same time be rectified to secure perfect and permanent results, and these plastic operations can better be combined with other operative procedures than with Alexander's operation. Then, the operation when performed is successful in only a percentage of cases, and has not a lower mortality than ventral or vaginal fixation, which operations give more lasting and better results and are more far-reaching in their applicability. Finally, it may be added that in Alexander's operation there are two chances for subsequent hernia against one in ventral fixation and against none in vaginal fixation. I am aware that Mundé states in his article in the MEDICAL RECORD of July 14, 1894, that he at that time had never had a ventral hernia follow Alexander's operation in his hands; and in a conversation I had the pleasure of having recently with Dr. Cullen, assistant gynæcologist at the Johns Hopkins Hospital, I understood him to say that Kelly had never had a ventral hernia follow hysterorrhaphy, and Kelly has perhaps performed this operation as many or more times than any other single operator. Still the chance of a hernia exists, even though, when the divided tissues are well approximated, it be a small one.

Wylie's and Dudley's operations, while ingenious and while they have the advantage over Alexander's operation in that, it being necessary to open the abdominal cavity to perform them, any existing adhesions may be broken up, have still but little to recommend them. If the abdominal cavity is opened at all, ventral fixation possesses incalculable superiority over these operations.

In ventral fixation we have an operation which undoubtedly effects a permanent cure in cases of retrodisplacement, and, in the hands of Howard Kelly and other of our prominent American operators, has given excellent results. It is doubtful, however, if, so far as results are concerned, it has much advantage over vaginal fixation, and, if we can approximate the same results by vaginal fixation, it presents itself to me as a much more desirable operation. I am surprised that it has not received the notice it deserves at the hands of American surgeons. In none of the recent works on gynæcology which I have seen has it even received mention. Yet it is an operation which in the hands of Prof. August Martin and Dührssen, of Berlin, and other German operators, has given most satisfactory and brilliant results. I am pleased to acknowledge the notice taken of this operation by Clinton Cushing, of San Francisco, in a paper read before

the American Association of Obstetricians and Gynæcologists at Toronto, Canada, September 19, 1894.

While in Berlin last year I had the pleasure and privilege of seeing Martin perform this operation a great many times. The operation pleased me very much, as it seems to fill a long felt want, and the results, so far as I was able to follow them, were very satisfactory, and Professor Martin, after having given the operation a rigid trial for the last three years, expresses himself as well pleased with it, and he relies almost wholly upon it for the relief of retrodisplacements in his patients. While I was with him I saw him do only one ventral fixation, and in that case the abdominal cavity was not opened for that purpose, but, being inside the abdominal cavity and finding the fundus large and backwardly displaced, he fastened it to the anterior abdominal wall when closing his incision. On the other hand, I saw him perform the operation of anterior vaginal fixation probably fifty or sixty times.

In the *Journal of the American Medical Association* for September 2, 1894, Kelly speaks of the inadvisability of performing ventral fixation unless any relaxation of the vaginal outlet which may exist is remedied at or about the same time. This applies of course with equal force to any operation which may be undertaken for the relief of retrodisplacement; and every operator must be struck with the ease with which repair of the relaxed vaginal outlet can be performed in conjunction with the operation of anterior vaginal fixation of the uterus.

When vagino-fixation was first performed, the sutures fastening the uterus to the vaginal wall embraced the fundus too high up, promoting possibility of complications at future pregnancies. As it is now performed by Martin, however, I think it will interfere little if at all with pregnancy, should this condition supervene.

For the benefit of those who are not familiar with it, perhaps it would not be out of place for me to describe accurately Martin's present method of procedure.

The patient being placed in the lithotomy position, and the vagina being opened up by retractors, the centre of the anterior lip of the cervix is grasped by a tenaculum forceps and pulled downward and outward to the vulval opening; another tenaculum forceps grasps the anterior vaginal wall about an inch from the meatus. An instrument devised by Orthmann, Martin's chief assistant, is next used to steady the cervix. (This instrument is a combined sound and volsellum, the two teeth of the volsellum, when the instrument is closed, embracing the sound between them about two or two and a half inches from its tip.) The sound part is inserted into the cervical canal and the teeth of the volsellum part grasp the anterior lip of the cervix about an eighth of an inch to the left of the tenaculum forceps, which already is in the cervical lip; this tenaculum forceps is then moved about an eighth of an inch to the right, so that the centre of the space between the two instruments will be the middle of the anterior cervical lip. Traction now being made on all these instruments (upward traction on the upper tenaculum forceps which grasps the vaginal wall and downward traction on the forceps which have hold of the cervix), the anterior vaginal wall is put on the stretch and a light incision is made through the thin vaginal wall, commencing about half an inch below the upper tenaculum forceps and extending down between the two forceps which are in the cervix, to within about one-fourth of an inch of the end of the cervix. The edge of the vaginal wall being caught with a pair of dissecting forceps, about an inch of the vaginal wall on each side of the incision through its whole length is dissected away from the underlying cellular tissue. Then with a pair of blunt-pointed scissors the cellular tissue lying on the cervix at the lower end of the incision is nicked through. The finger is then inserted into this nick and the cellular tissue is pushed backward from the cervix. After the finger has pushed its way backward along the cervix for about an inch or an inch and a half, a lateral vaginal retractor is inserted between this cellular tissue which has been dissected up from the cervix and the cervix itself, and one of the assistants by gentle traction on this retractor keeps this cellular tissue out of the way, and the finger, continuing its dissection between the retractor and the cervix, keeping all the time in close apposition to the cervix, will soon reach the peritoneum. If the assistant has kept gently pushing the retractor along as the finger has continued its dissection, one can usually see this fold of peritoneum very distinctly, and with a pair of blunt scissors it is nicked through close to the cervix. Orthmann's instrument, which has up to this time steadied the cervix, is now with the tenaculum forceps removed. The retractor is pushed through the cut in the peritoneum into the pelvic cavity, and, upward traction being made on it, the bladder and ureters are held out of the operator's way. The fingers of the left hand are passed into the pelvic cavity behind the uterus and the fundus is lifted upward and forward, any existing adhesions being broken up. The fundus is then grasped by a tenaculum forceps about midway between the internal os and the crest of the fundus. The placing of this tenaculum forceps not only permits the operator to draw the uterus up to his vaginal incision but also marks the place for his upper suture. The retractor which has held the bladder up out of the way is then taken out, and the uterus is drawn forward to the vaginal incision and sutured thereto by three interrupted sutures placed as follows: The first suture is passed from left to right through the vaginal wall on the left side opposite or a little above the point where the uterus is grasped by the tenaculum forceps; the peritoneum is grasped and pulled down by a dissecting forceps, and the suture passes from above downward through this peritoneal flap on the left side, then passes through the substance of the fundus, then up through the flap of peritoneum again on the right side, and out through the right vaginal wall at a point directly opposite to where it went in on the left side. The tenaculum forceps is then removed from the fundus and this suture is tied. A second interrupted suture is put in a little above the internal os, passing through the left vaginal wall, then through the substance of the uterus, and out through the right vaginal wall opposite its point of entrance. This suture is then tied. A third interrupted suture is similarly placed between the external and internal ora and tied, and then whatever gaps remain in the vaginal wall after these three interrupted sutures are placed and tied are closed by a fine continuous suture running from below upward. The ends of the sutures are then cut and a little sterilized gauze is placed in the vagina as a dressing, and the operation is completed. Martin always uses catgut for his suture material in this operation.

The possible danger in this operation is injury to the bladder. Careful attention, however, to the details of the technique, as given above, will prevent this accident. The three points to be kept in mind in order to avoid injuring the bladder are: 1. The incision in the vaginal wall must extend simply through the mucous wall and must not include the cellular tissue lying between the vaginal wall and the bladder. 2. In dissecting away the cellular tissues from the cervix, the finger must always be kept in close apposition to the cervix. 3. After the pelvic cavity has been opened into, the bladder must be lifted upward out of the operator's way by means of a lateral vaginal

retractor. When any doubt exists at any time during the course of the operation as to whether the bladder is in danger of being injured, a male catheter or sound may be carefully inserted into the bladder and its position ascertained. When the operation is completed, whatever urine is in the bladder should be drawn off to see that it comes away clear, and thus assure one's self that the bladder has escaped all injury.

I would like to emphasize the fact that this means of access into the pelvic cavity through the anterior vaginal wall in the manner described above, is a very practical one and useful for other purposes than merely as a means by which retrodisplacement may be treated. Martin goes into the pelvic cavity in this way oftentimes for merely diagnostic purposes. The cervix being pushed back into the posterior cul-de-sac of the vagina, the fundus can be grasped by tenaculum forceps and pulled out through the incision into the vagina and examined. The ovaries and tubes, too, can be grasped with ovarian forceps and pulled forward so as to be examined *in situ*, and should they be found purulent can easily be ligated off and removed. Small ovarian cysts can also be emptied and the cyst sac closed up by sutures or removed. Submucous or intramural fibroids of the uterus, of moderate size, can also be easily removed by splitting the fundus down to the fibrous mass and shelling out the tumor with the fingers, and then carefully closing up by sutures the incision that has been made in the uterus. I have seen Martin remove good-sized fibroids in this way. I have also seen that distinguished operator go into the pelvic cavity in the same manner and perform plastic operations on the Fallopian tubes for occlusion of the same which gave rise to sterility, and in one case that I know of, and probably in others that I don't know of, pregnancy followed the operation. I merely mention these examples as illustrative of the many operations that can be performed in the pelvis by gaining access thereto through the anterior vaginal wall, thereby saving the patient the greater shock which is attendant upon a laparotomy.

A BRIEF STUDY OF CHLOROFORM ANÆSTHESIA IN RELATION TO SEASONS AND CARBON DIOXIDE.

By THOMAS R. EVANS, M.D.,

Charleston, W. Va.

Several years ago I wrote a communication to the Medical Record in which I suggested that the season of the year might have an unconsidered influence in the causation of death from chloroform anæsthesia. Since that time I think that this view has been confirmed. The Medical Record publishes a number of such cases from England in a late issue.

The latter portion of winter and the spring months seem to furnish the most cases of death. Then the air is heavy with moisture, while the cold chloroform is less easily vaporized and exhaled; hence the greater liability to tissue saturation unless great care is used. The chloroform may be condensed in the lungs like dew. At all times allowance must be made for the specific gravity of chloroform, and during spring for the largest amount of carbon dioxide exhaled, or there is danger of double anæsthesia. Warming the chloroform at such times should more generally be resorted to.

The hypodermic of morphine is a doubtful expedient, but the dietetic management and the time of day for operating are important. An empty stomach, not altogether for mechanical reasons, and the early morning hours, are the conditions of election. A drink of whiskey and water half an hour before the operation is a salutary measure—whiskey at once and for some time lessening the exhalation of carbon dioxide, while water increases the production of oxygen.

The muscularity of the subject increases the production of carbon dioxide. Hence the comparative ease and safety with which persons in the opposite condition are chloroformed.

Women in labor, excreting some of their hitherto superabundance of carbon in the lochia, are proverbially safe against chloroform casualties, due allowance being made for other favoring conditions. Carbon dioxide is incompatible with the early stage of chloroforming.

The administration of milk toddy before giving chloroform is contraindicated, as milk generates carbon dioxide.

Physiological refinements should not be tabooed in the consideration of so important a subject.

Clinical Department.

THE GAUZE DRAIN IN AURAL INFLAMMATION.

By GEORGE B. McAULIFFE, M.D.,

Assistant Surgeon, New York Eye and Ear Infirmary.

Influenced by the strong advocacy of gauze drainage by Gradenigo, Burnett, and other aurists, I have used this adjuvant in the antiseptic treatment of the exudative forms of middle-ear catarrh and in the acute types after paracentesis. The numbers treated in the New York Eye and Ear Infirmary, where, as in all clinics, a strict adherence to surgical asepsis is difficult to gain, and privately, where this accomplishment is more practicable, have fully shown the great advantages gained by the proper use of the gauze and the disadvantages which follow its use in unsuitable cases.

The advantages of the gauze are that it serves to keep sterile the external canal, and thereby cuts off one of the entrances of the staphylococcus—the germ admitted to be the cause of the chronicity of otorrhœa: that it drains and asepticizes the exudation from the tympanum.

The disadvantages of the gauze are that it is generally irritating to the canal, and thereby interferes with the comfort of the patient and with the efficiency of the drainage by setting up a dermatitis which stenoses the canal; that the drainage of exudation varies in the different cases, so that no fixed time can be allowed for the retention of each dressing. This latter fact accounts for the failure of the gauze to do good in certain cases in which the drain is retained too long, and not only loses its power of absorption, but, in addition, acts as an impediment to drainage.

Iodoform gauze is generally used. I have no experience with the chinolin-naphthalated gauze of Haug, which is supposed to obviate the disadvantages of iodoform gauze. The second disadvantage is sometimes removed by allowing the patient, after full instructions in the necessity of cleanliness in the dressings, to renew the gauze when he thinks it is moist. This permission, however, introduces the uncertainty of asepsis in the treatment, yet in the present state of otology, while ambulatory treatment embraces almost all pathological conditions of the ear, it is the best plan to pursue.

In acute middle-ear catarrh demanding paracentesis, the canal and drum should be thoroughly cleansed of cerumen (which in normal ears has often been found to be the resting-place of the staphylococcus), and carefully bathed with an antiseptic fluid; the knife should be dipped in alcohol and the incision made in

the drum, a narrow strip of gauze carried up the canal almost its length, and a loose dressing applied in the concha, covered by a piece of American skin plaster, which is transparent, thereby allowing inspection of the gauze without removal. If there is not much secretion the dressing should be renewed perhaps once or twice a day, without any other interference. In a few days the site of the paracentesis will be indicated by a simple blood clot. The drum will be without evidence of inflammation.

The nasopharynx demands treatment also, since it is the fountain of the infection. Nitrate of silver is still the best remedy for the tubal orifice.

When acute cases do not take this benign course, the reason is generally found in a failure to follow out all the steps laid down.

Cases of acute middle-ear catarrh which have gone on to the stage of exudation, will respond or not to this plan of treatment, according to the character and amount of the secretion.

There are several varieties of this type. Some have a thick, tenacious discharge; others have a thin, profuse exudation; some are very septic; others benign. In the treatment of these varieties the use of the drain will be determined by its adaptability for drainage. When the discharge is thick and tenacious, the gauze does not help but prevents drainage. Here it is better to use antiseptic douches frequently, and a light dressing of gauze in the concha. When the secretion is profuse, it is well not to use the drain (unless you have the case under constant supervision), because the secretion is formed too rapidly to be carried off by a one-fourth-inch strip without renewals more frequent than the average patient would make. The dressing in the concha should be used. The patient can change this as frequently as necessary.

Two cases with profuse discharges developed mastoiditis rapidly while under the drain treatment—one in two days. Here it was evident that the gauze was not renewed often enough, and, becoming clogged, helped to retard drainage.

In septic exudations antiseptic douches with the concha dressing give the best results.

Old cases of chronic purulent otitis media, in the absence of serious local obstacles to healing, will dry up very rapidly under douches and the introduction of gauze.

TREATMENT OF MELANCHOLIA WITH OPIUM.

By LILLIAN J. NUCKOLLS, M.D.,

ASSISTANT PHYSICIAN, ILLINOIS CENTRAL HOSPITAL FOR THE INSANE, JACKSONVILLE, ILL.

Much has been said concerning the use of opium in the treatment of melancholia. Some condemn the drug, while others are loud in its praise. Dr. Clouston, the eminent Edinburgh physician, says: "Opium in the treatment of melancholia I utterly disbelieve in;" while Dr. Spitzka, who is regarded as a neurologist of great authority, says: "Opium is the most generally useful of all drugs in insanity. It has a direct influence on the mind, antithetical to the painful emotional state of melancholia, and to the persecutory delusions of monomania." I have had, during my service at the Illinois Central Hospital for the Insane, a large number of melancholics for treatment, as the majority of our patients are subjects of melancholia or of mania. With the experience that I have had in the treatment of these diseases, I feel confident that opium is the drug, par excellence, in the treatment of motor or excited melancholia. I have had the best results with deodorized tincture of opium, giving it in doses of from fifteen to twenty minims, gradually increasing until the maximum dose of forty or sixty minims is given three or four times a day. Occasionally there are cases in which it is necessary to repeat the drug oftener, say fifteen minims every two hours.

As a rule these patients are debilitated, and I usually put them upon tincture of nux vomica. Wholesome food, fresh air, and exercise are necessary. While it is a fact that opium is constipating, I have had no serious effects from the use of it in my cases. Insane women, like the most of the sex, are habitually constipated. I append notes of three cases of excited melancholia, in which I gave the deodorized tincture of opium with good results.

Case I.—Mrs. L. C——, aged twenty-eight, was admitted to this hospital March 6, 1896. Duration of attack at the time of admission, six months. A few days previous to coming here, she attempted suicide by saturating her dress with kerosene and igniting it, the result being a large burn on her chest and neck. The patient on entering was very melancholy, being constantly tortured with the idea that she was to die in some horrible way, either by being burned, hanged, or smothered. She cried and walked the floor, wringing her hands, declaring that she was unworthy to live, yet feared to die. Physically she was not in good health. She was put upon the deodorized tincture of opium in doses of twenty minims each, four times a day, gradually increasing the dose until forty minims were taken at a dose. In a few days she became more quiet, slept better, and her appetite improved. Opium was decreased slowly, until by the middle of April it had been entirely withdrawn. The patient was cheerful. June 27, 1896, she was discharged from the hospital recovered. She gained twelve pounds in weight while here. No other drugs were given, except a sleeping-remedy for the first ten days.

Case II.—Mrs. J. T——, aged thirty-three, admitted March 3, 1896. Insane one month. She was very much disturbed, imagined her children were being destroyed, cried and worried continually, would stand and weep for hours if allowed to do so. She was put on deodorized tincture of opium in twenty-minim doses, gradually increased. She became more quiet; after a month the opium was discontinued. The patient was discharged June 1, 1896, apparently recovered.

Case III.—Mrs. B——, aged thirty-eight, admitted July 20, 1896. At the time of admission the patient weighed seventy-six pounds. She was very weak and emaciated, and had been insane nine months before she was committed to this institution. She attempted to drown herself two days before entering. She insisted that she had no stomach; that all the viscera, in fact, were absent; thought herself to be the devil, and believed she would defile all with whom she came in contact. It was necessary to feed her by means of the stomach tube. I began with the opium and increased to doses of sixty minims t.i.d. The medicine was discontinued at the end of ten weeks. The patient was sent home December 14, 1896, recovered, having gained fifty-four pounds.

While I do not say that opium is a panacea for all cases of melancholia, I do believe that in the agitated form it is the best remedy we have.

In Certain Gynecological Troubles Günsburg has found ichthyol, administered according to the following formula, of the greatest service in chronic affections of the genitalia, with reflex disturbances of the digestive system: Ichthyol, four grams; licorice extract and powder, q.s. Mix and divide into forty pills; take two pills three times a day. He has them keratinized. Dyspepsia, constipation, abdominal pains, and menorrhagia are rapidly improved or cured.—*La Semaine Médicale.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 19, 1897.

THE SERUM DIAGNOSIS OF TYPHOID FEVER.

THE diagnosis of typical cases of typhoid fever is attended with no real difficulty, but the clinician not rarely encounters cases in which many of the usual symptoms are wanting, and even the temperature curve may be misleading. Besides, it is not an uncommon experience to find that cases of suspected typhoid fever run anomalous courses, so that the real nature of the disease in the individual attack may remain surrounded with doubt. Of the importance and the desirability of some reliable diagnostic test there will be no difference of opinion; the utility of such a resource is too obvious to require elaboration. Whether or not this desideratum has been found in the serum test—the clumping and loss of motility of typhoid bacilli in culture media on the addition of the blood or the blood serum of persons passing through or convalescing from an attack of typhoid fever—is yet to be determined. The evidence thus far accumulated is encouraging, but it cannot yet be said with positiveness that the reaction can be obtained in every case of typhoid fever and fails to appear under any other conditions. The result is somewhat influenced by the period with relation to the attack at which the blood serum is obtained, the degree of dilution of the culture medium, the age and activity of the bacilli, and other details of technique. The opinions expressed at the recent congress of American physicians and surgeons and at the semicentennial meeting of the American Medical Association are in accord with those already placed on record, both in this country and abroad, *i.e.*, that the test, although it cannot be viewed as infallible, is an important aid to diagnosis, especially in doubtful cases, a positive reaction obviously being of more significance than a negative one.

In a communication upon this subject in the *Centralblatt für innere Medicin*, No. 20, 1897, Hofmann points out that the results obtained by various investigators in the practice of serum diagnosis have been so uniformly positive as to arouse suspicion that those of the opposite kind may be due not to the procedure itself, but to some defect in its application. Upon the instigation of Professor Eichhorst, of the medical clinic of the University of Zurich, Hofmann examined the blood with regard to its reaction with cultures of typhoid bacilli in thirty-one cases of typhoid fever, four of febrile intestinal catarrh, three of miliary tuberculosis, one of influenza, twenty-five of partly febrile and partly afebrile disease of varied kind, and two of tuberculous meningitis, and found the serum reaction present in all of the cases of typhoid fever and in none of the others. The blood was obtained in a variety of ways—by puncture with a hollow needle of a vein of a constricted member, by aspiration with a syringe, by incision of a vein with a sharp-pointed scalpel. The last method proved the simplest and permitted best of maintaining conditions of sterility. As, however, microscopic examination proved to be the most trustworthy, a few drops of blood were obtained by puncture of the cleaned finger tip with a special needle and centrifugated. One part of the serum was added to ten parts of bouillon culture of typhoid bacilli, and control observations were made with unmixed cultures. At once or within a few minutes the bacilli began to display loss of motility, although often a quarter of an hour elapsed before any change was noticed. Exceptionally all movement was lost within three hours, but usually this result was not reached before five or six hours. The diminution in motility began at the periphery and advanced toward the centre. The speediness with which the reaction resulted appeared to be related to the vitality of the organism, rather than to the concentration of the culture. So-called immediate diagnoses are to be viewed with doubt, and the results of macroscopic observation are equally not to be relied upon. After apparent agglutination following the use of concentrated cultures, microscopic examination showed active motility of the micro-organisms. In five cases of typhoid fever, in addition to the reaction obtained with the blood serum, a similar result was secured with the serum from a blister induced artificially. A corresponding though somewhat less pronounced reaction was obtained with the fluid of a pleural effusion, in which culture failed to disclose the presence of typhoid bacilli. A study of the blood of forty-two cases in which typhoid fever had occurred previously, at periods varying from one month to thirty-three years, showed the reaction to be present in only six. In the most remote of the attacks, which occurred twelve years before the application of the test, the illness had been a severe one. In the remainder no reaction at all was obtained. These observations would seem to show the transient character of the conditions on which the reaction depends.

A further practical application of the serum reaction has recently been suggested by Johnston,[1] who proposes to test by this means the presence of typhoid bacilli in suspected water. He found that after inoculating water with cultures of typhoid bacilli, then inoculating peptone bouillon, and injecting this, sterilized, into the peritoneal cavity of a rabbit, a typical serum reaction with a typhoid culture could be obtained with the blood serum of this animal. From what has already been developed we may reasonably hope that the scope and the field of usefulness of serum diagnosis will continue to expand, and that we have in the

[1] New York Medical Journal, June 5, 1897, p. 764.

as yet undetermined principles upon which the reaction depends a potent resource not only in diagnosis, but also in prophylaxis and perhaps also in treatment.

THE PRINCE OF WALES' HOSPITAL FUND AND THE ANTIVIVISECTIONISTS.

Notwithstanding the issue of the hospital stamps, the advertising, and the devices of all kinds resorted to in order to attract the attention and extract the money from the pockets of philanthropists, the Prince of Wales' hospital fund languishes. The sum collected as yet does not reach $500,000. It was estimated at first that probably $5,000,000 would be gathered this year, and it was predicted by the enthusiastic that enough would be brought into the coffers of the hospitals to produce an annual income of more than $500,000, and thus keep them forever free from debt. That such a result will not be attained is now certain.

There is present in London an uneasy feeling that something is radically wrong with the management of these charitable institutions, and until the necessary reforms are instituted and this feeling is allayed, the British public will continue to keep its pockets closed. The antivivisectionists have lately been bringing grave charges against several of the hospitals in London, which fortunately they have not in any way been able to substantiate. The Hon. Hartley Coleridge, acting as the mouthpiece of the Antivivisection Society, published letters stating as a positive fact that in many of the London hospitals vivisection was carried on to a large extent. Mr. Burdett took up the cudgels on behalf of the hospitals, and an acrimonious correspondence ensued, in which Mr. Burdett was clearly the victor. The Hon. Coleridge could prove none of his contentions, and only exhibited his skill as a letter writer by his ability to evade the points at issue. It was distinctly proved that the harrowing pictures of vivisection as portrayed by the antivivisectionists existed only in their imaginations. Still this episode has tended further to militate against the success of the hospital fund. So much was this felt to be the case that the Prince of Wales, who presided a short time ago at the opening of the new buildings at Guy's Hospital, tendered an explanation. This speech is referred to in a prominent English weekly as follows:

"The speech of the Prince of Wales will relieve the minds of many subscribers to the 'Jubilee Hospital Fund.' Quite apart from the extremely difficult question as to the limits within which vivisection is permissible at all, the suggestion that money subscribed for the relief of human suffering might go to the support of laboratories where vivisection is practised came as an unpleasant shock. The suggestion has been put about broadcast by the Antivivisection Society, and has been made more sinister by the publication of misleading statistics as to experiments performed without anæsthetics. The Prince of Wales has been at the trouble to inquire into the truth of these statements, and has made it plain that the experiments conducted without anæsthetics consist of nothing but inoculations, which are instantaneous and practically painless pin pricks. He might have added that the medical schools are separate from the hospitals and under the control of different governing bodies, and moreover that the increasing specialism of modern work is separating laboratory teaching from work in the wards. At all the great London hospitals the teachers of physiology are specialists who have nothing to do with the treatment of patients."

LEGITIMATE WORK FOR THE HEALTH DEPARTMENT.

In view of the many things which the health department might well do, but leaves undone for want of funds or other reasons, it is more than a pity that it continues a mandate which an intelligent and conscientious profession feels it a duty not to heed. If the board is really interested in the public health rather than in making history for its members, for one thing it may well turn its attention to the ventilation and cleanliness of places of public assemblage. Probably no night in the year passes without in this city a dozen to a hundred halls, theatres, or other places of public meeting being filled with throngs of people who pant and swelter in a stifling air, and pray that it may dawn upon the managers or attendants to open a ventilator or a window. But their prayer is in vain, for what do managers know of the necessity for air or care for the health of the public? Besides, in cold weather does not a close room with many people save fuel? In warm weather, in the absence of compulsory ventilation of public buildings, what is everybody's concern is always left undone. Who is there who has not found himself placed in some cul-de-sac of a theatre where air had neither entrance nor exit, and where the exhalations of the multitude lingered about his olfactories with the persistence of time, and the flickering heart seemed to welcome the pale mask of eternity? It was thus years ago, and it is no better to-day.

But while this is going on and constitutions are being undermined, crowds being compelled because of criminal carelessness to inhale over and over an atmosphere surcharged with carbonic-acid gas and the effluvia of their own bodies, the board of health hopes to check tuberculosis by issuing edicts prohibiting expectoration and writing down as suspects one-tenth or more of the population. For equal result on the public health and comfort, the board could probably put in force no regulation with so little outlay of money and labor as one compelling the best use of present ventilating facilities in halls and theatres, and prohibiting the erection in the future of any building for public assemblage without ample facilities for ventilation, even of every gallery and box, and that, too, without creating dangerous air currents. One or more inspectors should make visits often enough to insure observance of the regulations. These should be printed and posted throughout the buildings, with information where to enter complaint. The condition of the atmosphere should be indicated as far as possible by instruments of precision, such as the thermometer.

When the board of health has carried out this much

needed and perfectly feasible reform, there are others that will suggest themselves, but until then the opinion is likely to prevail that it is wasting its resources if not exceeding its authority in trying to enforce compulsory reporting of cases of tuberculosis.

A NEW DISPENSARY ABUSE.

A REPORT comes to us as we are about to go to press (as the *County Weekly* puts it), to the effect that a physician has been dismissed from one of the most fashionable dispensaries in a neighboring city (of course it could not occur in New York) for abstracting a fifty-dollar banknote from the purse of a patient.

The pocketbook was left upon the dispensary desk, it is said, while the lady entered an adjoining room to prepare for examination. The plea made to the governing board by the physician was that he had been overworked, having treated over four hundred patients at the dispensary during the three days preceding the temptation which caused his fall, and that during this time he had been unable to procure but one full meal. Hunger and the means at hand to appease it may have proven too strong a combination for his overwrought nerves, but this naturally did not weigh with the board. The *clientèle* of the institution must be made to feel that while a patron is undergoing treatment his valuables are safe. The argument was used by one of the governors that, if the patients' money is to be taken from them, they might as well go to a physician's office and be done with it.

The crime of robbing a dispensary patient cannot be too severely punished, since such acts would soon deter many persons of wealth from patronizing these institutions. It is therefore most fitting that the culprit in the present instance will be forced to take his chances for the future in private practice.

There is something to be said upon the other side. It seems unwise for applicants to carry with them and display at the dispensary large sums of money, diamonds, and the like. It would surely seem to be in the nature of contributory negligence if in the future applicants for free treatment put temptation in the way of doctors, who after all are only human and often hungry.

The Late Dr. Sumner A. Mason.—The following resolutions were adopted by the West End Medical Society at its regular meeting, June 5, 1897:

"The members of the West End Medical Society have learned with regret of the death of their colleague and fellow-member, Dr. Sumner A. Mason.

"Those who were well acquainted with Dr. Mason knew him to be most conscientious and unremitting in his efforts as a physician. As a citizen he contended for the best interests of all, and was most honorable in all his relations.

"*Be it Resolved*, That this expression of our esteem and of our loss sustained be entered upon the minutes, forwarded to the family, and published in the medical journals of this city.

[Signed] "F. J. BOWLES, M.D.,
"E. J. WARE, M.D., *Committee.*"

News of the Week.

The International Medical Congress. — The following are the names of those who have been invited to deliver orations at the general sessions of the Moscow Congress. The titles of all the orations have not yet been announced. Lauder Brunton, of London, on the "Relationship between Physiology, Pharmacology, Pathology, and Clinical Medicine;" Nicholas Senn, of Chicago, on the "Diagnosis and Surgical Treatment of Acute Forms of Peritonitis;" Krafft-Ebing, of Vienna, on the "Etiology of Progressive Paralysis;" Danilevski, of Khartov, on "The Action of Electric Rays on the Animal Organism at a Distance;" Lombroso, of Turin, on "New Horizons in Psychiatry;" Leyden, of Berlin, on the "Present Modes of Treating Consumptives and their State Control;" Herzen, of Lausanne, on the "Significance of Physiological Psychology for Medical Education;" Robert, of Barcelona, and Lukianov, of St. Petersburg, have not yet announced the titles of their addresses. Virchow, of Berlin, and Roux, of Paris, have been invited to deliver orations, but no word had been received from them by the Moscow committee at the time the above announcement was made.

Information of service to those intending to attend the congress is very difficult to obtain. Dr. A. Jacobi, chairman of the American National Committee, which was established at the request and under the authority of the general committee of the Twelfth International Medical Congress, writes to inform the numerous gentlemen who are constantly applying for information concerning certificates, trip, fares, hotels, etc., etc., that he has none to give, not having heard from the general committee these two months.

Yellow Fever from the Isthmus.—Cases of yellow fever are being brought from Panama to both the Atlantic and the Pacific ports of the country. Nearly every ship arriving from Colon now has one or more deaths among the passengers, and the *City of Para* arrived in San Francisco on June 13th with one case of yellow fever aboard, two deaths having occurred during the voyage up from the isthmus. It is stated that the disease is epidemic at Panama on the Pacific side, but that no cases have yet occurred at Colon on the Atlantic side, all the passengers to this port who have had the disease having contracted it at Panama. No apprehension is felt of the entrance of yellow fever into New York.

The Accommodations at the Moscow Congress promise to be somewhat limited. The reception committee has been able to find but seven hundred beds upon which they can count in the hotels, and sixteen hundred in furnished apartments scattered throughout the city. In addition about fifty Moscow physicians have announced their readiness to entertain each one or more guests during the congress week. A circular containing information as to rooms and charges will be handed each member upon his arrival in Moscow.

The Eyesight of the Queen.—A cable despatch to *The Sun* asserts that Queen Victoria has recently

become almost totally blind and will be unable to see any of the vast throng that will gather to do her honor next Tuesday. It is not known what the cause of the Queen's affliction is, but it is probably not of very recent origin, since her eyes were so bad some time ago that she sent to Germany for an oculist to examine them.

College Consolidation Falls Through.—It is stated that Bellevue College and the University Medical School are not to unite on the plan announced some months ago, but that the former will erect a new building at once to replace the one burned down.

Calcutta was seriously damaged by a severe earthquake on June 12th. Many houses were levelled and there is scarcely one which was not more or less damaged. It is believed that the sewers have been broken, and the gravest fears are entertained of the sanitary condition of the city, which was none of the best even before this calamity occurred.

Obituary Notes.—Dr. Frederick J. McNulty died at his home in Boston, on June 14th, at the age of sixty-two years. He was a native of Richmond, Va., and was graduated from the Georgetown College of Medicine in 1860. He then entered the medical service of the United States navy, but resigned almost immediately and entered the Confederate army. Afterward he was surgeon on the *Shenandoah*, which continued to fly the Confederate flag several months after all the land forces had surrendered. After the war he enlisted in the Chilian navy. In 1869 he accepted a commission in the Cuban patriot army, but was prevented by the United States authorities from leaving the country. He made several attempts to reach Cuba, but he did not succeed. Afterward he settled in Worcester, Mass., and in 1879 he moved to Boston, where, in 1885, he became the superintendent of the City Lunatic Asylum at Austin Farm. He was a member of the Massachusetts Medical Society.—Dr. Samuel S. Troth died at Philadelphia on June 11th, at the age of seventy-two years. He was graduated from Jefferson Medical College in 1849.—Dr. George K. Edwards, of Newcastle, Del., died at Princeton, N. J., on June 14th. He was suffering from consumption, but had returned to Princeton for the commencement exercises at the university.—Dr. J. M. Robert Amthor, one of the earliest homœopathic physicians to practise in Baltimore, died in that city on May 19th.

The International Leprosy Congress.—Among the subjects announced for discussion at the leprosy conference, which is to open in Berlin on October 11th, are the following: "Pathological Anatomy," to be opened by Virchow; "Bacteriology," by Neisser; "Infectiousness," by Koch; "Etiology," by Besnier; "Diet in Relation to Leprosy," by Hutchinson. From the numerous favorable responses already received by the committee, it is believed that the attendance at the conference will be very large and representative of all countries and shades of opinion.

Harlem Medical Association.—The following officers were elected at the ninth regular meeting of this association, held on June 2, 1897: *President*, Dr. Philip Arthur Malleson; *Vice-President*, Dr. Henry Walton Mooney; *Secretary*, Dr. Joseph Edward Lumbard; *Treasurer*, Dr. Charles A. Clinton; *Trustees*, Dr. H. J. Wolf, Dr. S. E. Gibbs, Dr. David Franklin.

The Osteopathy Bill passed by the Illinois legislature, the object of which was to legalize this peculiar form of irregular practice, has been vetoed by Governor Tanner of that State.

The Bellevue Graduates' Association of Trained Nurses has organized a course of lectures and practical demonstrations for the benefit of its members. The first of the series was given recently by Dr. G. M. Swift on typhoid-fever nursing. Following the lecture a demonstration of the bath treatment was given by Miss M. E. Hirschliffe, who also gave an illustration of the dry-pack treatment, with ablution for tonic effect in nervous diseases.

The Board of Medical Examiners for the State of Maryland has completed the examination of the ninety-seven candidates who presented themselves. Out of this number fifty failed. The law requires a general average of 75 per cent. on the scale of 100. and an applicant who falls below 33⅓ in any one of the twelve subjects is disqualified.

Pathological Society of Philadelphia.—A stated meeting of the Pathological Society of Philadelphia was held on June 10th, the president, Dr. J. H. Musser, in the chair. Dr. W. M. L. Coplin exhibited a specimen of cirrhosis of the liver and also sections of the morbid process from a human being and from a pig. Dr. Frank White exhibited a kidney with a double ureter, each portion of which arose from a separate pelvis, but united just before entering the bladder. Dr. J. Dutton Steele exhibited a tuberculous kidney and also a tuberculous testicle. Dr. Joseph Sailer discussed briefly the degenerative changes that take place in nerve cells. Dr. A. A. Eshner reported a case of multiple sarcomata in a child two and a quarter years old, with the primary lesion probably in the right kidney. Dr. D. Riesman exhibited specimens of valvulitis and cardiac thrombosis, splenic infarction, and uterine fibroids from a case of paretic dementia in which there was also cerebral embolism with softening. Dr. J. M. Baldy exhibited soft myomata of the pelvis, malignant adenoma of the fundus of the uterus, and membranes from a case of pelvic hæmatoma of the pelvis. Dr. Wilmer Krusen exhibited a large cystic tumor of the vermiform appendix.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C. Changes in the medical corps of the United States navy for the week ending June 12, 1897. June 8th.—Surgeon M. H. Simons ordered to the *Iowa*, June 16th. June 10th.—Washington B. Grove commissioned assistant surgeon from June 3d. Passed Assistant Surgeon R. P. Crandall detached from Naval Hospital, Norfolk, June 14th, and ordered to the *Iowa*, June 16th. Medical Inspector W. G. Farwell detached from special duty, marine rendezvous, Philadelphia, continuing other special duty. Surgeon D. O. Lewis after completion of examining board, Naval Academy, ordered to the marine rendezvous, Philadelphia.

The Late Dr. J. Lewis Smith.—At a special meeting of the medical board of the New York Foundling Hospital, held June 11, 1897, the following resolution was adopted:

"J. Lewis Smith, M.D., who died June 9, 1897, was for twenty-five years visiting physician to this institution.

"*Whereas*, The medical board has lost by death its oldest member, Dr. J. Lewis Smith, be it resolved that it record this tribute to his memory.

"His fame and his faithfulness have ever been devoted to the interests of this institution.

"*Resolved*, That this board attend the funeral in a body; that a copy of these resolutions be spread upon the minutes and forwarded to the current medical periodicals, copies of the same being sent to the family of the deceased.

[Signed] "JOHN J. REID, *President*.
"W. P. NORTHRUP, M.D., *Secretary*.

A New Hospital Building in Passaic.—The cornerstone of St. Mary's Hospital was laid on a recent Sunday afternoon by Bishop Wigger. Addresses were made by Bishop McQuade, of Rochester, and Governor Griggs. The building is to be erected on the corner of Aycrigg and Pennington Avenues.

Dr. Haffkine will in future be paid a salary of 2,000 rupees (about $1,000 silver) a month by the Indian government, for his work in searching for remedies for the endemic diseases of India.

Doctorless Regions.—There are said to be, out of 36,000 communes in France, 29,000 without any medical practitioner.

Obituary.

J. LEWIS SMITH, A.M., M.D.,

NEW YORK.

THE announcement of the death of this eminent physician came as a shock to the profession of this city. Although he was in his seventieth year and had nearly reached the limit of life fixed by the Psalmist, yet his activity in his daily duties and his devotion to the interests of medical societies gave an impression of better health and greater physical endurance than actually existed. He had not had good health for several years and at times was quite incapacitated for the fatiguing duties of general practice, but he would never yield to the advice of his medical friends and take a prolonged vacation. Though a great lover of nature and rural life, and fond of the pursuit of the natural sciences, no condition or circumstance could long detain him from the daily round of professional work in the city. His health was still further impaired a few months since in a runaway accident, in which he received a considerable nervous shock. He had scarcely recovered from its effects when he was thrown from a cable car, and so much lameness was the result that he was confined to his room. His digestion now became very much disturbed, followed by loss of strength and enfeeblement of the heart. The end came quite suddenly on the morning of the 9th instant after a comfortable sleep, in a paroxysm of dyspnœa with cardiac syncope.

Dr. Smith was a native of Onondaga County, N. Y., where he was born on October 15, 1827. His father, Hon. Lewis Smith, a prominent citizen of that county, was descended from John Smith, one of the founders of the New Haven colony. Dr. Smith's grandfather, Job Smith, was an officer of the fifth regiment, Connecticut line, in the war of the Revolution. On the side of his mother, Chloe Benson, he came of the Massachusetts Puritan stock. He received his preparatory education at the public schools and the Cortland Academy, Homer, N. Y., having as classmates Prof. John Bascom, of Williams College; Judge Woolworth, of Omaha; Rev. T. T. Munger, of New Haven. He entered the third term of the freshman class of Yale College in 1845, of which President Timothy Dwight was a member, and graduated in 1849, having won several prizes. He began the study of medicine with Dr. Caleb Green, of Homer, N. Y., professor of materia medica in Geneva Medical College. In 1851 he became a pupil of Prof. Austin Flint, Sr., and Prof. Frank H. Hamilton, both of whom were at that time professors in the Buffalo Medical College. He attended a course of lectures in that school and served one year as interne of the Buffalo Hospital of the Sisters of Charity. In 1853 he graduated from the College of Physicians and Surgeons of New York and immediately located in practice in this city. He had already a predilection for the study of the diseases of children, and formed his plans to devote his life to that department of medicine as a specialty. He improved every available opportunity to study the pathology of infantile diseases and for this purpose early sought and obtained the appointment of curator to the Nursery and Child's Hospital in Lexington Avenue. Here he made some of his most important original investigations. In 1858 he became connected with the Northwestern Dispensary and established its department of diseases of children, which he conducted with great success for several years. In 1868 he was appointed visiting physician to the New York Infant Asylum and soon after to the Foundling Asylum, with both of which institutions he remained connected during the remainder of his life. These institutions, which have comprised for many years a total population of upward of twenty-five hundred infants and children, afforded an incomparable field for the study of his specialty. And it was fully improved by him in every particular. For a quarter of a century he wrought in these fields with unremitting toil, and gave to the world the results of his investigations in the vast number of papers which he contributed to the current medical literature of the period. It was in these institutions that he tested every new "food for infants" and every new remedy for the diseases of children which was brought to his attention. From the large experience here gained he deduced those practical rules of feeding children which form one of the most useful features of his treatise. He was a very close observer, taking ample notes with his own hand, and weighing with judicial accuracy every detail in each case. He was naturally and proverbially slow in reaching conclusions, but when his judgment was finally formed there was no mental wavering or doubt; hence he was very conservative in his views, accepting no new opinion or theory without the most careful personal investigation and test of its merits.

Dr. Smith's career as a teacher began with his appointment as "clinical professor of diseases of children" in Bellevue Hospital Medical College, a position which he held for upward of a score of years. His clinics were always amply supplied with illustrative cases drawn from the outdoor department of the hospital. His method of teaching was purely clinical, each case serving as a text for a complete discussion of the main features of the disease to which it belonged. His manner was quiet and undemonstrative, but very emphatic in regard to the special features which each patient illustrated. Many of

these clinical lectures were published and attracted wide attention.

Although Dr. Smith cultivated the diseases of children as his specialty, he held the position of visiting physician to Charity Hospital for many years. In referring to this position and to the fact that he had a large general practice, he once remarked to a medical friend: "Any specialist in my opinion is a better specialist for being a good general practitioner."

Dr. Smith's first contribution to medical literature was made in the year 1854; it was an elaborate paper entitled "A Review of Epidemic Small-Pox as it Prevailed in New York at Different Periods during the Last Fifty Years," *New York Journal of Medicine*, July, 1854. The object of this paper was to illustrate the value of vaccination in saving infantile life. The same journal published the following papers: in September, 1855, and January, March, and May, 1856, an elaborate statistical paper on "Hydrophobia;" in January, 1857, a paper on "Remittent Fever in Children;" in March, 1857, a paper on "Infantile Pneumonia;" in July, 1858, a paper on "Post-mortem Appearances in Eleven Cases of Cholera Infantum."

During these earlier years of his professional life Dr. Smith seems to have been the only physician in this city who made the diseases of children a specialty; if indeed we judge by the medical literature of that period, he was the pioneer in this field, as he was the only constant contributor of papers on this subject to the current medical journals. From 1858 till his death, his more important papers contributed to the current medical periodicals aggregated upward of one hundred in number. He also made large additions during that period to the following works, viz.: "Supplement to Ziemssen's Cyclopædia of the Practice of Medicine," Ashhurst's "International Encyclopædia of Surgery," Starr's "Diseases of Children," Keating's "Cyclopædia of Children's Diseases," "Sajous' Annual," Pepper's "System of the Practice of Medicine," "Reference Handbook of the Medical Sciences," "Babyhood," etc.

Dr. Smith's reputation as an authority on the diseases of children gradually increased with the successive publication of papers as the years went on, until 1869, when the Lea Brothers, of Philadelphia, made flattering proposals to him to publish a complete treatise on the diseases of children. At that time but two original works on this subject had been published in this country, namely, that of Professor Dewes, of Philadelphia, and that of Dr. James Stewart, of New York. Both of these works had long been out of print. Dr. Smith at first positively declined the offer, alleging his unfitness for such a task; however, his medical friends urged him with such earnestness that he finally consented to undertake it. The first edition appeared in January, 1869, and was of very modest pretention, consisting of six hundred pages. It was received with very great favor. In the preface he states with characteristic modesty: "While the author has respected the opinions of previous writers, and has adopted them so far as they seem to be correct, he has depended much more for the material of his treatise on clinical observations and the inspection of the cadaver." A new edition was soon called for, and from that period to the present time new editions have been issued at intervals of two or three years, until the number reached eight in 1896. Permission has been asked to have it translated into German and other languages, but the only translation made was into Spanish. That this work should have been kept during his lifetime, by his own almost unaided efforts, so thoroughly abreast of the times as to maintain its position as the leading text-book, though it had numerous and formidable competitors, proves the large resources of its author and his great ability as a teacher. At the recent meeting of the American Pædiatric Society at Washington, the president, speaking of the evolution of pædiatric literature in the United States, said of Dr. Smith's treatise on the "Diseases of Children:" "It is a work on the 'Diseases of Children' that has immortalized his name, and his heart must throb with pride upon realizing that he has been able after twenty-seven years of active professional life to issue the eighth edition." On the day before his death he read these lines and, with a characteristic smile of diffidence, said: "This greatly overrates me."

Dr. Smith was a man of very quiet and unobtrusive nature and of unfailing devotion to his professional duties. He was very faithful to his friends and genial in his intercourse with his associates. He had a very high sense of professional honor. He was a member of the Episcopal church, and at his funeral services the Rev. Dr. Lynde, of New Haven, spoke very fittingly of his association with Dr. Smith and of his admiration for his gentle and faithful performance of his duties, having been often with him in his visits to institutions. Dr. Smith lost his wife many years since; he had eight children, four sons and four daughters. A few years since he lost his eldest son, J. Lewis Smith, Jr., a very promising physician. His eldest daughter is the widow of the late Dr. Frederic M. Warner, and his second daughter is the wife of Dr. Henry Comstock Hazen; two daughters are unmarried. He was a brother of Dr. Stephen Smith, of this city. He was interred in the family plot at Greenwood, beside his wife and children.

WILLIAM THOMPSON LUSK, M.D., LL.D.

NEW YORK.

Dr. William T. Lusk died on Saturday afternoon last, in the midst of apparent health, from cerebral hemorrhage. He was born on May 23, 1838, in Norwich, Conn. After one year passed at Yale College he went to Germany and studied medicine there for three years. In 1861 he returned to this country and enlisted in the union army as a private, but rapidly rose to be assistant adjutant-general. After serving three years he was retired, and then attended a course of lectures at Bellevue Hospital Medical College, receiving his medical degree in 1864. After eighteen months of further study in Paris, Vienna, Prague, and Edinburgh, he returned to New York and began practice here in 1865. His first professional chair was that of physiology in the Long Island College Hospital, which he held from 1868 until his appointment to the chair of obstetrics and diseases of women in the Bellevue Hospital Medical School in 1871. For a time also he was lecturer on physiology in the Harvard Medical School. He was also at one period editor of the *New York Medical Journal*. He received the honorary degree of A.M. from Yale in 1872, and that of LL.D. from the same college in 1894.

Dr. Lusk was always an active professional worker and soon reached the front rank among the leaders in his chosen field. He was a writer of mark, and his work on "The Science and Art of Midwifery" has been translated into several European languages, as well as into Arabic. He was also the author of a number of contributions to periodical literature. He was a member of many societies, was an ex-president of the American Gynecological Society, an ex-president of the New York Obstetrical Society, a corresponding fellow of the Edinburgh and London Obstetrical Societies, and one of the founders of the International Congress of Obstetrics and Gynecology. Dr. Lusk leaves three daughters and two sons, one of the latter a professor at Yale University and the other a practising physician in this city.

Reviews and Notices.

LECTURES ON RENAL AND URINARY DISEASES. By ROBERT SAUNDBY, M.D. Ed., Fellow of the Royal College of Physicians, London; Emeritus Senior President of the Royal Medical Society; Fellow of the Royal Medico-Chirurgical Society; Member of the Pathological Society of London; Physician to the General Hospital; Consulting Physician to the Eye Hospital; Consulting Physician to the Hospital for Diseases of Women; Professor of Medicine in Mason's College, Birmingham. With Numerous Illustrations. Second Edition. Philadelphia: W. B. Saunders. 1897.

TO the carefully revised previous edition has been added a section on "Miscellaneous Affections of the Kidneys." With the exception of four colored plates showing albuminuric and diabetic retinitis, the illustrations are mostly small woodcuts of urinary sediments, etc.

The pathologic studies upon Bright's disease and diabetes are especially valuable. Due importance has been attached to the eye changes in both these affections.

A PRACTICAL WORKING HANDBOOK IN THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE GENITO-URINARY SYSTEM AND SYPHILIS. Being the Revised and Enlarged Notes with Additions by GEORGE PARKER HOLDEN, M.D., of Clinical Lectures Delivered in Flower Hospital Amphitheatre by F. E. DOUGHTY, M.D., Professor of Genito-Urinary Diseases in the New York Homœopathic Medical College. Philadelphia: Boericke & Tafel. 1897.

THIS work of over four hundred pages began as a brochure of eighty-eight pages, published some years ago as "Clinical Lectures." Since then a demand for Professor Doughty's lectures have caused the author to revise and publish notes taken in the classroom over a series of years. There are few illustrations in the text, but an "armamentarium" following the preface contains pictures of the instruments habitually employed. The diagnosis and management of these special forms of disease do not materially differ from those found in the text-books of the so-called old school.

EATING AND DRINKING. The Alkalinity of the Blood the Test of Food and Drink in Health and Disease. By ALBERT HARRIS HOY, M.D. Chicago: A. C. McClure & Co. 1896.

A THOROUGHLY sound-sensed treatise, showing that the author has given much thought to the subject.

While containing much of interest to medical men in the way of original matter, etc., the text is such that any one can understand the reasoning.

ARTIFICIAL ANÆSTHESIA. A Manual of Anæsthetic Agents and their Employment in the Treatment of Disease. By LAWRENCE TURNBULL, M.D., Ph.G., Aural Surgeon to the Jefferson Medical College Hospital, Philadelphia; late Honorary President to the Otological Subsection of the British Medical Association, and of the Section of Laryngology and Otology of the American Medical Association. Fourth Edition. Revised and Enlarged, with Illustrations. Philadelphia: P. Blakiston, Son & Co. 1896.

THE present edition of this manual of anæsthesia has been increased to five hundred and fifty pages. The whole question appears to have been extensively entered into, including inhalations of oxygen and other gases in the treatment of disease. Illustrations of apparatus are given. A good index makes reference to any particular subject easy.

GENITO-URINARY SURGERY AND VENEREAL DISEASES. By J. WILLIAM WHITE, M.D., Professor of Clinical Surgery, University of Pennsylvania, and EDWARD MARTIN, M.D., Clinical Professor of Genito-Urinary Diseases, University of Pennsylvania. Philadelphia: J. B. Lippincott Company. 1897.

DRAWING upon the literature of the subjects, the authors have given in an acceptable manner those views which agree with their own experience, and have indicated those lines of treatment which they have personally found most successful. Two hundred and forty-three engravings and seven colored plates embellish the work. These illustrations, which have been taken largely from the collection of Dr. George H. Fox, are for the most part excellent. One, showing by shadowgraph the presence of a calculus in the pelvis of the kidney, indicates an important diagnostic method still in its infancy. French authors have been largely followed.

One commendable feature is the attention which has been paid to changes in the urine and their bearing upon the various pathologic processes. The technique of operative work has been carefully considered. The work is open to the same criticisms which apply to any conjoint or collaborative production. There is lacking that individuality which alone can hold the prolonged interest of the reader. The material could be gathered and put together by a score of men almost as well as by any two. The index is extensive but might have been better arranged for ease of reference.

ARCHIVES OF CLINICAL SKIAGRAPHY. Edited by SYDNEY ROWLAND, B.A. Camb. A series of collotype illustrations, with descriptive text, illustrating applications of the new photography to medicine and surgery. London: The Rebman Publishing Company, Limited. 1896.

THE present fasciculus (No. 3) shows skiagrams of wired fractures, ununited fractures, deformities, double monster, etc. The plates are loosely inserted and can be utilized for purposes of instruction, to illustrate lectures, etc. The descriptive text is brief.

ESSAYS AND ADDRESSES. By Sir J. RUSSELL REYNOLDS, Bart., F.R.S., M.D. Lond., LL.D. Ed., LL.D. Aber., President of the Royal College of Physicians of London, President of the British Medical Association, Physician to Her Majesty's Household, and Consulting Physician to the University College Hospital. London: Macmillan & Co., Limited. 1896.

A BEAUTIFULLY printed collection of writings of the late Dr. Reynolds, together with a brief sketch of his life, published by his widow. The essays are all examples of literary and scientific merit, and that on "Specialism" of itself makes the book worth having. The last essay, on "The Organized Progress of Medicine," delivered as the presidential address of the British Association in 1895, completes the volume.

HIGH ALTITUDES AND CONSUMPTION: Principles or Guides for a Better Selection or Classification of Consumptives Amenable to High-Altitude Treatment and to the Selection of Patients who may be More Successfully Treated in the Environment to which They were Accustomed Previous to their Illness. By A. EDGAR TARSEY, M.D., Adjunct Professor of Diseases of the Chest in the Philadelphia Polyclinic and School for Graduates in Medicine, and Consulting Physician to the Central Branch of the Y. M. C. A. Gymnasium, Fifteenth and Chestnut Streets, Philadelphia. Philadelphia: P. Blakiston, Son & Co. 1896.

THE title "High Altitudes and Consumption" on the outside cover of this work is a somewhat misleading one, for, with the exception of one chapter devoted to a consideration of that point, little mention is made of high altitudes; the major part of the volume has tuberculosis and environment for its subjects. There is no doubt that the author is correct when he says that in many instances a patient in an advanced stage of phthisis is ordered away to another climate by his doctor, and not only derives no benefit but sustains distinct harm from the change of air.

THE PRACTICE OF MEDICINE. A Text-Book for Practitioners and Students, with Special Reference to Diagnosis and Treatment. By JAMES TYSON, M.D., Professor of Clinical Medicine in the University of Pennsylvania and Physician to the Hospital of the University, Physician to the Philadelphia Hospital, Fellow of the College of Physicians of Philadelphia, etc. Octavo, pp. 1,183. Illustrated. Philadelphia: P. Blakiston, Son & Co. 1896.

THIS extensive work is divided into fifteen sections, to which an appendix is added, with tables of maximum doses which have been given with impunity, and minimum dangerous doses; schemes for transferring from the metric to the English system, centigrade to Fahrenheit, etc.

One is impressed at the outset by the business-like manner in which the author enters upon his work. Practicability and the imparting of truths as they exist in the

author's mind seem to predominate and permeate the various sections.

Despite the size of the work, there is little or no prolixity. The modern physician of the younger generation will take exception to the offhand way in which the antitoxin question is dealt with, unless he assumes that, since the preparation of the work has extended over a number of years, this chapter, as well as that on typhoid, was written early and prepared for press before much of a definite nature could be said about the latest tests in diagnosis and serum "cures."

A somewhat dogmatic manner of statement here and there is readily accepted by the reader, since he is made to feel that the author is giving honest opinions in a frank, straightforward manner; and, when blood-letting in pneumonia is advocated, the impression is left upon the reader that, if an author of Dr. Tyson's experience says so, there must be not only something but much in it. In the same way the statements regarding the employment of large doses of digitalis in this affection, especially in the stage of consolidation, carry conviction. It is, as the author says, a useful drug, but to do good and not harm it must be most judiciously employed. Dry cupping is advocated, not only to give relief from the distressing symptoms, but to hasten crisis and shorten the course.

In typhoid the bath treatment is strongly advocated and well described.

It would be strange if omissions, oversights, and errors had not occurred; so the reader may be prepared to find perhaps a little more than the average for works of this number of pages. One of the most complete sections—if not the most so—is section X., on diseases of the nervous system. It is written with thoughtful care, and shows the author's familiarity with this difficult class of diseases.

Morphinomanie et Morphinisme. Par le Dr. Paul Rodet, Médecin-Directeur de l'Établissement Hydrothérapeutique d'Auteuil; Lauréat de l'Académie de Médecine (Prix Capuron, 1894; Prix Falret, 1896). (Ouvrage Couronné par l'Académie de Médecine). Paris: Felix Alcan. 1897.

This work, which has been crowned by the Academy of Medicine of Paris, is a well-written treatise on a subject that is comparatively little known. Certainly much has been written in lay literature concerning the morphine habit, but this is the first attempt that has been made to treat the question exhaustively as regarded from a medical and scientific point of view. In the first instance, the terms morphinism and morphinomania are defined as follows: Morphinism is that state of intoxication by means of morphine in which the drug only influences action by physical troubles, while the term morphinomania is applied to those cases which present psycho-sensorial symptoms. In this book a complete history of morphinism is presented; the morphine habit is traced through its successive stages until it passes into that of confirmed disease; the ways and modes of morphinomaniacs are described in detail; and statistics bearing upon the matter are shown, which have been gathered from all parts of the world. From these statistics it is learned that, so far as the prevalence of morphinomania is concerned, Germany stands first on the list, then France, with the United States third. This is a statement that one would hardly expect to see. The author naïvely remarks that "in America observations on morphinism commence timidly to appear." It is further stated that in Germany there are entire villages whose inhabitants are all addicted to the morphine habit. The author rebuts the generally entertained belief that Paris is full of morphinists, and says that the numbers are greatly exaggerated. Statistics taken of one thousand cases collected from all countries, six hundred and fifty men and three hundred and fifty women, show that among the male morphinists medical men preponderate, claiming no fewer than forty per cent.; men of leisure come next with fifteen per cent.; among the females, the most numerous are the women of means, forty-three per cent.; the wives of doctors supply ten per cent. The chapter on the symptomatology of morphinism is followed by that on abstinence, and both are especially important; in fact, it is indispensable to have studied them closely in order to be able to follow the disease in its different phases. From the standpoint of medical jurisprudence, the question of the responsibility of those under the influence of the poison is fully entered into, and the following conclusions are arrived at: that when a person who has not long been given to the use of morphine is in a state of intoxication, such a person is responsible; on the other hand, that a person who is in a state of chronic morphine intoxication, and whose brain has in consequence undergone more or less grave changes, may not in many instances be responsible. Of course these cases must be decided by expert evidence. The fact is referred to as somewhat peculiar that morphine acts directly on the organs of generation in both sexes, producing impotence in the male and amenorrhœa in the female. Authors are divided in opinion as to the exact cause of the amenorrhœa, but all agree that morphine has a direct effect on the ovary, bringing about atrophy of that gland. The most important chapter in the book is the one that deals with the treatment. According to the author, the prognosis is usually favorable; he states that a morphinomaniac can be definitely cured, but that relapses are very frequent. The style and diction of the work are effective, and on the whole the book may be termed a distinct addition to the literature of medicine.

Racial Deterioration: The Relation Between Phthisis and Insanity. A paper read in part (as far as time would permit) before the American Public Health Association at its meeting at Buffalo in September, 1896. By Lawrence Irwell, M.A., B.C.L.

This paper, as its title implies, deals with a much-discussed subject. It cannot, however, be affirmed that fresh light is thrown on the question by its publication. It is rather a *réchauffé* of the opinions of eminent authorities, for the most part English, that tend to uphold the views of the neo-Darwinian school of biology, which are also the views of Mr. Irwell. The paper is well worded and compiled, and the effort to show in a clear manner the link of connection between insanity and the tuberculous diathesis is plausibly attempted.

Leprosy and the Charity of the Church. By L. W. Mulhane. Chicago and New York: D. H. McBride & Co.

This is, as the author states, merely a compilation of facts picked up here and there relating to the "awful scourge of leprosy," pointing to the heroic work performed by the sons and daughters of Holy Church. It is a small book of one hundred and fifty pages, containing some illustrations.

A Practical Treatise on Diseases of the Skin. For the Use of Students and Practitioners. Fourth and Revised Edition. By James Nevins Hyde, A.M., M.D., Professor of Skin and Venereal Diseases, Rush Medical College, Chicago; Dermatologist to the Presbyterian, Agustana, and Michael Reese Hospitals of Chicago; and Consulting Dermatologist to the Chicago Hospital for Women and Children; and Frank H. Montgomery, M.D., Lecturer on Dermatology and Genito-Urinary Diseases, and Chief Assistant to the Clinic for Skin and Venereal Diseases, Rush Medical College, Chicago; Attending Physician for Skin and Venereal Diseases, St. Elizabeth Hospital, Chicago. Illustrated with 110 Engravings and 12 Plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1897.

The popularity of Dr. Hyde's work is again illustrated in the most tangible manner. The list of those diseases which have necessitated the rewriting of many chapters is too long and contains too many novel names to be here reproduced. Among new illustrations are five engravings and three plate pictures. As an evidence of appreciation of the services rendered in this edition by the author's associate, Dr. Montgomery, the latter's name has been placed upon the title-page.

It may be truthfully said that the present edition, though following the last after so short an interval, has been greatly improved and brought well up to date.

A Text-Book of Bacteriology. Including the Etiology and Prevention of Infective Diseases, and a Short Account of Yeasts and Moulds, Hæmatozoa, and Psorosperms. By Edgar M. Crookshank, M.B., Professor of Comparative Pathology and Bacteriology, and Fellow of King's College, London. Fourth edition. Reconstructed, revised, and greatly enlarged. London: H. K. Lewis. 1896.

In the revision twenty-six chapters have been added, which, taken in conjunction with the many changes and amplifica-

tions necessitated by the rapid advances in this branch, make of this fourth edition practically a new work. As with the previous issues, this one will undoubtedly be found of great value in the bacteriological laboratory and to health officers, as well as at times to all interested in contagious diseases and their prevention. Part I. deals with stainings and recent technical methods; Part II. with the bacteria of infective processes; and Part III. with descriptions of bacteria, making this portion rather complete for laboratory use, but not so generally useful otherwise. The work is freely and beautifully illustrated, several new colored plates having been added from originals by the author.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

WILLIAM H. WELCH, M.D., OF BALTIMORE, PRESIDENT.

(Continued from page 862.)

AMERICAN DERMATOLOGICAL ASSOCIATION.

Second Day—Wednesday, May 5th.

IN the first session of the second day's proceedings new officers and members were elected. The former were: *President*, Dr. Hyde, of Chicago; *Vice-President*, Dr. Bronson, of New York; *Secretary and Treasurer*, Dr. Bowen, of Boston (re-elected). The new members taken in were Dr. Montgomery, of Chicago, and Dr. Hutchins, of Atlanta. It was decided to meet next year upon the first Tuesday in June in or near New York City.

Dermatitis Due to X-Rays was one of the questions discussed in connection with the exhibition of photographs and drawings. Among the now rather frequent ill effects noted, aside from the more superficial lesions, are deep ulcerations, periostitis, and ostitis. Cases were reported by DR. GILCHRIST and DR. BRONSON. In some instances there is a rather deep indolent slough, which takes a long time to separate and is followed by very slow healing. The theory of bombardment by minute metallic particles was the one favored, and suggestions for prevention by the interposition of some non-penetrable screen were made. Dr. Gilchrist stated that those subjects who show after the first exposure any idiosyncrasy in this respect should be exposed a second time only in the most cautious manner.

Hereditary and Continuous Shedding of the Fingernails.—DR. DOUGLASS W. MONTGOMERY, of San Francisco, reported the case of a strong healthy man of thirty-five years of age, who had been troubled from birth with a constant shedding of the fingernails. He stated that his mother's nails fell like his own, one or two nails being affected every seven or eight months. He had two maternal uncles whose nails fell every three years or so. Other members of the family on both sides had bad nails, but the patient could not say that they fell off. His immediate family had no affection of the nails. There were no stigmata of hereditary syphilis, no indications of psoriasis or eczema, nor of the generalized exfoliative diseases of the skin, nor of any constitutional disease whatever. There was a small quantity of albumin in the urine, but the patient did not appear to be suffering from Bright's disease. The patient said that one or two of his nails were constantly falling, six to eleven months completing the cycle. A nail first became a dull yellowish-white over the lunula, and then began to lift away from the nail bed from behind forward till it fell off. The shedding was completed in about three months, after which the nail grew in again perfectly normal in from three to eight months. There were no subjective symptoms attending the process, and there was no order in which the nails were attacked.

DR. WHITE asked if there were any trophic changes noted in the hair, or if other members of the family had been similarly affected. He referred to photographs in the exhibition room, which he had brought to illustrate how combined trophic changes in the hair and nails ran through three generations of a family.

DR. KLOTZ spoke of similar changes affecting the teeth.

DR. MONTGOMERY said that the theory of degeneration would not apply. There were no changes in the hair or teeth; the nails were healthy in appearance and were shed unchanged. The patient's mother and maternal uncle had been similarly affected, while the father's nails had been reported as being "crumbly."

Symmetrical Atrophy of the Skin.—DR. J. A. FORDYCE, of New York City, reported a case which occurred in a woman, aged forty years. The hands, elbows, knees, and ankles were the seats of atrophic lesions, which were surrounded by a dusky-red zone of dilated capillaries. The atrophy followed closely on the hyperæmia, which seemed to be the primary condition. Clinically the affection resembled the cases described by Buchwald, Pospelow, Touton, Bronson, and others. The eruption was absolutely symmetrical, and had up to a short time before been progressive. On microscopic examination the atrophy was found to be secondary to an inflammation which was located in the skin and underlying connective tissue. The epidermis was invaded by exudation corpuscles, which had produced a thinning and degeneration of its constituent cells. No organic affection of the nervous system could be detected, although there was evidence of vasomotor disturbance.

DR. KLOTZ spoke of a case which seemed to have originated in rheumatism.

DR. HYDE thought some of the appearances were very suggestive of the erythematous form of lupus.

DR. GILCHRIST approved the term idiopathic atrophy.

DR. BRONSON thought there might be some central nerve lesion or possibly a spinal affection behind the process. While similar to his own case, it differed in being more diffuse.

DR. DUHRING said the condition was properly classed with the atrophies. Other diseases belonging in the same class, such as that known as striæ atrophicæ as well as morphœa, were preceded by inflammation. The latter, however, occurring in one stage of a disease, did not of necessity throw the affection out of this class, since in subsequent stages all inflammatory symptoms disappeared.

Some Cases of Feigned Skin Diseases.—DR. F. J. SHEPHERD, of Montreal, read the paper. The first case was of a woman who was employed in a hospital, and who had patches of dry gangrene on both hands and forearms. The patches were about one inch in diameter and circular. They had been coming out for ten days before being seen by Dr. Shepherd. The hands were carefully bandaged with a starch bandage over cotton wool, and no more spots appeared. The girl rapidly got well. Some of the patches showed an appearance of concentric rings, and were evidently produced by a heated metal disc.

The next case was one of huge blisters on both cheeks of a woman, aged fifty, a cook on a farm. The blisters always came out after working in the fields—a proceeding to which she strongly objected. The blisters fused together, and one blister would cover

the whole of one cheek. Some acid no doubt produced the lesions.

The third case was one of persistent croton-oil eruption after a single application two years previously. This patient, when the rash on the cheek faded, had an inflamed face, followed always by the development of huge blisters on each cheek. The patient was a young woman of a decidedly hysterical temperament, and seemed to take a delight in showing her breasts covered with croton-oil eruptions to the students.

The fourth case was one of patches of gangrene on the dorsum of the left foot. This was the third attack in four years. The first followed recovery from typhoid fever. As soon as the gangrenous skin separated, the ulcer left behind soon healed. The girl liked being in the hospital, where she attracted some attention, owing to the peculiarity of her case and the absence of cause, as the patches did not affect any one area supplied by a special nerve, and the ends of the toes in which the circulation was good were quite normal. The girl was addicted to liquor and tobacco. On one occasion in the hospital she set fire to her clothes. Dr. Shepherd drew attention to the similarity of these gangrenous patches to those occasionally produced by hot-water bottles applied to unconscious patients. The absence of motive in a case would not preclude the diagnosis of a feigned disease. A desire to obtain sympathy or notoriety is sufficient cause in many cases.

Dr. Allen believed that we should make a distinction between hysterical eruptions and those intentionally produced. He referred to an instance of multiple gangrene as belonging with the first class. He spoke of the great importance of differentiation between these conditions and burns from hot-water bottles closely simulated in one of the reader's photographs.

Dr. Duhring agreed as to the importance of excluding hysterical eruptions, and thought that before we can call an eruption "feigned" we must have absolute proof that it is such. He had personally observed but few instances of feigned lesions, and had proven in numerous instances that cases which had been so designated were in reality of neurotic origin.

Dr. Grindon spoke of artificial eruptions which were not feigned, instancing a young man who inflicted burns upon the skin as a sort of penance.

Dr. Bronson spoke of the morbid susceptibility on the part of the patient, especially in the matter of hot-water-bag burns, and thought the reduced condition of the patient had much to do with the severity of the traumatism. Similar lesions may occur not so much by design as because of some peculiar exaggeration of reaction to slight injury.

Dr. White could not agree with Dr. Duhring that absolute proof was required. It would rarely happen that one could be detected in the act of self-mutilation. In convictions for murder, circumstantial evidence may have been the strongest if not the sole proof. Why should we not admit it here? He referred to an ulcerative dermatitis about the region of the mouth, evidently due to some application for removing hairs, but the use of all such applications was most strenuously denied by the patient.

Impetigo Herpetiformis.—Dr. M. B. Hartzell, of Philadelphia, reported a case of this nature in a woman over seventy years of age. An eruption of pustules upon the trunk, attended by chill and fever, was followed by similar lesions upon the face, neck, and extremities. The lesions were grouped, and followed by crusting with miliary pustules about the border. There were severe constitutional symptoms. There were several recurrences, and death finally resulted. Of the twenty-one cases reported, three have occurred in men. Tuberculosis has been found in three of the seven instances in which autopsy was made.

Impetigo Herpetiformis or Dermatitis Herpetiformis.—Dr. J. A. Fordyce, of New York City, reported a case occurring in a man, aged sixty-six. The eruption when first seen was nearly universal. It was made up of grouped vesicles and vesico-pustules, which became confluent over the legs and arms. Over the thighs and abdomen large irregularly rounded plaques were seen, which extended in a peripheral manner, while slowly clearing in the centre. A new outbreak of lesions was accompanied by an elevation of temperature and intense pruritus. After existing for several weeks the eruption slowly disappeared, leaving larger pigmented areas on which new groups of vesico-pustules would appear. Papillomatous lesions developed in both axillary spaces. A small amount of albumin and some granular casts were found in the urine. The blood and serum from the vesicles contained a large number of eosinophile cells. A piece of skin from a recent lesion excised for microscopic examination showed an acute inflammation of the derma and the presence of vesicles in the deep layers of the epidermis. The cell exudation contained large numbers of polynuclear leucocytes and numerous eosinophile cells. The eruption presented certain features pertaining to both impetigo herpetiformis and Duhring's disease, and seemed to justify the view which this writer originally held, that they should both be included in the same class.

Dr. Duhring said that in Dr. Hartzell's case he had been impressed by the thickening of the skin from chronic œdema, considerable corium being involved. The grouping was irregular. There would seem to be a close connection between this disease and pemphigus vegetans, to which it bears marked analogy. The mucous layer of the corium is thickened in both. Dr. Fordyce's case should be ranged with those of impetigo herpetiformis, in which there is marked herpetiform arrangement, but the lesions are deeper seated than in dermatitis herpetiformis. He thought it well to retain the term proposed by Hebra for this class.

Dr. Johnson said he had seen two cases, one in a male subject. The condition of the skin described by Dr. Duhring as soft and leathery was not present in these cases. He regarded Dr. Fordyce's case as dermatitis herpetiformis, among other reasons because there was a vesicular eruption.

Dr. Gilchrist thought bacteriology offered much better chances than clinical observations in arriving at the etiology of these affections. Eosinophiles are found to be present in a variety of vesicles, including those due to poison ivy.

Dr. Hyde said eosinophile cells were present in abundance at times in the lesions of dermatitis herpetiformis.

Dr. Hartzell said that in his case the grouping was marked, but the distinctive feature was the surrounding ring of miliary pustules.

Dr. Fordyce said a peculiarity in his case was an entire absence of scarring, thus differing from dermatitis herpetiformis. He agreed that the two conditions were closely related to each other and also to pemphigus vegetans. A tendency to papillary formation is common to all these conditions.

Dr. Duhring said Dr. Fordyce's observations relating to scarring differed from his own. He did not recall any case of permanent scarring in uncomplicated dermatitis herpetiformis.

Third Day—Thursday, May 6th.

Strong Applications of the Ichthyol Group was the first paper of the second day's session, by Dr. H. G. Klotz, of New York. Ichthyol, thiol, and tumenol,

members of the "reducing" group of drugs, are usually applied only in weak combinations in skin diseases. The reader had found by experience that strong applications are very effective even in acute inflammatory conditions of the skin, if judiciously used at the proper intervals. Besides the effect on cornification, the contracting power upon the blood-vessels and the antiparasitic properties came into play. The speaker laid particular stress upon the facts that ichthyol dries rapidly on the skin and forms a suitable protective without further dressing. He has used it besides in erysipelas, in which its value is widely known; in other forms of acute dermatitis, viz., dermatitis venenata, with particularly good effects in dermatitis from burns and from freezing; in traumatic dermatitis (mostly from intertrigo and scratching); further in acute eczema, herpes zoster, and he thinks it will be found useful in erythema multiforme, dermatitis herpetiformis, urticaria, and in the acute exanthemata. In chronic inflammations the effect is more pronounced if preceded by cauterization or strong stimulation.

Discussing Dr. Klotz's paper the speakers recognized the value of ichthyol in many affections and thought well of the suggestions as to modes of application. Tumenol was stated to be more efficacious in relieving pruritic affections. It is claimed by Bronson that stronger solutions of bichloride can be used with advantage when combined with ichthyol than in watery solution. Since ichthyol in strong watery solution dries into a varnish-like coat, as has been shown by Klotz, the futile attempts to find a suitable medium for its application as a protective dressing may be abandoned. It was thought, however, that in certain conditions, such as erysipelas, collodion might in itself exert a beneficial influence upon the dilated vessels, and thus aid in the reducing and antiparasitic action of the drug.

The Nature of the Xanthomata was the title of a paper presented by Dr. S. Politzer, of New York. The peculiar yellow plaques and nodules in the skin known as xanthoma have been the subject of extensive studies on the part of pathologists and dermatologists, ever since they were first described by Addison and Gull in 1850. The greatest diversity of opinion exists as to their nature. This is due probably in part to the fact that different authors have examined different stages of the disease, and in part to the fact that the different forms of xanthoma have been assumed to be merely different clinical manifestations of the same process. The author's histological studies are based on thirteen cases—five of them cases of xanthoma planum palpebrarum, four of xanthoma tuberosum, and four of xanthoma diabeticorum. The clinical grounds for separating xanthoma of the eyelids from multiple xanthoma are as follows: The nodules of xanthoma multiplex are firm, round, elevated papules; the patches of eyelid xanthoma are soft plaques in the level of the skin. Eyelid xanthoma persists through life; multiple xanthoma sooner or later undergoes involution. Eyelid xanthoma is quite common; multiple xanthoma is extremely rare. If the eyelids were in this preponderating degree the seat of predilection for a common xanthoma, we should expect to find the eyelids affected in every case of multiple xanthoma; but, as a matter of fact, the two forms are rarely associated in the same individual. With the extensive material at his command the author has been able to show that common eyelid xanthoma is not a new growth, but is due to a degeneration of pre-existing, embryonally misplaced muscle tissue. The so-called xanthoma cell is a fragmented muscle fibre in a state of granulo-fatty degeneration, with proliferation of the muscle-cell nuclei. The various stages of the change from normal muscle fibre to "xanthoma cell" were demonstrated in sections under the microscope, drawings made by Dr. Ira Van Gieson, and microphotographs. This explanation of the origin of eyelid xanthoma harmonizes with a number of hitherto unexplained clinical and pathological facts, *e.g.*, the absence of any clinical signs of tumor; its almost exclusive occurrence in the face, where peculiar muscular conditions prevail; its heredity; its usual development after middle age, when degenerative processes are apt to occur; the peculiar yellow pigment that is always present in muscles undergoing fatty degeneration, etc. The structure of multiple xanthoma is shown to be wholly different from that of eyelid xanthoma. It forms a sharply circumscribed tumor in the cutis. It is an irritative hyperplastic development of connective tissue, whose cells produce fibrous tissue on the one hand, or undergo fatty degeneration on the other. In diabetic xanthoma the process is a little more diffuse and the tendency toward fatty degeneration more marked than in the non-diabetic multiple xanthoma. In both, irregular patches of granulo-fatty matter, interspersed with cellular detritus, occur in the middle of the nodules as the results of the fatty degeneration of the cells. In over eighty-five per cent. of the recorded cases of multiple xanthoma, far too large a number to be accounted a mere chance, there was either diabetes or some severe lesion of the liver with jaundice. The author thinks it likely that further research may show that the fibrous nodes and fusiform enlargements of tendons in chronic rheumatism are to be placed in the same general class as the nodes of xanthoma. We should then have a large group of diseases, hepatic, diabetic, rheumatic, all characterized by toxæmic conditions, in all of which irritative connective tissue lesions occur in the skin and elsewhere. At one end of this series we should have the persistent fibrous node of rheumatism; at the other, the transient nodules of diabetic xanthoma, while between them, intermediate in its tendency toward the formation of fibrous tissue and fatty degeneration, ultimately undergoing involution, would stand the nodule of common multiple xanthoma.

Discussing this paper Dr. Hyde said that while it was unusual for xanthoma planum of the lids to occur in diabetics, he had observed such an instance. He agreed with the reader that there were objections to the qualitative "diabeticorum" for the variety to which it was applied.

Dr. Johnson said the fact that the lesions in multiple diabetic xanthoma might disappear coincidently with a decrease in the sugar of the urine, and recur with a renewed excess of the latter, plainly took these lesions out of the class of new growths. Xanthoma of the lids could therefore on this ground alone be separately considered.

Dr. Morrow thought there was a direct causal connection between the presence of sugar in the urine and the development and exacerbation of lesions in the diabetic variety. Lesions tend to recur after removal, as he had shown in a case of his own.

Dr. Allen said that at the last meeting he had advocated in a paper on "glycosuric dermatoses" that the term "diabeticomm" be dropped in describing several affections occurring in the presence of the symptom glycosuria.

Dr. Bowen thought the reader's theory of the formation of the xanthoma cell was very likely to be correct. It was greatly to be desired that transition forms should be demonstrated to strengthen the reader's claims.

Dr. Shepherd reminded the members of the case he had presented in Montreal, in which the lesions of xanthoma multiplex had promptly disappeared upon the removal of a mass of calculi from the gall bladder.

Dr. Politzer closed the discussion by stating his

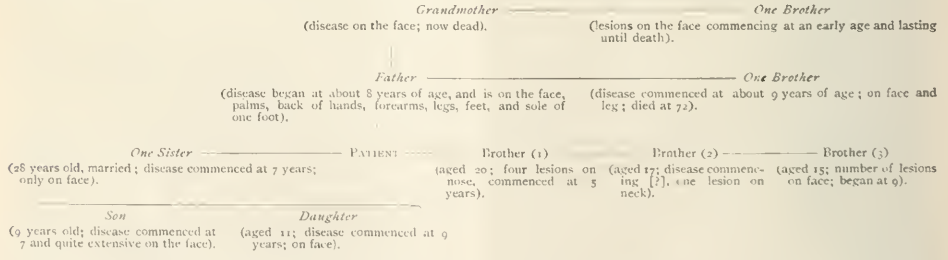
belief that the generalized form of xanthoma occurring upon the hands, face, etc., was of the connective-tissue variety, and that hence it was capable of disappearing spontaneously. Glycosuria in patients with eyelid xanthoma was a coincidence only. Behind the sugar there probably existed a toxæmia acting in a causative way to produce the multiplex form called "diabetic."

The Dermatologist in Pathology.—Dr. Welch, president of the congress, was present at this session and made a brief address, in which he referred to the opportunities which were being grasped by those working in cutaneous medicine for the elucidation of complex pathological questions. In no other field were such facilities offered for combined clinical and pathological observation and experiment. The skin more than other tissues is subject to a great variety of external irritants and infections whose reactionary effects can be closely watched in the living subject and excised for microscopic study. Properly pursued investigations in this department he confidently expected would in the near future add enormously to our knowledge in the broader realm of general pathology. He expressed much personal satisfaction with the section's work.

A Universally Adaptable Scale of Measurements for the Accurate and Uniform Description of Cutaneous Lesions.—This paper was presented by Dr. C. W. Allen, of New York, who showed first the desirability of a system which could be adopted for all countries. The inaccuracy of description by reference to seeds, grains, nuts, fruits, vegetables, coins, and the like was gone over, and the international confusion often occasioned in important questions was dwelt upon. The scheme proposed took for the unit one-quarter of a millimetre, suggestively called by the reader a *tetmil*, from the Greek equivalent indicating "one-quarter." The sizes range from one to five hundred, and a series of numbered circles inclosed in the larger circle of the scale show at a glance their relative size. It was suggested to authors to insert the scale in their text-books on dermatology, and that by its use the writer would be saved long descriptions and the reader would soon familiarize himself with the numbers and secure a more adequate idea of the size and form of lesions than by the older method. Scientific accuracy was, however, the desideratum, especially as to the smaller lesions, upon whose exact size a diagnosis often rested. A table of equivalents giving the old terms and their corresponding scale size was incorporated in the paper, based upon actual measurements, and it was thought by the reader that this feature alone, if adopted, would prove of value as giving to the various objects now employed for comparison a definite dimension based upon the average sizes of objects which often varied greatly as between themselves. The proposed scheme was discussed and it was generally admitted that reform in the direction proposed was called for. It was voted to refer the matter to a committee which should bring the question up at the next international congress.

A Peculiar Affection of the Hair Follicle was the paper next read by Dr. Joseph Grindon, of St. Louis. The affection consists of a chronic inflammation of the hair follicle characterized by extrusion of a portion of the root-sheath proper *en masse*, which remains threaded over the hair and is carried up with it in its growth, the process being repeated from time to time until successive masses bearing a superficial resemblance to nits are strung along the hair. It is accompanied by slight redness about the mouth of the follicle and results in a curable alopecia. There are found little grayish-white masses threaded beadwise on the hair. In their size, color, and distribution they are so like the ova of the pediculus capitis that one is almost certain to mistake them for the latter at first sight. The little masses consist of the cells of both layers of the internal root sheath (Huxley's and Henle's) surrounded by a layer of amorphous detritus and sebum. Besides pediculosis there are other clinical conditions which superficially simulate this form of folliculitis. Among them are trichorrhexis nodosa, monilethrix, piedra, leptothrix, and a few clinical curiosities, such as Hodara's disease, Giovannini's disease, etc. In the discussion this observation was considered of interest and importance in connection with nomenclature of the diseases of the hair, as well as in differential diagnosis.

Parakeratosis.—Eleven cases of parakeratosis (Mibelli) or hyperkeratosis excentrica (Respighi) in one family were reported in a paper by Dr. T. Caspar Gilchrist, of Baltimore. "These two patients, father and son, whom I am able to exhibit to-day, are two of the eleven cases of this very rare disease. The first patient whom I have named in the scheme which I present below I have called "the patient," as he was the first of the cases. The father, who is sixty-four years old, shows almost all the typical lesions of this disease, especially on the backs of both hands, fingers, wrists, forearm, and palms, as well as on the legs and dorsum of the feet. The patient is a young man, twenty-one years of age, who has had the disease since he was five years old, when it commenced on his ears, nose, chin, neck, back of hands, and right forearm. The lesions were extremely slow in appearing and in growing. The most remarkable feature about the whole case is the family history, which is here given in a tabular form, together with a very brief description of the disease in each case.



Grandmother
(disease on the face; now dead).
One Brother
(lesions on the face commencing at an early age and lasting until death).
Father
(disease began at about 8 years of age, and is on the face, palms, back of hands, forearms, legs, feet, and sole of one foot).
One Brother
(disease commenced at about 9 years of age; on face and leg; died at 72).
One Sister
(28 years old, married; disease commenced at 7 years; only on face).
PATIENT
Brother (1)
(aged 20; four lesions on nose, commenced at 5 years).
Brother (2)
(aged 17; disease commencing [?], one lesion on neck).
Brother (3)
(aged 15; number of lesions on face; began at 9).
Son
(9 years old; disease commenced at 7 and quite extensive on the face).
Daughter
(aged 11; disease commenced at 9 years; on face).

"There have been eleven cases in four generations, eight males and three females. Of these, eight had been examined personally. The separate descriptions given by three of the family of the disease as it occurred in the others, whom I examined later, were so correct that I have fully accepted the statement that it was the same disease which occurred on the deceased members. The patient (first) has been under my care eighteen months, and the disease was not diagnosed until many histological specimens were examined. The eruption consists of lesions of various sizes and forms, which present two varieties, viz., the smallest, which are chiefly on the face, and consist of minute (0.5 to 1 mm. in diameter), dirty brown, semiglobular elevations of a

horny nature. They grow very gradually, and when they reach the size of a small pinhead (1 to 2 mm.) the centre sinks in and a peripheral horny ridge is found. Coursing along the ridge appears a minute groove, and as the patch becomes large the centre takes on an atrophic though callous appearance. The largest patches are about split-pea sized. In the father's case there was absence of sweating within the areas of the largest patches. It was found that after removal of some of the lesions with a curette and the application of the silver-nitrate stick, the characteristic papule would reappear on the scar. They did not return after excision. New lesions had been seen to appear during the course of weekly observations of the patient. Microscopical examinations were made of sections obtained from twenty lesions excised from the patient, three from the father, two from one of the brothers, and one from the nephew; and the result showed that the disease began either as a marked hyperkeratosis of the sweat pore and upper portion of the duct, or of the opening of the sebaceous gland, or of the two adjoining openings of both glands. This was followed in some instances by dilatation of the sweat duct and gland beneath, followed by atrophy of the glomerules. Sections from some of the oldest lesions presented a picture almost like that of psorospermosis follicularis vegetans (Darier).

"Mibelli has reported three cases and very briefly referred to three others in Italy; Respighi reported seven cases of this disease and also briefly referred to four others, but only one case has been published outside of Italy, and that was by Hutchins, of Atlanta, Ga. (He gave only a clinical description.) Neither Mibelli nor Respighi thought that this disease was hereditary, but these eleven cases in four generations show very strong evidence of an hereditary taint.

"The reader proposes the name porokeratosis excentrica for this disease, as the former refers to the chief pathological factor, and the latter to a very striking clinical feature."

What Conditions Influence the Course of Syphilis? was the subject for general discussion, which was opened by Dr. R. W. Taylor, of New York, who presented the adult aspects of the case. The subject of infection and course of syphilis was exhaustively reviewed, and the conclusion reached that a great variety of conditions modify the effects of the virus in different individuals.

Infantile Syphilis.—Dr. James Nevins Hyde, of Chicago, opened the discussion on "Infantile Syphilis—What Conditions Influence its Course? (*a*) The Virus? (*b*) The Individual?" He considered, first, the phenomena of syphilis in intra-uterine life, syphilis of the ovum and of the fœtus; second, extra-uterine or hereditary syphilis of the infant; third, acquired infantile syphilis. With reference to the first, the author considered its frequency in several social states of the people, the errors most commonly committed in the interpretation of the signs of the disease, and the percentage of abortions and miscarriages in the products of conception. Collating the fruits of seventeen hundred pregnancies, it was shown that about one-third terminated by the death of the ovum or fœtus. With reference to the facts of extra-uterine syphilis of the products of conception, after a review of the sources of error, it was shown that of seventeen hundred pregnancies there were born eleven hundred and twenty-one living children, of whom nine hundred and fifty-six died within the first twelvemonth after the conclusion of pregnancy. Considering then the relative importance of both virus and individual, the struggle for existence would appear to be hopeless were it not for a single and remarkable fact. The mothers who can offer breast milk to their syphilitic children save between ten and twenty per cent. of the patients who are set down by some authors as inevitably lost if not nourished at the breast of the mother. This remarkable result is due and solely due to the improved nutrition of the victim of the disease. Acquired infantile syphilis was shown to result in an enormous proportion of all cases with favorable results as regards the new being, the author citing a number of illustrative facts, and concluding that in these cases, as in acquired disease of adults, "he is indeed blind who cannot see . . . the wall that is ever and again built as a bulwark to the encroachments of disease by the sound constitution, the satisfactory habits, and the hygienic environment of the selected individual."

In the discussion Dr. Atkinson took the ground that the intensity of the poison depends largely upon the susceptibility of the individual.

Dr. Grindon thought the dosage a matter of importance which had not been touched upon, and spoke of certain observations which had been made in connection with vaccination, which went to show that the amount of virus inserted at times influenced the result.

Dr. Hartzell thought it largely a question of soil, and that bacteriology substantiated this view in relation to many similar processes.

Dr. Allen thought there were two sides to the question, and that reasoning from analogy we must admit an occasional intensity of virus—as in a succession of nerve and cerebral cases.

Dr. Montgomery spoke of superinfections, and objected to the use of the term symbiosis in this connection.

Dr. Klotz called attention to his own paper, which had not been referred to, but which went over the whole question. He said his own conclusions had been as hypothetical as those arrived at by the speakers.

Dr. Fordyce had confirmed the observation of Van Gieson, that secondary infiltrations occur at an early period (a few days) at some distance from the initial sore. In gouty subjects syphilis is apt to be severe—the late sclerosis may be a combination of a lithæmic state superadded to the specific virus effects.

Dr. Sherwell agreed with Dr. Klotz that the germs of tuberculosis and syphilis are antagonistic, and does not believe that syphilis leads or predisposes to tuberculosis.

Dr. Morrow held that the soil and not the seed determined the nature of a given case. Analogy does not help us in the solution of the problem. We must rely upon clinical data. In hereditary syphilis we must assume that in succeeding pregnancies there has been a succesive attenuation of the virus.

Congenital Ichthyosis.—Dr. James M. Winfield and Dr. J. M. Van Cott presented conjointly "A Contribution to the Etiology of Congenital Ichthyosis. Report of a Case with Absence of the Thyroid, with Microscopic Report of the Condition of the Skin." After giving the family history, the paper entered into the history of the mother. She had been pregnant seven times, and four times gave birth to normal children; two were ichthyotic, the first of which was reported by Dr. Sherwell before the American Dermatological Association in 1894. During the first, second, third, fourth, and sixth pregnancies the mother's condition was excellent, she being neither nervous nor sick. During the fifth, which resulted in the first ichthyotic infant, she was subjected to considerable anxiety, and at the sixth month received a severe nervous shock. When she became pregnant for the last time she immediately grew exceedingly nervous and worried lest she should become the mother of another deformed baby.

At delivery the infant weighed about four pounds. The body was enveloped in what appeared to be a thick coating of vernix caseosa, which on removal left the

skin red and shiny. If no lubricating protective was used the whole cutaneous surface soon became scaly and fissured. Four days after delivery it appeared as follows: the whole body was covered with thick reddish-brown epidermic plates, which were larger and more marked over the extensor surfaces; some of them were from one-sixteenth to one-tenth of an inch in thickness, and one-half to two inches in diameter; between the plates were fissures of varying depths. Movement of the limbs produced cracks about the flexures of the joints, which extended deeply into the underlying tissues. The autopsy was made about eight hours after death. The body was considerably emaciated, and covered with large fatty epidermic scales. On examining the neck the thyroid gland was found to be absent. There was no sign or trace of its ever having existed.

A number of slides were prepared from portions of the skin taken from the back, thighs, arms, and scalp. Dr. Van Cott's report was: "The horny layer of the skin is considerably thickened; the rete Malpighii appears fairly normal. The sweat and sebaceous follicles are present. Both the rete and subcutaneous areolar tissue present in some of the sections evidences of necrosis with small round-cell infiltration, and in certain areas the lymph spaces are occluded with bodies resembling in every respect micrococci. Those lymph spaces which are filled with these morphological elements are more common in the neighborhood of the blood-vessels, both arterioles and venules.

"The important etiological points are: First, the absence of the thyroid. Second, the presence of micro-organisms in and about the lymph spaces. That the thyroid has some influence on the nutrition of the skin is an established fact, as is evidenced by the occurrence of various dermatoses when this body is atrophied or diseased; and, further, there are numerous recorded instances in which the administration of thyroid extract has exerted a beneficial influence on skin affections when hyperkeratinization and thickening were prominent features. Just what etiological bearing the absence of the thyroid has on the production of ichthyosis congenita and kindred diseases cannot be positively stated without further clinical and post-mortem proof; still from the above facts it is but fair to conclude that in this case, at least, the absence of this body had some marked effect on the nutrition of the skin and the development of this cutaneous affection. The occurrence of micro-organisms in the lymph spaces at once brings up the question whether this and similar cases are types of true ichthyosis, or, as Dr. Van Cott puts it, a variety of dermatitis. If these micro-organisms were the cause of this excessive plate formation, it is possible that the term ichthyosis sebacea is the correct one; for a bacterial irritation could easily produce a universal seborrhœa."

Pseudolupus of the Face Due to the Presence and Growth of Blastomyces was the title of a paper presented by Dr. T. C. Gilchrist, of Baltimore. A photograph was passed showing an extensive lesion of the face, which had evidently destroyed the eyelids to a great extent and caused marked disfigurement. The objective appearances were those of a lupus vulgaris, or of a tuberculosis of the skin. The affection had begun a number of years before as a papule near the ear, from which point extension had gradually occurred, leaving scar tissue to mark its path. A plaque covering the back of one hand had existed for four years. A chart was exhibited showing a series of inoculation experiments in animals, which resulted in nodules in the lungs, from which cultures were made and other animals inoculated. In every instance pseudotubercle pustulation or caseation was the result, and which by inoculation would always produce lesions similar to those of tuberculosis, which latter disease was, however, always most carefully excluded. The bodies which produce this blastomycetic dermatitis are doubly contoured, budding organisms, resembling the yeast plant and growing in the same way. They have never before been shown to possess interest to the dermatologist. They were demonstrated under the microscope.

Lymphangioma of the Labia Majora was the title of a paper presented by Dr. J. C. White, of Boston. The affection had existed for several years in the person of a young lady, and assumed the form of papillomatous growths resembling lymphangiectases as much as they did lymphangioma. The diagnosis was difficult, and the reader did not know in just what way it was fully to be determined. Drawings were shown and the microscopic appearances demonstrated.

(To be Continued.)

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

GENERAL MEDICAL COUNCIL—CHRONIC HYDROCEPHALUS IN ADULT—WOUND OF MESENTERY—HERNIA—FEMORAL HERNIA WITH APPENDIX IN SAC—ROYALTY AT GUY'S—DINNER TO LISTER—THE LATE DR. ROBERTSON AND MR. NIXON.

London, May 28, 1897.

The General Medical Council met on Tuesday, under the presidency of Sir Richard Quain, whose address on the occasion followed the old lines. Much pleasure was expressed that the president was able to be present after his severe illness, and, considering his advanced age, Sir Richard looked quite himself again, and delivered his address with remarkable energy and clearness.

The council bowed, as in duty bound, to the decision of the privy council respecting the Apothecaries' Hall of Dublin, and referred to a committee the matter of reporting on the appointment of examiners and their remuneration.

The attention of the council was called by Mr. Brown to the low standard of the preliminary examinations, and some strong remarks were made as to the passing of candidates who are not well grounded in the rules of the English language.

Sir D. Duckworth declared that some boards passed men who would not be taken as ushers in private schools, and yet they were considered good enough for the medical profession. He thought it time the council found out which boards passed men whose ignorance disgraced the profession.

The midwives question was brought up, and after some rather strong remarks it was agreed to inquire whether the privy council desired the bill for registration to be considered in the present session.

On Wednesday the procedure under the penal clauses was discussed, and the report on dental education received and ordered to be sent to the licensing bodies concerned for consideration before the November meeting.

At the request of the president, Sir William Turner was asked to preside for the rest of the session.

Yesterday penal cases were heard, an address to the Queen on her long reign was voted, and a statement was received from the president regarding a deputation to the local government board on death certification.

The council further agreed to make representations to the privy council with reference to the proposal of Italy to restrain practice by foreign medical men in that country.

The report of the pharmacopœia committee was

adopted. The work is in an advanced state, proofs were in the hands of members, and it is expected the volume may be completed in time for the November session.

Chronic hydrocephalus producing practically no symptoms up to the age of sixteen and one-half years, and then followed by cerebral symptoms proving fatal, is certainly very unusual, but such a case was related at the last meeting of the Clinical Society by Dr. Frederic Taylor, under whose care it came in Guy's Hospital on September 11th. For some days there had been severe headache and vomiting, and on admission the gait was unsteady and the boy's head measured twenty-three inches in circumference. On the 19th paralysis began, and he died the next day, conscious up to three hours before his death. At the post-mortem thinning of the skull bone was found, and the cerebral ventricles contained thirty ounces of liquid.

A case of wound of the mesentery with subsequent gangrene of the intestine was related by Mr. Lockwood. The patient, aged sixty-four, stabbed himself with a carving knife. The abdomen was opened to stop hemorrhage, which was found to come from several rents in the mesentery, one being one-half inch from the bowel; but it was hoped that there was room for anastomosis. The man died two days afterward, and the bowel opposite the wound was becoming gangrenous. The vascular supply of the mesentery and bowel had been examined in the dissecting-room, and no anastomotic loops were found less than one inch from the bowel, which should therefore have been resected. Some other cases were mentioned bearing upon the anastomosis of the mesenteric vessels, which was considered untrustworthy.

Mr. Howard Marsh then related a case of strangulated inguinal hernia, in which the coils of small intestine were so distended with fluid that he found it necessary to incise them freely before they could be repaired. He closed the incisions by Lembert's sutures. The patient recovered without a drawback.

Mr. Spencer remarked that section of the nerves supplying a ligated portion of intestine produces accumulation of clear fluid inside it, suggesting that in this case the nerve supply had been in some way interfered with. The plan of incision adopted was generally approved.

Mr. Bidwell then related two cases, both in women, of irreducible femoral hernia, in which the sac was occupied by the vermiform appendix and distended by clear fluid. He reduced the appendix in both cases after notching Gimbernat's ligament. Only a few such cases have been recorded, and in most of them the appendix was excised.

A similar case was mentioned by Mr. Langton, who would have notched Hey's ligament rather than Gimbernat's, as causing less weakness of the abdominal wall.

Mr. Eccles referred to a case he related last year in the Pathological Society, and thought the appendix had a great tendency to form adhesions. In that event it was easier to excise it.

The Prince of Wales opened the new buildings of Guy's Hospital Medical School on Wednesday. The preparations were well arranged, and the function went off most successfully. In the colonnades were a number of patients on couches or chairs, and as the prince passed he made sympathetic inquiries. Heavy rain played havoc with the millinery of the visitors in the midst of the proceedings, but they were carried out with precision. After declaring the building open, the prince spoke eloquently of the great work to which it was devoted, and urged the students to make the best use of the opportunities provided. "Take care," he concluded, "that the great profession to which you have aspired to belong shall, when you leave it, stand as high in the service and in the affection of the public as it does at the present time." He also said he had satisfied himself as to the vivisections performed at Guy's.

The dinner to Lord Lister by his former house surgeons and dressers was held on Wednesday, and was a most agreeable reunion. A souvenir was distributed to those present, with a list arranged in chronological order of all who had held these offices, so far as could be ascertained. There was also an excellent portrait of his lordship.

Dr. Lockhart Robertson died on the 18th inst. He had been a lord chancellor's visitor in lunacy, president of the Medico-Psychological Association, and for a time editor of the *Journal of Mental Science*, to which he freely contributed. He was president of the section of psychology at the International Congress in London, and one of the translators of Griesinger's work on "Mental Disease."

Mr. F. A. Nixon, of Dublin, died on Sunday. He had been seized with apoplexy the previous Tuesday. He was on the surgical staff of Mercer's Hospital, and of course so far involved in the conflict thereat. He was professor at the College of Surgeons, an able teacher and surgeon, and much esteemed.

The name Nixon reminds me that the accident mentioned in a former letter of mine (MEDICAL RECORD, May 15th) did not happen to Sir Christopher, as I stated "from information received," but to a namesake, as my informant tells me.

THE HOSPITAL PAY SYSTEM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am glad to see you take a hand in the fight for the correction of "The Abuses of the Hospital Pay System," and commend all you say in your article in the MEDICAL RECORD of June 5th. You have touched a chord that should, and I have no doubt will, electrify the medical profession at large.

Every physician knows that numerous persons, who occasionally call him in and pay him, go to the hospitals and dispensaries for treatment—"not free," they say, "for I pay for my medicine, and sometimes contribute to their support" (but they don't say how little they pay), thereby easing their conscience and pride, if they have any; and some of these people make a show of "living in style." It is a gross injustice to the layman as well as to the physician. The liberal, generous layman A contributes of his resources—which, as a rule, are not much above his necessities—to support these institutions, and never for a moment does he think of applying to them for relief, but, like the man he is, he calls in or goes to some physician and pays him for his services: while B, who is equally or perhaps better able to contribute to the support of the hospitals, does not, but does go to them for free treatment. Now B robs, yes, robs A: he might just as well take the money from the pocket of A, and use it to pay the little mite that he is required to pay for his treatment and medicine.

There is another abuse which you do not mention, but which in my judgment and experience is equally as bad as the others, and that is that the public is supporting institutions that benefit a few physicians and surgeons who are favored by appointment on the staff of the institution, and to the detriment of the many. These institutions are close corporations, and do not permit any other physician to attend even the patient he sends there, nor do they permit the patient who may elect to go to a hospital, either as "free" or "pay," the privilege of calling the physician of his

choice; he must take such as the hospital furnishes him.

Many persons are so situated that it is inconvenient, sometimes impossible, for them to get necessary care and nourishment. They may be obliged to go to the hospital, but are anxious to have and to pay their physician, who is familiar with their present as well as their past history, to continue to attend them. The moment, however, a sick person crosses the threshold of a hospital, he is deprived of his choice, and the physician loses patient and fees, while generally the hospital staff treats him free; he may, however, pay for his board, lodging, and nursing.

Every physician cannot be on the staff of hospitals, but he should have the privilege of attending the patients he sends into the hospitals; and patients who are admitted should be permitted to call any physician they may want. A few hospitals have this system, and it does not cause any friction, nor does it cast any reflection upon the institution; on the other hand, it tends to invite patronage. It is because physicians are not allowed to attend their patients who require hospital care and enter the hospital, that so many hospitals are springing up everywhere. No medical man wants to lose his livelihood, neither does he want to lose his interesting cases; therefore, if he can induce some of his friends to join him, he obtains a charter and starts a hospital. Open the wards to all physicians and you will see fewer of the smaller hospitals and sanatoriums, and the larger ones will not have to go begging for patients or money either. Let the physician have an interest in the hospitals, and he will send many patients that he otherwise would strive to keep away.

If the public knew it was supporting a system of, in reality, private sanatoriums, it would decry it, and say: "Open your doors and let in the 'light of liberty.'"

C. C. Henry, M.D.

Brooklyn, N. Y.

CONCERNING SUNSTROKE.

To the Editor of the Medical Record.

Sir: Many years ago there were general practitioners in the land—a race now nearly extinct. I remember that, when I was practising on the lower east side, just after the war, we had a "heated term," during which sunstrokes were frequent. Persons who had fallen insensible in the street were brought by policemen or passers-by into our offices, and we treated them as best we could, usually in a rear area, by pouring cold water over their heads and rubbing their bodies with mustard and water, while the policeman went for a push-cart or peddler's wagon to take the victim home or to the station house, meanwhile telegraphing for the police surgeon. There were no telephones. I think we saved some lives by this stimulating treatment, before the days of tub baths and strychnine and ambulances. We realized that we were dealing with a condition of profound nervous depression or shock, and we treated the patient accordingly.

Drs. Lembert and Van Gieson, and others who discussed the subject on Thursday evening at the Academy of Medicine, have added largely to our knowledge of the pathology of heatstroke and deserve the highest praise, but for lack of time little reference was made to a very important phase of the subject—that of prophylaxis. When the history was obtainable in the cases related, there were well-marked prodromes—such as headache, dizziness, chromatopsia, thirst, and dryness of the skin.

With this in mind, should we not warn those who are exposed to excessive heat against neglect of these danger signals? It is far better for the laborer to lose his daily wage or even his job than to work at the peril of his life. A day's rest in a cool room (if possible), with the head kept thoroughly wet, may save the life.

Can we not supplement the efforts of the board of health by suggesting to the managers of charitable societies the supreme importance of the simple precaution I have mentioned? Through their visitors they can reach the class who need this instruction the most. They might warn them also against the use of alcohol in any form, as it is certainly a predisposing cause of sunstroke in the vast majority of cases.

The fierce heat of previous summers may be repeated, and we should do our best to guard the public against it.

Henry E. Crampton, M.D.

THE COMMITTEE ON EXHIBITS OF THE BRITISH MEDICAL ASSOCIATION.

To the Editor of the Medical Record.

Sir: In justice to the writer and his committee, I would ask that this have a prominent position in the next issue of your very valuable paper. The same is in answer to an article published in your issue of June 5th, page 809, among the items of the week, having been copied from *The Lancet* of a previous date, and having additional comments, made of course in good faith by some of your staff. Now I might say that I regret that such a paper as *The Lancet* should employ one as their correspondent who would write up an article of this nature, with a vein of condemnation running through it, for the article is quite incorrect and never had the indorsement of the officials connected with the museum committee. Had such information been sought for, the writer of *The Lancet* article would have ascertained that the following was the correct state of affairs:

The museum committee of the British Medical Association has leased the largest building in Montreal, namely, the Victoria Skating-Rink, and is spending a large sum in flooring and tabling the same, having drawn up a neat, colored, lithographed plan, showing the layout, and which is being adhered to. Prices are also being maintained as originally arranged for. Space has been readily taken up, so that at the present moment there will not be much left for any who may "hysterically clamor" for the same. I might say that the American manufacturers have come forward in their usual princely manner, so that those visiting Montreal next August will be able to view one of the largest and finest pharmaceutical exhibitions ever held in North America.

As for the museum catalogue, the committee are more than satisfied with their success regarding it, both as to the style and its financial aspect. We have again to say that the success of this edition is entirely due to our American neighbors.

I presume I have said enough over my name to satisfy the readers of your valuable journal that the statements made in *The Lancet* are far from what is officially given out, and that *The Lancet's* Montreal correspondent would better in the future ascertain the correctness of the articles he sends to his paper, or I am afraid *The Lancet* readers will find Montreal news in the future a very uncertain matter, and therefore detracting very much from your contemporary across the Atlantic.

James M. Jack, M.D.,
Honorary Secretary, Museum Committee.

Montreal, June 9, 1897.

Prolapse of the Rectum.—Torsion as for urethrocele, twisting all the layers of the rectal wall to the level of the levator ani.—*Gaz. des Hôp.*

Therapeutic Hints.

Oxyuris Vermicularis.—

℞ Menthol ..... 0.25 cgm.
Ol. oliv ..... 60 gm.

Or:

℞ Ether. sulphurici ..... gtt. xx.
Glycerini ..... 30 gm.
Aquæ ..... 150 gm.

To inject after an evacuating enema.

—Comby, *La Pratique de la Méd. inf.*, 1897.

Mouth Hygiene.—The following soap is useful for brushing the teeth, etc.:

℞ Medicinal soap ..... 30 gm.
Glycerin ..... 30 "
Alcohol at 90 per cent ..... 15 "
Salicylic acid ..... 1 "
Essence of peppermint,
Coloring matter .....āā q.s.

M. S. Mouth soap.

—Chompret.

Cough of Phthisis.—

℞ Peronin ..... 0.50 cgm.
Aq. dest ..... 100. gm.

M. S. A teaspoonful in a glass of sweetened water before retiring.

Or:

℞ Peronin ..... 0.30 cgm.
Pulv. ext. glycerrhizæ, q.s. ut ft. pil. div. No. xxx.

S. Two or three at bedtime.

—Schroeder, *Therap. Monats.*, No. 1.

Rebellious Epistaxis.—

℞ Antipyrin 0.50
Tannin ..... 1.
Pulv. sacch. alb ..... 10.

M. S. Snuff several times daily.

—Rendu.

Pertussis.—

℞ Pulv. benzoini,
Bism. salicyl .....āā 10 gm.
Quin. sulphat ..... 2 "

Nasal insufflations, at first five times daily.—Moizard.

Hyperidrosis.—

℞ Bals. peruvian ..... gr. xxiv.
Ac. formici,
Chloral. hydrat .....āā ʒ ij.
Alcohol ..... ʒ v.

M. S. Apply with pledget of cotton or in generalized hyperidrosis as spray.

—Heusner.

Vaginismus.—

℞ Cocainæ hydrochlor ..... gr. iij.
Ext. belladonnæ ..... gr. iiss.
Strontii bromid ..... gr. iv.
Ol. theobrom ..... ʒ ij.

M. ft. suppositor. vaginal.

—Touvenaint.

Coryza.—

℞ Cocaini ..... gr. v.
Menthol ..... gr. iv.
Salol ..... ʒ iss.
Ac. boric ..... ʒ iij.

M. S. Use as a snuff.

—Lermayez.

Oil of Cinnamon by inhalation causes diminution in number and disappearance of tubercle bacilli from the sputum in phthisis, and tends to cure the disease by arresting growth of bacilli and by preventing organisms capable of growth from passing along the bronchi to infect new lobules.—Thompson.

Epilepsy.—Voisin maintains that of all drugs the bromide of potassium is the one which has done the greatest service. Germain Sée, Constantin Paul, Dujardin-Beaumetz, agree that bromide of strontium is less active. The potassium salt may be given to the adult up to eight or ten grams daily, and Féré has gone as high as twenty grams.—Delmis.

Bites and Stings of Insects.—Ichthyol in its purity is superior to ammonia.—Ottinger.

Toothache.—

℞ Lini aconiti (B. P.),
Chloroformi .....āā ʒ iij.
Tr. capsici ..... ʒ i.
Tr. pyrethri,
Ol. caryophylli,
Pulv. camphoræ .....āā ʒ ss.

M. S. A few drops on cotton to be placed in the cavity.

Pustular Acne.—

℞ Ichthyol 1
Bismuth subnitrate 1
White precipitate 1
Vaseline 10

S. Apply at night.

—Hebra *and* Ullman.

Hoarseness in Singers.—A light purgative, moderate diet, baked apples; spray throat with:

Cocain. hydrochlorat ..... 1 gm.
Strychninæ sulphat ..... 0.05 cgm.
Aq. dest ..... 100 gm.

and give as pastils to dissolve in the mouth:

℞ Cocain. hydrochlorat ..... 0.05 cgm.
Tr. aconit ..... gtt. x.
Sacch. alb.,
Marshmallow .....āā q.s.

For eighty pastils.

An hour before going on the stage the singer is to take five strychnine granules of one milligram each.—Ricardo Botey.

Habitual Congestion of the face in lupus, acne, varicose conditions, etc.:

℞ Dry extract of hamamelis ..... 0.01 cgm.
Bicarb. of sodium ..... 0.25 "
Calcined magnesia ..... 0.20 "
Powdered ergot ..... 0.05 "
Socotrine aloes ..... 0.05 "
Powdered nux vomica ..... 0.02 "

Two such powders daily for twenty days. Then after an interval begin again.—Brocq.

Vegetations of the Vulva.—

℞ Pulv. savin ..... 1 gm.
Alum. desiccat ..... 25 "
Hydrarg. chlorid. corros ..... 1 "

A more active application is the following:

℞ Pulv. savin,
Iodoform,
Acid. salicylic .....āā p. æ.

—*New York Medical Journal.*

Exuberant Granulations in varicose ulcers:

℞ Argenti nit ..... 50 cgm. to 1 gm.
Bals. Peru ..... 10 "
Vaseline ..... 100 "

—Unna.

Cramps of Pregnancy.—

℞ Chloroform ..... 10 gm.
Bals. Fioraventi ..... 50 "
Alc. camphorat ..... 40 "

M. S. To apply with friction several times daily to the contracting muscles.

—Tarnier.

Sulphate of Quinine in Labor.—Dr. Schwab (*Revue Obstétricale et Gynécologique*, December, 1896) considers quinine as an efficient oxytocic. Quinine stimulates uterine fibres when they have once begun to contract, and hence is useful in lingering labor; but as it does not set contractions going, it is not an abortifacient. Quinine has this advantage over ergot:

the contractions which it sets going retain their normal intermittent character. It acts within twenty-five minutes as a rule. Dr. Schwab gives a gram in two "cachets," taken at an interval of ten minutes. He prescribes this remedy particularly when the membranes are ruptured and it is advisable to end the labor as soon as possible. It is harmless to both mother and child, and, in case of failure, forceps can be used and there is no danger from the tonic contractions of ergot. There is a slight tendency to internal hemorrhage. Coules advocated quinine in abortion with retention of fœtal remnants. Schwab has used it in three cases with good results, but his experience does not enable him to say in how far the quinine contributed to the good results.

Gastric Psychopathies.—The only treatment required is to remove the subject from the influences of his surroundings, and give back to him the habits of normal alimentation by forcing him from the start to take the necessary quantity of food with proper reassurances. Once cured of their phobia, these patients must be overfed and kept upon a tonic *régime*.—SOLLIER.

Rachitism.—

R Phosphorus	0.01	cgm.
Dissolve in		
Ol. amygd. dulc.	10	gm.
Add		
Pulv. gum. arab.	5	gm.
Syr. simp.	5	gm.
Aq. dest.	80	gm.

Each teaspoonful contains half a milligram or one-twentieth grain of phosphorus. Dose below the age of one year, one teaspoonful daily; from the twelfth to the fifteenth month, two; and over two years of age, four teaspoonfuls daily.—KASSOWITZ.

Early Symptoms of Rachitis.—The very young infant and the young child suffer from rachitis in many ways. Insomnia is quite frequent. Many sleep better when carried about on the arm, because the cerebral congestion is lessened in the erect posture. As soon as they are laid down the brain becomes hyperæmic; the child wakes up and makes night hideous. Such children have night terrors on waking up; they are very irritable, easily frightened, peevish, or morose and bad-tempered, sometimes to a degree of moral or intellectual insanity. The suspicion of rachitis ought to be aroused when children perspire copiously all over, or mainly on the head. They rub their heads on the pillow to such a degree as to become bald on the occiput. I wish I could impress the necessity of connecting these signs with rachitis, and the advisability of not waiting for all its most prominent symptoms to appear before the diagnosis is made. The regulation of the diet is the principal remedy, but it is a mistake to believe that a food which does not disturb the bowels is for that reason alone a sufficient nutriment and a safeguard against rachitis.—DR. A. JACOBI, *Archives of Pediatrics*, November, 1896.

Dulcin, a derivative of Berlin blue, is said to be two hundred and fifty times sweeter than sugar. It is a crystallized white powder, fusible at 173 F., soluble in eight hundred parts of water at 15 C., in fifty of boiling water, and in fifteen of alcohol at ninety per cent. It is absolutely inoffensive in the dose agreeable to diabetics. Pastils containing twenty-five milligrams, the equivalent of five grams of sugar, have been made. The taste is much more like sugar than is the case with saccharin. Some of the author's diabetic subjects have used the preparation for a year without any bad effects.—*Journal de Medecine de Paris*, February 7th.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 12, 1897:

	Cases.	Deaths.
Tuberculosis	129	90
Typhoid fever	11	2
Scarlet fever	157	13
Cerebro-spinal meningitis	2	5
Measles	214	10
Diphtheria	261	31
Laryngeal diphtheria (croup)	12	6
Small-pox	4	1
Chicken-pox	18	0

Legislative Summary for New York State.—The public-health law was amended, § 187, so that the article relating to pharmacy shall not apply to the sale by retail dealers or merchants of ammonia, bicarbonate of sodium, borax, camphor, castor oil, cream of tartar, dye stuffs, Epsom salts, essence of ginger, essence of peppermint, essence of wintergreen, Glauber's salts, glycerin, licorice, olive oil, Rochelle salts, sal ammoniac, saltpetre, salts of tartar, sal soda, and sulphur. In the same section, "usual domestic remedies" include also paregoric and essence of anise; but the following were stricken out from the list as it was before: Epsom salts, Rochelle salts, salts of tartar, borax, sulphur, camphor, castor oil, olive oil, origanum, spike, amber, wintergreen, peppermint, wormwood, and glycerin. This amendment is known as chapter 297.

Chapter 282 amends § 20 of the public-health law, relating to local boards of health, so that the members of village boards of health shall continue in office until their successors are appointed, unless removed therefrom; provided, however, that upon failure to appoint a board of health at the first meeting such appointment may be made at any subsequent meeting, in the event of no appointment having been made by the county judge as thereinafter provided. In town boards of health the citizen added to the town board shall be appointed at the annual town meeting instead of within thirty days thereafter, and he shall hold office for one year, or until his successor is appointed. The physician appointed as health officer of the town shall be a resident of the town.

The following amendments to the public-health law did not pass, the numbers referring to sections: 145, subdivision 4, relative to admission to examination, providing that the regents may, in their discretion, accept as the equivalent of the first year of the fourth requirement evidence of graduation from a registered college after four years of general preliminary education in addition to the high-school course fixed by law as a minimum, provided that such college course shall have included not less than the minimum required for such admission to advanced standing in languages, physics, chemistry, and biology, and provided that such substitution be specified in the license; 22, providing that, when one or more towns and the incorporated villages therein unite in one registration district, the registrar of vital statistics of such combined district will be required to make separate returns to the State board of health of village and town certificates of births, marriages, and deaths; 22, allowing a certificate of birth to be returned by the parent or custodian of a child born, if there was no physician or midwife in attendance; 141, State board of medical examiners, allowing representation to the New York State Medical Association; 207*b*, giving the State Pathological Institute privileges as to cadavers from

State hospitals; 145, requiring candidates for examination for the practice of medicine to be citizens of the United States; 211 to 217, new sections requiring proper sanitary conditions and ventilation in public buildings and schoolhouses; 160, making more strict regulations for the practice of dentistry; 43, providing that the State board of health shall appoint inspectors to sample and analyze ale, beer, and porter; 148, relative to licenses, providing that applicants who commenced the prescribed three years' course provided for by section 2, chapter 468, laws of 1889, prior to January 1, 1888, who have attended upon the course prescribed by any registered medical school of this State for at least two years prior to June 1, 1892, who received the degree of M.D. from a chartered medical school prior to August 1, 1895, who received the degree of M.D. from a registered medical school prior to August 1, 1896, and who have been duly licensed by a State medical board to practise medicine, surgery, and obstetrics in such State, may without further examination, on payment of $10 to the regents, and on submitting such evidence as they may require, receive from them an indorsement of their licenses or diplomas, conferring all rights and privileges of a regents' license issued after examination; 2, allowing the governor to appoint five members of the State board of health, instead of three; 3, giving a salary of $3,000 to each of the five members to be appointed by the governor; 6, giving the State board of health power to declare garbage and fertilizer plants as nuisances.

A bill failed to pass providing for bath commissioners in cities of the first and second class. Also a bill constituting the State board of health and the State engineer a water board to investigate and report upon a supply of pure water for the principal cities and towns of the State.

Section 412, subdivision 1, of the penal code was amended so as to forbid the use of what are known as "knock-out drops." The law, chapter 42, reads as follows: "A person (other than a duly licensed physician or surgeon engaged in the lawful practice of his profession) who has in his possession any narcotic or anæsthetic substance, compound, or preparation, capable of producing stupor or unconsciousness, with intent to administer the same or cause the same to be administered to another, without the latter's consent, unless by direction of a duly licensed physician, is guilty of a felony, punishable by imprisonment in the State prison for not more than ten years. The possession by any person (other than as exempted in the foregoing subdivision) of any such narcotic or anæsthetic substance or compound, concealed or furtively carried on the person, is presumptive evidence of an intent to administer the same or cause the same to be administered in violation of the provisions of this section."

The same code was sought, but without success, to be amended so as to forbid any one to commit any act injurious to the public health, to public morals, etc. The following amendments to the code of civil procedure did not pass: Abolishing coroners' juries; requiring surrogates, besides funeral expenses, to pay all debts against the estate for services rendered and materials furnished by physicians, pharmacists, and nurses; forbidding pharmacists, as well as physicians, from disclosing confidential communications; exempting lawfully practising physicians and surgeon dentists from jury duty.

The pharmacists had a bill introduced reducing their licenses under the Raines liquor-tax law, but the amendment was passed as one of the general amendments to that law.

A law was passed permitting the examination of dental students matriculated prior to January 1, 1896, under the conditions as to preliminary education in force at the date of their matriculation; but a bill requiring persons practising dentistry to display professional signs failed to pass.

The administration of the State Veterinary College was changed as to State funds; but a bill creating a State veterinarian and several bills relating to the practice of veterinary medicine and surgery failed to pass. General amendments to the plumbing act also failed.

An amendment to the tax law was passed, providing that a lot or building owned and actually used for hospital purposes, by a free public hospital, depending for maintenance and support upon voluntary charity, shall not be taxed as to a portion thereof leased or otherwise used for the purposes of income, when such income is necessary for and is actually applied to the maintenance and support of such hospital.

Perhaps the most important bill that did not pass was that of Senator Sullivan's, relating to and defining dispensaries, requiring them to be incorporated or licensed, forbidding their establishment in a "drug store" or a "tenement house," providing that the word "dispensary" shall only be used in connection with an incorporated or licensed dispensary, that persons shall not obtain relief from dispensaries by false representations, and that a violation of this act shall be a misdemeanor; also empowering the State board of charities to make rules and regulations and to annul or suspend incorporations and to revoke licenses.

Among the other bills that did not pass were the following: Repealing the charter of the Pedic Society of the State of New York; regulating the practice of optometry in the State of New York; requiring an analysis of patent medicines; forbidding the manufacture and sale of cigarettes; forbidding the deposit of dumpage, garbage, and refuse matter within the territory of any town, village, or city, without the consent of the board of health therefor.

Laws relating to New York City were passed as follows: Amending the charter of the Society of the Lying-in Hospital relative to subscriptions, the election of subscribers as members, and the election of physicians and surgeons; amending section 484 of the consolidation act, so that every hotel, theatre, hospital, asylum, or school, hereafter built, must be fireproof if over seventy-five feet high; exempting the real estate of the Montefiore Home for chronic invalids from taxation, assessments, and water rates; authorizing, by condemnation proceedings if necessary, the acquirement of a site in the twelfth ward for a public hospital; amending the Greater New York charter so that the board of pharmacy shall be constituted, two members by the New York College of Pharmacy, one member by the German Apothecaries' Society, and two members by the Kings County Pharmaceutical Association, and providing that three-fifths of surplus and penalties shall go to the New York College of Pharmacy and two-fifths to the Brooklyn College of Pharmacy; appropriating $5,000 for the use of the health officer of the port of New York, for the purpose of preventing the introduction of infectious and contagious diseases; allowing, from the city funds, forty cents a day to the Mt. Sinai Hospital for each charity patient, the aggregate not to exceed $35,000 a year.

These bills relating to New York City did not pass: Amending section 1,776 of the consolidation act so that if any body is found lying in any street, park, or public place, or in any building where the same will interfere with the free use thereof, the officer in command of the police precinct wherein such body is found may cause removal to be made; establishing a municipal laboratory, with one department of chemistry and toxicology, and another of pathology and bacteriology; for the relief of the Beth Israel Hospital Association from taxes and water rents;

appropriating $75,000 of State money for new quarantine buildings on Swinburne Island; allowing, from the city funds, $1 a day to the Seton Hospital for charity patients, the aggregate not to exceed $30,000 a year; providing that persons retired from the health department may have half-pay pensions not to exceed $1,200 a year.

The charter of Brooklyn was amended so that the Manhattan Hospital and dispensaries were added to those already drawing appropriations. These bills failed: Changing the corporate name of the Central Throat Hospital and Polyclinic Dispensary of Brooklyn to Central Hospital and Dispensary; creating a board of physicians and surgeons for the city of Brooklyn, defining the duties thereof, and abolishing all surgeons connected with any of the departments of said city except the department of health; converting the Inebriates' Home for Kings County into a State institution, and establishing the New York State Hospital for Dipsomaniacs and Inebriates; amending the charter of Brooklyn, relating to the erection and maintenance of public hospitals for the treatment of persons suffering from infectious or contagious diseases.

Outside of New York and Brooklyn, these laws were passed: Authorizing the commissioners of the almshouse of the city and town of Newburg to pay to Saint Luke's Home and Hospital of Newburg the sum of $1,000 per annum, for the care and maintenance of indigent persons; authorizing the raising and appropriating by the towns of Hempstead, North Hempstead, and Oyster Bay of moneys to support inmates of the hospital of the Nassau Hospital Association, at Mineola, in the town of North Hempstead; allowing not to exceed twenty governors of the Albany Hospital, and authorizing the park commissioners to set apart a site for a new building; granting a charter for the House of Providence to establish hospitals, etc., in Onondaga County; allowing the supervisors of Richmond County to give not to exceed $10,000 a year to the S. R. Smith Infirmary; a new midwifery law for Chautauqua County; amending the Erie County midwifery law, so as to increase the examiners from five to nine, the term of office to be three years.

These bills did not pass: Charter for the Lucy A. Wood Rowe Memorial Association of Troy; allowing the Riverview Sanatorium at Fishkill to treat inebriates.

The supply bill had an item (which was passed) of $6,000 for the Pasteur Institute, in full, for services. The same bill contained an item of $10,000 for the faculty of the medical department of the University of Buffalo, for the equipment and maintenance of a laboratory to be devoted to an investigation into the causes, nature, mortality rate, and treatment of cancer, and the salaries of officials of the same. This item was vetoed by the governor in these words: "I cannot approve a proposed policy which requires the State to engage in the investigation of the causes of various diseases with which the human family is afflicted. I think that the interest of the people themselves and the skill, intelligence, and enterprise of physicians may be depended upon to make such investigation."

Abortion Dangerous in England.—A member of a distinguished family in England telegraphed to a no less distinguished dermatologist: "How can I abort eczema?" The police, getting wind of such a dispatch being sent, and thinking "Eczema" was a woman's name, placed the gentleman under arrest. The tragedy itself was, however, aborted by a prompt explanation that ex-Emma and eczema were not the same.

X-Rays Prevent Operation.—Dr. Vasseur, of Marseilles, swallowed a bone, which lodged in his throat. Thinking it still there, an operation was about to be undertaken, when the rays were utilized and showed that the foreign body had passed on, leaving only its irritation behind. An operation was thus obviated.—*Deutsche medicinische Zeitung.*

Unusual Foreign Body in a Pig's Stomach.—The Paris correspondent of the *British Medical Journal* relates that two banknotes of £40, enclosed in a metal sheath, were recently found in the stomach of a pig which was slaughtered immediately after it had been bought at a fair. The notes were in a perfectly clean condition, and the sheath was but slightly affected by the action of the gastric juice.

The Struggles of Sir James Y. Simpson.—A life of the late Sir James Simpson has just been published, written by his daughter, and contains many interesting facts connected with his life not generally known before. James Simpson was the son of the village baker at Bathgate in Linlithgowshire. At the age of fourteen he went to the University of Edinburgh, and was one of the hard-working, frugal race of Scotch scholars. He lived on $50 a year, his only extravagances being books. A significant entry is quoted from his diary; it is as follows: "Finnan haddies, 2*d.* (4 cents); bones of the leg, £1 10*s.* ($7.50)." In 1838, when he was twenty-seven years old, he became lecturer in obstetric medicine in the Extra Mural School. Two years after he was appointed professor of obstetrics at the university. In 1847 he discovered chloroform. At the early age of fifty-eight he died, his end hastened by overwork.

How the Smoke Test is Made.—In Mr. Wingate's communication on "The Insidious Influence of the Soil on Health" in the MEDICAL RECORD of May 1st he speaks of making a "smoke test" on a suburban residence. If not too much trouble will you kindly inform me how that test is made?

A. H. DORRIS, M.D.

LINCOLN, NEB.

[A small portable machine worked by a fan is placed on the roof of a building and the smoke made by burning tarred paper and sulphur is forced down the soil pipe and through all the branch pipes, and drains, under pressure. If there is the smallest leak in the plumbing, or if, as often occurs, any pipe is choked with rust, grease, or other obstruction, the defect can be exactly located. It is far more accurate than the peppermint test, especially as the latter is usually made.—C. F. WINGATE.]

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE TREATMENT OF ACUTE BRONCHO-PNEUMONIA IN YOUNG CHILDREN.[1]

BY HENRY DWIGHT CHAPIN, M.D.

PROFESSOR OF DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE frequency of broncho-pneumonia, as well as its serious nature, makes the subject of treatment important. In early life not only do inflammations spread rapidly by continuity along the bronchial mucous membrane until soon the ultimate tubes and alveoli are involved, but the histological structure of these organs is favorable to quick inflammatory action. Thus the bronchial tubes are large, with much development of interstitial connective tissue, while the alveoli are relatively small, with thick walls that harbor many capillary blood-vessels. In young subjects the bronchi are apt to get plugged with mucus which is not easily expelled, and this may lead to collapse of adjacent alveoli and spread of the pneumonia. The walls of the chest are soft and yielding, so that the movements of the thorax in the act of respiration easily become embarrassed, especially in rickety children. Owing to the fact that the physical signs of broncho-pneumonia may be obscure, especially in an early stage, the diagnosis is often not made until the disease is well advanced. This is unfortunate, as early recognition of the grave nature of the complaint, a guarded prognosis, and vigorous measures to sustain the patient are at once demanded. In addition to merely physical signs, a careful observation of the rational symptoms is of the greatest utility. Simple acceleration of the respiration and a change in the normal ratio between the respiration and pulse will help in the way of an early diagnosis, often before the physical signs are clearly recognized. This is important, as the physical signs vary widely according to the location and dissemination of the disease process. Thus in cases in which the interstitial alveolar connective tissue is more largely involved than the alveoli, the few fine râles heard only on deep inspiration may easily escape detection, but there will always be quick and somewhat labored breathing.

As the disease advances, the dyspnœa, dilatation of the alæ nasi, recession of the soft parts on inspiration, high temperature, and prostration will give the diagnosis and indicate the treatment even in those cases in which the physical signs are uncertain and shifting. The treatment resolves itself into sustaining the vital forces, at the same time following the indications that may arise in connection with high temperature and with the disturbed functions of the heart and lungs. The latter are largely mechanical, and the embarrassment of these organs can often be helped by timely efforts at relief. The general line of treatment here mentioned has been followed in several hundred cases in hospital and private practice. The treatment directed toward the vital forces is, of course, supporting. Frequent administration of easily assimilable nourishment is indicated. Milk, meat broths, expressed beef blood raw fresh eggs well beaten, and any similar substance may be used according to the judgment of the physician or taste of the patient. When the fever is high, kumyss, matzoon, or buttermilk is often relished. Water, either plain or aerated, is grateful and may be freely administered. A mistake is sometimes made of crowding the food too much in our zeal to sustain the patient. If an excess is given the patient is distressed by fermentation, and then flatulent distention of the stomach and bowels will further impede the already embarrassed respiration. Even after absorption takes place, if the blood is overloaded with nutritive material, a further burden may be placed upon the lungs in the aid required for its assimilation. Considerable judgment is often required to push feeding just to the proper point. No drug that will irritate the stomach or interfere with digestion must be given. Any temporary benefit that may be obtained by such administration will not count against loss of strength following interference with digestion and assimilation. Depressing drugs must not be given to infants, and be very carefully employed with older children. Stimulants and supporting drugs that aid in the maintenance of the vitality have also a favorable effect upon the disturbed action of the heart and lungs, and will be mentioned in such connection.

Considering first the respiratory function, the indication is to soothe and clear out the irritated bronchial tubes, promote the liquefaction and absorption of the exudate, and prevent if possible the spread of congestion. Anything that will promote the free access of pure air to the crippled lung will be a help. One aid consists in keeping free and clear the entrance to the respiratory tract—the nostrils. A little extra secretion that is apt to collect in these parts tends to embarrass the breathing. In slight occlusion a few drops of liquid albolene instilled into the nostrils will be sufficient, especially in young infants. In other cases free irrigation with a warm alkaline wash, such as half a teaspoonful of borax to a cup of water, will produce a beneficial effect upon the respiration. The air of the room should be as pure as good ventilation can secure. Such ventilation may be accomplished by opening windows from the top or by open fires. As long as direct draughts are avoided and the temperature of the room is maintained at 68 to 70° F. in winter, too much fresh air cannot be procured. A room with a sunny exposure is to be preferred, as the air is softer. In children under four or five years there is no expectoration, and yet great relief will follow if the mucus that collects in the larger tubes and is occasionally coughed up can be removed by the finger of the nurse rather than swallowed. The respiratory muscles are weak and their action is much impeded if mucus collects in the tubes, perhaps followed by congestion and atelectasis of adjacent areas of lung. The salts of ammonium seem to be the most valuable agents in aiding to clear the bronchi. I never employ the muriate on account of its nauseous taste, but rely upon the carbonate or aromatic spirits of ammonia. These preparations are given frequently in small dose. The carbonate is prescribed in watery solution and admin-

[1] Read at a meeting of the New York County Medical Society, April 26, 1897.

istered in milk. A baby of one year can take a grain every two hours, or even every hour, if the symptoms are urgent; the irritating qualities seem to be lost when it is given in this way. Perhaps even better are from five to fifteen drops of the aromatic spirits given in water, which makes a refreshing and stimulating drink. One of the best methods of easing the bronchial secretions is by inhalations. A constant teasing cough is relieved by breathing warm moist air. An ordinary croup kettle will serve the purpose, and a few drops of spirits of camphor or turpentine added to the water in the boiler will enhance the effect. The most satisfactory method of inhalation in my hands consists in employing the Whital & Tatum No. 3 vaporizer. In this apparatus, just over the boiler and separated from it by a perforated diaphragm, is a small receptacle holding a fine sponge, upon which is placed any substance that is to medicate the steam. Two parts of pix liquida in one part of alcohol make a good application with which to soak the sponge. The vapor generated by the boiling water passes through this sponge, and the fumes of the tar added to it are very agreeable to the respiratory organs. The inhalation may be given every two or three hours, or much oftener, in highly irritable cough. If the child objects to having the vaporizer near at hand, a partial tent can be extemporized by an umbrella. The tendency toward hypostatic congestion should cause the position of the child to be changed as much as possible. Infants must not be allowed to remain all the time in their cribs, but should be occasionally held in the arms of the nurse. Counter-irritation to the chest walls seems to give some relief. The skin may be reddened by the application of mustard pastes, or in urgent cases dry cups may be employed. In average cases the skin is thoroughly rubbed with warm camphorated oil, and a jacket of cotton batting, covered with oiled silk, applied. While this may not have any effect upon the inflammatory action, it keeps the skin at a uniform temperature and seems to add to the comfort of the patient. In severe cases the respiration fails, shown by rapid and labored breathing with more or less cyanosis. Here ozone or oxygen is indicated, as it tends to stimulate the respiration as well as temporarily relieve the blueness caused by the collection of carbon dioxide. As is well known, carbon dioxide is produced more abundantly in early life than in later years; hence the lungs have relatively more work to perform. Not only are the lungs crippled in their natural work in pneumonia, but the high temperature and inflammatory action increase still more the production of carbon dioxide, so that great strain is put upon the parts of these organs that are still able to perform their function. Add to this the filling of the bronchial tubes and the poor development of the respiratory muscles, and we can understand how a weakening and failure of respiration are what is constantly to be dreaded. The blood charged with carbon dioxide tends to sluggish movement in the lungs, soon followed by exudation and emigration into the alveoli and tubes. The fatality would be much greater were it not for the compensation of a vigorous heart and blood-vessels, and here is where the greatest advantage can be pursued in treatment. The right heart, which has to bear the brunt of the pulmonary obstruction, is relatively strong in early life, while the arteries, being healthy and elastic, aid the action of the left heart.

Thus in children with any form of pneumonia, heart failure is apt to be secondary to respiratory failure, just the reverse of what usually happens in adults. As the respiration becomes weaker and the lung more congested, the blood collects in the veins from the pulmonary obstruction, and the indication is to prevent stasis in the lungs by stimulating the heart, at the same time drawing off the blood as much as possible into the arteries. This may be accomplished by dilating the arteries, which, by lessening the amount of blood in the veins, takes off some of the pressure from the engorged pulmonary circulation. Nitroglycerin is thus most valuable in relaxing the arterial system, and hence to a certain extent emptying the veins into the arteries. One-two-hundredth of a grain may be given every two hours, or oftener in urgent cases, to an infant of one or two years. I have recently given nitrite of sodium, as it is reported to be more prolonged in its action than the nitroglycerin. Aconite will likewise relieve arterial tension, but is depressing upon the heart and should be carefully given in the pneumonia of childhood. One of the best stimulants to the heart and respiration, as well as the nervous system, is sulphate of strychnine. This is one of the most valuable drugs we possess in the treatment of pneumonia, in combining this threefold beneficial action without increasing arterial tension. One-four-hundredth of a grain of sulphate of strychnine may be given to a baby of a year old every two, three, or four hours, and even larger doses may be administered in urgent cases, as tolerance is soon established. Alcohol is also one of the best stimulants, and a one-year-old baby may have thirty drops of whiskey, well diluted in water, every two hours. This may be increased or diminished according to indications. In septic cases and in those marked by great prostration, alcohol is beneficial in large doses in sustaining the vital forces and the heart, and at the same time relaxing the arteries. In average attacks, however, it is best not to push alcoholic stimulants, as they frequently have the effect of lowering the tone of the digestive organs, especially if given for too long a time. Camphor and caffeine are occasionally to be given, and may be substituted for the alcohol. Digitalis is administered carefully, if at all, on account of its tightening effect upon the arteries, which increases the work of the heart as well as the venous congestion. If employed, it should be combined with a vasodilator.

With reference to temperature, no treatment is indicated in average cases. Especially is the use of the wood-tar derivatives to be deprecated. They are apt to be more harmful in their effects than the high temperature if let alone. Phenacetin is sometimes useful in small doses for the relief of nervous irritation and pain, and may thus be given combined with a stimulant. The application of cold is much the safest and most effectual way of reducing high temperature. Placing an ice poultice, made by mixing finely cracked ice with flaxseed meal, around and on top of the head is often effectual. This likewise relieves, to a certain extent, the deleterious effects of very high temperature upon the brain and nervous system. I have often used cool compresses around the chest, and when this procedure is properly followed it is rarely if ever necessary to employ the bath or the general cold pack. The child is stripped, wrapped in a blanket, and placed upon a table. A stimulant is given and the feet are placed in contact with hot bottles. A compress sufficient in size to surround the chest is plunged in water from 80° to 90° F., and applied about the chest. This is changed every ten or fifteen minutes, the temperature of the water being gradually lowered until the desired result is obtained. In cases of intra table fever, it may be necessary to reduce the water to 40° F. As long as the hands and feet are kept warm, the cool compresses may be applied, but coldness of these members is a contraindication to the local or general application of cold. When the temperature is reduced to 102° or 103° F., the compresses are not renewed, but are kept in position in case the temperature ascends again to an unsafe degree. In the mean time they act in the same way as a cotton-batting jacket.

I have sometimes kept a child in this position for several days, applying cold when indicated by hyperpyrexia, which tends to recur. This clinical fact is probably explained by a mixed infection, and not the pneumococcus alone being responsible for the disease. Wide variations in the temperature point to the former condition. When the temperature rises to 105° or 106° F., the respirations and pulse become extremely rapid, and unless the fever is quickly reduced there will be spread of the disease as well as great prostration. The reduction of the temperature by one or two degrees will sometimes mean 20 or 30 less respirations to the minute, with corresponding improvement in the circulation and general nervous tone. The cool compresses to the chest produce this result more safely and handily than any other method with which I am familiar.

To sum up, the treatment resolves itself into careful nourishment and support; in keeping the respiratory passages as clear as possible, from the nose to the ultimate bronchial tubes; in trying to maintain as good an action as possible of the lungs, and avoiding increased congestion and pulmonary obstruction by means of proper stimulation of the heart, and equalizing the balance of the circulation between the veins and arteries; in attacking hyperpyrexia. Frequent doses of strychnine and nitroglycerin are the drugs found most useful.

A STUDY OF MAXIMUM *X*-RAY EFFECTS WITH THE STATIC MACHINE.

By S. H. MONELL, M.D.,

BROOKLYN, N. Y.,

CHIEF INSTRUCTOR OF THE BROOKLYN POST-GRADUATE SCHOOL OF CLINICAL ELECTRO-THERAPEUTICS AND ROENTGEN PHOTOGRAPHY; FELLOW OF NEW YORK ACADEMY OF MEDICINE, KINGS COUNTY MEDICAL SOCIETY, ETC.

In the MEDICAL RECORD of February 6, 1897, I presented general memoranda of my observations with Crookes tubes and static machines prior to December 15, 1896, and expressed conclusions based upon experiments in adapting vacuum tubes to the discharges of the therapeutic Holtz machine so that satisfactory *x*-rays could readily be obtained without failure, fluctuations, or puncture of the tube.

These conclusions, which are confirmed by time, were: 1st. That no method now known, however costly, will surpass the efficiency of the Holtz machine with tubes suited to it. 2d. That the Holtz machine and tubes adapted to its maximum discharge will readily and economically equal or surpass the best *x*-ray effects producible by any or all other means of electrical excitation with any design of tubes that can now be obtained.

In that report no attempt was made to consider maximum effects or to determine the ultimate capability of powerful static bombardment in high vacua, and the results then spoken of can now be obtained by any physician employing similar apparatus and methods. It is of interest, however, to consider what are the present ultraordinary effects at the disposal of the surgeon who seeks to locate promptly a bullet in the skull, thorax, or pelvis, or to make an instantaneous examination into any of the larger joints and deeper structures of the body. It is becoming more and more manifest that beyond the ordinary *x*-radiance which suffices for examinations of the small joints and thinner portions of the body, there is an urgent demand for facilities to invade with the eye and the fluoroscope the densest opacity that the human trunk presents. All physicians now recognize this fact and eagerly inquire what can be done in this respect. I shall here set forth the notes of some recent experiments.

Given a powerful Holtz machine and the best fluoroscope, *x*-radiance beyond the ordinary depends upon the tube and the operator's skill. A high-efficiency Crookes tube is therefore the most essential factor in the maximum surgical utilization of *x*-rays. It is an instrument of extreme delicacy and variable nature, and is adapted to the uses of the expert rather than the beginner. To deserve the term high efficiency the selected tube must readily and profusely produce *x*-rays of constant and steady action which will penetrate powerfully to a considerable distance and give sharp detail and definition to shadows. Such a tube requires a high vacuum, and, while tubes of lower resistance can be kept in continuous action with the static machine for more hours than any operator would desire, the achievement of higher intensities is accompanied by some limitation in the time during which uninterrupted excitability can be maintained.

Intensity in effect within vacuum tubes is proportionate to intensity of cause, and the *x*-ray potential rises toward the maximum in proportion to the expenditure of high potential electrical energy. A high-resistance state is therefore required for maximum results, and it will be found to demand a reasonable practice in tube manipulation to operate a really magnificent high-vacuum tube and produce its startling and grand effects. As the same demand for reasonable skill exists in all fields of instrumental work, the fact can hardly be cited as a deterrent peculiar to Crookes tubes. In testing a large number of tubes which have been made according to my suggestions, and which physicians can now readily obtain, I have observed the following effects under favorable conditions:

(1) A completely darkened room, daylight and gaslight excluded, and the eyes reasonably guarded from the bright glow of the tube, so as to prepare them for the differentiation of dim shadows.

(2) A competent fluoroscope. That used by me at present is one of the improved barium-platino-cyanide screens recently introduced.

(3) A high-efficiency Crookes tube developed to its maximum of *x*-ray generation.

(4) An eight-plate Holtz machine producing its maximum current.

(5) A pair of the usual interrupters correctly adjusted to suit a given tube and current.

Tests.—My test piece is a strip of half-inch pine board backed with assorted metallic objects of various sizes, from a small point to a medium-sized key, and wound with a dozen spirals of fine copper wire.

The shadow of the key is visible through the board at thirty-six feet distance from the tube; at fifteen feet the small objects and fine wires show plain definition; at five feet the board is like thin porcelain held in front of an incandescent lamp; and at six inches the test piece appears almost in a glow of light.

Placing Webster's "Unabridged Dictionary" and two encyclopædia volumes six inches in front of the tube, I have an aggregate of thirty-six hundred pages of paper plus six heavy board covers, through which the objects upon the test piece against the screen are clearly defined to the eye. Through a metal footplate electrode, composed of two heavy layers of sheet copper one inch apart, the objects on the test piece are visible twelve to twenty inches from the tube.

The mechanism of the hand, wrist, arm, ankle, and all small and thin parts appears upon the screen three feet from the tube. Between the distance of thirty-six and twelve inches from the tube, all gradations of transparency, such as the surgeon may require for these parts, are secured. When the object is nearer than twelve inches, the bones become sufficiently transparent to allow the ready detection of a broken needle embedded in the radius or ulna, or bones of

the hand, one of the most difficult of foreign bodies to locate with the fluoroscope.

The shoulder and knee-joints are quite distinctly shadowed at three feet from the tube, and the increase in transparency up to six inches is adequate for full surgical examination.

The head of a grown person viewed through the screen from side to side at all distances, from three feet down to four inches between the tube bulb and the ear, shows increasing transparency, until not only the lighter portions—frontal sinus, antrum, nose, etc.—are penetrated, but any small metallic object placed opposite the thickest part is plainly seen wherever it is moved, showing that a bullet anywhere in the head could be quickly located with ease. At the maximum of radiance the transparency of the skull is about equal to the transparency of the hand as exhibited to me by operators employing tubes of ordinary efficiency with medium-coil currents.

The spinal column and the osseous detail of the trunk are visible in clear outline and may be studied in different degrees of transparency at all distances up to three feet. The detection of a bullet, fracture, or dislocation by the fluoroscope in even the densest parts of the body is thus assured with these rays.

At between three and four feet from the tube the heart of an ordinary man is seen in nearly normal position and size. In a man of spare build it is as plainly seen, in as sharp detail and exact definition, as would be a pear or acorn held behind the fluoroscope. The heart shadow is magnified (as are all other objects) when inspections close to the tube are required by low-efficiency apparatus, but when thirty or forty inches may intervene between the eye and the reflector the mass of the heart stands out in clear and undistorted relief upon the fluorescing screen. The MEDICAL RECORD of April 10th contains an article upon "Fluorography for Determining the Position, Size, and Movements of the Heart." It describes quite a complicated and rather uncertain process of mapping or tracing the heart outline, a process which consumes, it is said, about fifteen minutes' time with an expert, and can hardly be accomplished at all in many subjects. I would like to quote the technique in full, but it fills seventy lines of the MEDICAL RECORD, and space forbids. With a high-efficiency tube my own technique consists in seating the patient on a stool a couple of feet in front of the tube, with the screen over the heart anteriorly. I then sit down and look into the fluoroscope while the patient shifts forward, until the heart shadow is most distinct. That is all there is to it. As the whole outline is clear cut and sharp, there is no need of tracing paper, the draughtman's art, or the delay of the fluorographic method so interestingly reported as the outcome of a month of experiment and study. I do not need to "map out the heart with a tracing pencil," for I can see it with sufficient plainness in almost every subject examined; but the recent discussion before the Academy of Medicine illustrates the difficulties against which operators without high-efficiency apparatus have been earnestly contending in their enthusiastic desire to harness the *x*-ray to important medical uses.

The advantages of great penetration, sharp definition, and wide radius of action are too obvious to require comment (for every one is seeking them), but one of the interesting side effects in my own experiments has been the observation of my own vertebræ, shoulder-joint, clavicle, ribs, and heart movement, as well as outlines of the skull bones through their covering. The shadows thus seen are distorted by the necessary position of the screen, and are by no means so clear as when witnessed by a second person who does not have to crane his neck to peer into the fluoroscope. A modified shape of this instrument could, however, easily be devised to enable every physician either to note his own anatomy or gratify others who might desire to do so.

In respect to photographic work, it is sufficient to say that by the aid of *x*-rays that penetrate rapidly to long distances the object may be placed at more than ordinary distance from the tube if desired, and the familiar exposure time may be reduced. At sixteen and a half inches I have secured the ribs of a man upon the negative in one and a half minutes, but for a full and satisfactory picture of the trunk of the body, showing all the osseous detail, five minutes should be allowed, with the sensitive plate twenty or twenty-five inches from the reflector. The pelvis and knee have thicker bones, and exposure times for these must be governed by the result desired, but any picture that formerly took thirty minutes with good apparatus can now be made in one-third of the time.

These capabilities indicate an efficiency which will prove helpful for rapid surgical examinations in all parts of the body. To reduce penetration when examining thin parts and small joints, we have but to slow down the machine a little to reduce the potential of the current; or we may remove the object farther from the tube, for penetration is inversely as the square of the distance from the source of *x*-rays, and if objects of small opacity are too transparent when within the field of maximum radiance, it is simpler and easier to move back ten, twenty, or thirty inches from the tube than to modify the action in any other way. To examine thicker objects requiring maximum penetration, revolve the plates at the greatest safe speed and approach the object and fluoroscope as near to the tube as proper definition requires.

With regard to the tendency of a high-efficiency Crookes tube to increase its already high resistance during active electrical excitement and the consequent increase of difficulty in its satisfactory operation, I may say that such a tube should glow promptly upon starting the machine into action, and maintain an even and brilliant radiance during a reasonable length of time, or be caused to do so by such reasonably brief manipulation as nearly every tube in frequent use requires. By this is meant a period varying from a few seconds to five minutes. If occasionally, at very rare intervals, I consume ten minutes in establishing the desired action, I do not complain, but never spend more than this time upon a single tube to get it started. When it is once in proper action, I expect it to maintain its radiance as long as wished, without stopping the machine. From thirty minutes to two hours may be considered long enough for practical purposes, for coil tubes are usually rested at very short intervals.

When, however, a high-efficiency static tube is successfully started into action and is pushed for magnificent effects by an expert operator, who drives through this fragile cell the most furious electrical tornado that can burst forth from the flying wheels of a powerful Holtz machine, the polarization may suddenly become rapid and the tube may revolt at further work. It then needs treatment according to the phenomena displayed. A single tube will not work daily

with uniform efficiency, for very near the border line of maximum effects there may be developed a resistance so great that the current will not establish a circuit through the vacuum. It does not, however, permanently disable the tube when this border line of high excitability is once passed, for again and again throughout months of service we can reduce the resistance, bring back the proper electrical state, and repeat for an indefinite number of times the best effects that were obtainable in the beginning.

When the original construction and exhaustion of a Crookes tube has been demonstrated to be correctly adapted to the static current, we may feel confident of securing in future work the equal of the best radiance that was produced when the earliest test was made. This fact is reassuring when at length we find that a time-tried and priceless tube appears to have lost its glow forever. At this point some operative experience and skill are a source of confidence and serenity, for in two or three minutes often, and almost certainly within ten minutes, we may coax back the radiant glow as steadily as before. If overuse has altered the resisting state until it will not yield immediate surrender, the expert does not hover in eager and anxious uncertainty over the vacuum, but at once recognizes the nature of the functional derangement and proceeds according to the indications for treatment; and if the tube finally needs a fresh exhaustion, this involves but a small cost.

It constitutes a great economy of time as well as an unspeakable comfort to be able to step from guesswork to certainty in understanding the behavior of a Crookes tube; to know at a glance or by a moment's test whether it is a good tube or a poor one; whether any apparent revolt is acute or chronic; whether it is past remedy, or whether it can be quickly recalled out of apparently hopeless aberration and illuminated again with the glow of its best estate. When we know at once what is the matter with a refractory tube and how to correct it, we have made a long step toward satisfactory *x*-ray work. It is the state of doubt as to the significance of phenomena visible within a tube which perplexes and distracts the uninstructed physician. Maximum effects of any kind, or such as I have referred to above, are now equally within reach of any physician who understands the management of *x*-ray tubes. My remarks here do not apply to occasional flashes of great radiance followed by days without again witnessing a similar view, but report effects which are reproduced at will at different times with different tubes, and as often as the conditions are made to conform to the limitations of the fluoroscope.

Simplicity, convenience, and safety in static machine work stand out in strong contrast with other methods of *x*-ray generation. During the height of current action the operator may safely touch any connecting wire and with impunity hold the bulb of the glowing tube in his hand; nor does the current need to be switched off every five minutes to cool the tube. When I once start a demonstration with a given tube I do not stop the current till I get through, and thirty minutes' continuous action produces no apparent necessity for any cooling process.

In closing this report I may again repeat what I stated in my former article, that since September 1, 1896, I have never punctured or broken one of my own tubes in regular work. I may also add that I find the improved interrupters, as somewhat modified by my further experience, a decided convenience in adjusting the current strength.

REPORT ON HYDROPHOBIA.[1]

By CHARLES W. DULLES, M.D.,
PHILADELPHIA.

It is now eleven years since the Medical Society of the State of Pennsylvania, by resolution, requested me to continue the studies in regard to hydrophobia of which at that time I made a report, and to communicate the results of these studies to it from time to time. Several of these communications have already been made, and I now wish to report the cases of so-called hydrophobia that I have collected and studied during the two years since the meeting in 1895. The accumulation of these cases has required a great deal of labor, and I have taken pains to verify, as far as possible, the facts, and to correct the errors of published accounts by correspondence with the physicians who have had the care of the cases. I have sent to a large number of physicians a blank, in order to obtain answers of a systematic character. Many of my correspondents, in addition to filling up these blanks, have communicated with me by letter, explaining points outside of those referred to in the blank, or giving fuller details than the blank permitted.

I think it proper to remark (as others may) that there have come to me only those cases occurring east of the Mississippi River. I have at times had information of cases further west, but either the disease is very infrequent in the far West or the reports of cases do not reach the East as do those of cases occurring in the latter section.

I find that I have collated forty cases. Of these, twenty-three occurred in the States of New York, New Jersey, and Pennsylvania; six occurred in Ohio, Kentucky, and West Virginia; four in Maryland; one in Washington, D. C.; two in Georgia; two in Louisiana; and one in Illinois. A large number of these cases, to my mind, fall plainly under the head of spurious cases, but they have all been considered by those who treated them, or by their friends, as genuine cases of hydrophobia. For example, a little child died last year at the Pennsylvania Hospital, in Philadelphia, of what was believed to be hydrophobia by the medical men in attendance, though experimental investigations made by the then bacteriologist to the Board of Health of Philadelphia, Dr. Bolton, led to absolutely negative results; and, according to the test which is spoken of as infallible by those who follow the lead of Pasteur, the child could not have died of hydrophobia. Another case was that of a man believed to have died of hydrophobia, but who was found by a coroner's inquest and autopsy to have died of pneumonia and uræmia.

Two very striking cases occurred within a year at Duryea, near Wilkes-Barre, Pa. One was that of a boy bitten by a dog that had no symptoms of rabies whatever, who was sent to New York and treated in the Pasteur Institute, and soon after his return (May 12, 1896) died of paralytic rabies—a form of rabies that was unknown before the time of Pasteur's so-called prophylactic treatment. The other boy died March 14, 1897, six or eight weeks after a dog bite, and my correspondent in Duryea writes me that a dog and three other children bitten at the same time are still alive and well. The boy that died lived within five hundred yards of the boy that died in 1896, and he had been so talked to about hydrophobia and was so nervous that he was in constant dread of the disorder and was afraid to go abroad.

A specimen of an imperfect account is furnished by the case of a man who died July 23, 1895, in Chicago. The victim had rescued a child from the attack of a dog some months before at Perth Amboy, N. J., and was bitten in the leg. He was cauterized. After the

[1] Read before the Medical Society of the State of Pennsylvania, May 18, 1897.

lapse of several months he appeared in Chicago, unable to talk coherently and not able to remember how he had reached Chicago from New York. The account states that "a physician declared that Bulow had the rabies." He was strapped in bed, and in a short time died.

Another curious case is that of a little boy, who died February 19, 1896, in Brooklyn, after an attack of some apparent inflammation of the throat, and the opinion given by a physician of the New York Pasteur Institute that his case was hopeless. It is regretted that chloral was freely administered from first to last. At an autopsy it was found that the cause of death was œdema of the lungs, while the meninges of the brain were somewhat inflamed. The father of this boy was treated at the New York Pasteur Institute, because it was feared that he had received some of the boy's saliva in a cut (how recent is not stated) upon his thumb.

Another interesting case is that of a young woman of New Jersey (whose death is not recorded and whose case is not in my table), who, in March, 1896, had all the symptoms of hydrophobia except inability to swallow—which the account hopefully says "may come later." She was a nervous person. Her clothing had been torn by a dog, although her skin was not injured. She was a constant reader of hydrophobia literature.

A point of interest to me in this investigation has been to compare the number of deaths that I find after bites of animals believed to be rabid with those that are the foundation of a great many statistics. In 1895 I reported finding three deaths in one hundred and seventy-five persons bitten. Of these three, one had been treated in the Pasteur Institute in New York; of the second I have no details at all; and the third was a child that died three weeks after being bitten, and while the dog was still alive and as active as ever. Since then I have investigated ninety-two cases of persons bitten by dogs believed to be rabid, with five deaths; and every one of these five patients had been treated at the New York Pasteur Institute. In these cases the bites were inflicted by animals that bit one or more persons and animals.

The figures just given, of course, do not represent what could be considered as an absolute ratio of deaths to the bites of animals believed to be rabid. They deserve careful consideration, however, from the fact that persons bitten under circumstances of such grave suspicion and so naturally alarming might be expected to furnish quite as large a quota of deaths as any class of bitten persons.

The most dramatic occurrence of the past two years in connection with hydrophobia is unquestionably the death of four children in Baltimore out of eight bitten by one dog, and all treated at the New York Pasteur Institute. I have a large correspondence in regard to these cases, and I went to Baltimore to learn more about them. I found the medical profession in that city naturally much impressed, and disposed to accept the opinion of those who attributed the deaths to the dog bite, and not to the treatment; but from my knowledge of the disease and my acquaintance with the peculiar features that have been introduced into its symptomatology since the practice of so-called "protective inoculations," I am strongly of the opinion that the boys died partly of laboratory rabies, partly of dread and mental impressions, and partly from the way in which they were treated. I am impressed more and more every year that the general mode of treating hydrophobia—the mode recommended in the text-books—is probably responsible for a considerable number of deaths charged against the disease. It is to me a most astounding thing, that when it must be known that narcotics have never rescued a single person from death, medical teachers will advise and medical men will practise the treatment of these diseases with morphine, atropine, chloral, bromides, and chloroform. I am satisfied that it would be better to administer no medicine at all than to continue this pernicious practice. One of my correspondents writes me that the father of his patient—a veterinary surgeon bitten by a dog that was not rabid, and who endeavored to fortify himself against his obvious fear by reading on the subject—requested him to give something to his son to kill the latter. He writes further that this he did not do, unless it might be that the opiates he gave produced the desired result.

A case interesting to me has occurred within the past year. Last May a child was brought to me, who had been bitten by a stray puppy with which it was playing. The child's wound was cauterized with nitrate of silver soon after. The dog died of fits at the Philadelphia pound, where the pound keepers state it was not rabid. A veterinary surgeon who had seen the dog and was obviously afraid of it, said that the dog was rabid. Experimental inoculations made with the medulla of the dog by the bacteriologist of the city of Philadelphia killed rabbits, and the opinion was positively given by the bacteriologist and by the coroner's physician of Philadelphia that the dog was rabid and that the child was in great danger. The father was advised to send the child to New York. At the suggestion of a physician who was interested in my investigations, the child was brought to me. I measurably allayed the horrible anxieties of the father and mother, although it was impossible entirely to remove the effect of what had been said to them, and undertook the care of the child. That child is to-day in perfect and blooming health. From what I know of the nervous make-up of the whole family, I should fear very much the effect on his mind of such associations as are inevitable to those who go to a Pasteur Institute for treatment, even if the inoculations there practised did not produce that deadly disease known to noncredulous observers as "laboratory rabies."

I have sometimes known a great deal to be made of the occurrence of so-called hydrophobia in very little children, and I have in my records cases of abject fear and a certain knowledge of the symptoms in children four or five years old, and I personally know of children under four years of age whose dread of dogs is so great that they might easily have the symptoms of any disease shaped largely by what is with them a dominant idea.

In this connection I may speak of what I may call a dominant idea of physicians and of the laity, namely, that persons with so-called hydrophobia may inoculate others with the disease. This is an absolutely [illegible] idea. There is not, in the whole history of hydrophobia, a single credible case in which a person suffering with hydrophobia has communicated this disorder to another human being or animal, and it is safe to say that all persons suffering with this disorder who show a disposition to bite are simply maniacal. My own observation and my studies convince me that those cases which have the greatest claim to consideration as cases of inoculation with rabies, present no such symptom as imitation of the action of dogs or a disposition to bite. When I read accounts of children only nine or ten years old requiring the combined strength of several men or restraining with ropes to keep them from injuring others, I regard it as a sad demonstration of the profound ignorance that members of the medical profession share with the laity in regard to this subject, and the weakening of their judgment by their fears.

In concluding this informal presentation of the panorama that has passed before me in the last two years, I would like to make a brief statement in regard to my own position.

I began to study hydrophobia more than fifteen years ago, and I have tried to familiarize myself with

the literature of the subject from the earliest times until the present; I have seen three cases in my own practice and in consultation; I have carefully studied the details of thousands; I have followed the discussions on the subject which have taken place in scientific societies in every part of the world; I have kept track of the doings of Pasteur and his colleagues and followers year by year since they were first made public; I have had a very large correspondence from all parts of the world in regard to it; I have tracked up many cases to ascertain facts not stated in public accounts, or to obtain explanations of what was stated; I have studied the diseases in which the symptoms of so-called hydrophobia occur, and I have endeavored correctly to interpret the facts that I have collected. At the beginning my views were those which I presume are now held by the most cautious minds; but, as my study has progressed, I have become entirely satisfied that hydrophobia cannot be considered as a specific disease. I think the word "hydrophobia" should be used just as we use the word "convulsions," without prejudice as to the cause of the phenomena. There can be no doubt that death with a peculiar train of symptoms has often followed the bite of a dog; but these symptoms and the usual fatal issue are in no way peculiar to injuries inflicted by animals believed to be rabid. There are very many cases in which the belief in the madness of the dog rests wholly upon the result in the person bitten, and it is not scientific to assume that this belief is more than a belief; and no person fit to discuss the question would treat it as a demonstration. Further, the symptoms appear in a great many diseases, and persons bitten by dogs enjoy no immunity from these diseases. Besides this, there are many cases in which persons have died of hydrophobia while the dogs have survived. There are other cases in which the symptoms of hydrophobia have appeared after various traumatisms; and such a traumatism as is caused by a dog-bite may (without assuming the presence of a specific virus) lead to nervous symptoms and death.

It is curious, in considering the effect of dog bites, to note that they should cause so many deaths in what we may call the private walks of life, and practically none among men who are constantly handling large numbers of dogs. My notes furnish me with but a single case of death from hydrophobia occurring in the person of a keeper or attendant in a public pound in any large city in the world, from Paris to Philadelphia, and from Moscow to San Francisco. The same is true in regard to persons who habitually take stray dogs upon the street, such as dog catchers, policemen (as in London), and the attendants of such an institution as the London Home for Lost and Straying Dogs, where over two hundred thousand dogs have been handled without a case of hydrophobia. I have consulted a number of keepers of so-called "kennels," and I have never learned of a death among any of them, although I have found innumerable bites, many of them by dogs believed by their owners to be rabid. It is a remarkable fact also that, though there has been such a fever of excitement about rabies in Paris in recent years, I learn of no deaths among the pound keepers and attendants there. If the bites received by the persons employed in such places could be counted, the customary figures in regard to the ratio of deaths to bites would have to be enormously modified. The often-quoted guess of John Hunter of 1 to 20, or the new-fashioned one of Pasteur of 1 to 16, would probably have to be exchanged for one much lower than that which I have seemingly gathered, of 1 to 75 or perhaps 100.[1]

All these things and many more that I cannot recount have led me to my present conviction.

[1] Let it be understood that the figures above, 5 to 92, I am disposed to attribute to the treatment of the Pasteur Institute.

Progress of Medical Science.

Treatment of Acromegaly with Pituitary and Thyroid Extracts.—At a recent meeting of the Medical Society of London, Rolleston (*British Medical Journal*, April 17, 1897) exhibited a woman, twenty-six years old, who had suffered from acromegaly for upward of two years and who for a period of five months had been treated with mixed pituitary and thyroid extracts, with great improvement. The superficial resemblance between acromegaly and myxœdema seemed to justify the administration of thyroid extract, especially as in several cases of acromegaly treatment with pituitary extract alone had failed to effect any improvement.

Unsuccessful Splenectomy for Rupture of the Spleen.—Strange and Ware (*British Medical Journal*, May 1, 1897) have reported the case of a laborer, fifty-one years old, who, while driving a cart, fell between the shaft of his own and the wheel of a passing wagon. He stood up and was taken to a neighboring inn, where brandy was administered, and he was then driven to the hospital. On admission, he complained of pain in the abdomen, especially on the left side, and he looked extremely ill. His face was pale, his lips were blue, his respirations were rapid, and his pulse was very collapsing. There was no evidence of fracture of ribs. The abdomen was almost motionless and the left side was exceedingly tender, there being distinct dulness in the flank, which did not alter with change in position. The right flank was resonant, except toward the extreme back. The urine contained no blood, and the bowels acted naturally. The condition of the patient grew progressively worse. The pallor had become intense and the pulse was extremely rapid and almost imperceptible; the dulness in the left flank now extended nearly to the middle line. A diagnosis of internal hemorrhage, with probable rupture of the spleen, having been made, two and a half pints of normal saline solution at a temperature of 105° were injected into the median basilic vein, and the abdomen was opened in the median line by an incision from about an inch below the tip of the ensiform cartilage to the umbilicus. There was at once a gush of blood from the peritoneal cavity. The liver was found to be intact, but after clearing out and tearing through large quantities of blood-clot the spleen was felt to be extensively ruptured on its anterior border. On attempting to bring the organ forward, it was found to be firmly fixed and of abnormal size. The adhesions were torn through, a transverse incision being additionally required, and at one spot on the convex surface the splenic substance was found to be torn. The spleen was now brought forward, traction on the pedicle increasing markedly the already collapsed condition of the patient. The pedicle having been tied with silk in three parts and the spleen removed as rapidly as possible, the peritoneal cavity was cleansed by means of sponges of an immense quantity of liquid and clotted blood. Transfusion was again resorted to and strychnine administered hypodermically. The patient, however, failed to rally and succumbed before the abdominal wound was entirely closed. The presence of adhesions, which were an unexpected complication, was attributed to previous malarial infection contracted in India.

Fibrinuria.—Dr. Arthur Klein gives the history of a case in which fibrinous clots were passed, and analyzes the previously recorded instances (four in number) in which this has occurred. The patient was a man of fifty-two, who had been ill for fifteen months with cough, headache, and dyspnœa on exertion, to which had recently been added swelling of the extrem-

ities and rigors (*The British Medical Journal*). Examination led to the diagnosis of Bright's disease; the urine was acid—specific gravity, 1.013—and contained a large quantity of albumin, with numerous hyalin and epithelial casts. Treatment consisted in hot baths and milk diet, and the patient improved considerably, the œdema almost completely disappearing. Ten days after admission it was noticed that the urine, which was slightly alkaline, contained a large number of grayish-white clots, some rounded and others flattened, and varying in length from half an inch to four inches; some were as much as two inches thick. These, if allowed to stand, settled to the bottom, and the supernatant urine sometimes showed a further curious phenomenon in the shape of fine threads which formed a network extending throughout the fluid. On shaking this became detached from the sides of the vessel, and formed a well-marked clot; the urine had thus clotted just like a serous fluid. The amount of deposit remained constant except just before a rigor, when it diminished, to return to its former amount with the subsidence of the temperature. If the clot were allowed to remain in the urine for a few hours, it disappeared entirely, probably by a sort of process of self-digestion. Chemical examination proved the clot to be composed of fibrin. The urine from which it was deposited showed, as compared with that voided at other times, alkalinity, much diminution in solid contents, an especially minute amount of phosphates, but an enormous quantity of albumin. There could be no doubt as to the renal origin of the fibrin, but it was very hard to define its pathological cause: evidences of nephrolithiasis, kidney abscess, etc., which had been present in former cases, were here wanting, nor did hæmaturia ever appear. Klein attributes the coagulation to the alkaline reaction, the large quantity of albumin, and the almost complete absence of phosphates; it bore also, no doubt, some relation to the sudden rigors and rises of temperature. Some time after the completion of the experiments the patient became worse and died; the kidneys were found to be in a condition of amyloid degeneration, and their tubules contained hyaline masses and threads giving Weigert's reaction for fibrin. Klein adds the notes of analyses of two other kinds of clots. The one was found in the urine in a case of cystitis; it consisted of a nucleo-albumin inclosed in a capsule of mucin. The other was a cast from a patient suffering from plastić bronchitis, and this failed to give the fibrin reaction either in bulk or in section; it consisted of mucin, and contained large colonies of diplococci.

Origin of Fat in the Body.—The subject of the origin of fat has once more been taken up by the experimentalist. Many years have now elapsed since the well-known French chemists, MM. Dumas and Boussingault, as the outcome of their researches, maintained that animals, whether herbivorous or carnivorous, were supplied with all their proximate principles by the vegetable kingdom—the former class directly, the latter indirectly through the herbivora on which they preyed. Animals, according to these observers, did not make fat, sugar, or albumin, but derived each and all of these substances from plants. This position was contested by Liebig, who contended in regard to fat that this was not altogether obtained by animals from the fat of their food. On the contrary, they were able to make it with either sugar or starch. He pointed out, as Huber had done before him, that bees fed on sugar or honey alone were capable of forming fat in the form of wax, but Huber had omitted to weigh the bees before dieting them, and Dumas and Boussingault ingeniously argued that the wax formed on a diet of pure farina or sugar was originally stored up in the bodies of the bees and utilized by them in the construction of their combs. Liebig therefore still supported the view of Huber, and held that the greater part of the fat which is deposited in the animal body and that which is found in the milk of nursing mothers is formed in the body and almost exclusively from the hydrocarbonaceous compounds of the food. The albuminoids, he thought, played quite a subordinate rôle from this point of view, as, indeed, seemed probable when it was considered that the food of the herbivora which store up much fat is chiefly composed of carbohydrates, while the bodies of the carnivora, whose food is chiefly albuminous, contain little or no fat. Moreover, he experimented on a goose, which from a lean condition was fattened to such an extent that three pounds of fat were obtained from it, although the maize with which it had been fed did not contain anything like that quantity of fat. Dumas and Boussingault returned to the charge by making a careful analysis of the food given to a cow for a year and determining the quantity of fat which the animal yielded in the milk. They found the fat introduced with the food to be considerably in excess of that eliminated by the milk, but Liebig scored a point by observing that nearly all the fat ingested with the food escaped undigested from the bowels in the fæces. Subsequent experiments, especially those of Lawes and Gilbert, on the herbivora clearly demonstrated that one, at least, of the sources of fat is the farinaceous material ingested. In the mean while various circumstances had led some investigators to adopt the view that the albuminoid or nitrogenous constituents of the food might play a part in the generation of fat. Thus it was found that animals fattened best when their food, if chiefly farinaceous, was mingled with some albuminous compounds; while Pettenkofer and Voit demonstrated that in a dog freely supplied with flesh the whole of the nitrogen thus introduced into the economy was recoverable from the urine and fæces, while the carbon remained in the economy and hence, probably, formed or aided in the formation of fat. The observations of Kemmerich on nursing bitches, of Subbotin on feeding dogs with palm oil and meat, of Hofmann on larvæ fed on defibrinated blood containing a known quantity of fat, all pointed in the same direction and led Voit to maintain, first, that the fat of animals is exclusively formed from the proteid aliments, and secondly, that hydrocarbonaceous compounds are not converted into fat in the animal organism, but simply preserve from oxidation the fat formed from the proteids. The latest researches on this point, however, are not quite in accordance with Voit's views. The most recent observer, Dr. Kaufmann, arrives at the following conclusions: The proteids, in common with the ternary compounds of the food, contribute to the formation of fat, but, contrary to Voit's statement, they are not the exclusive origin of it. When during digestion a large quantity of proteids is absorbed it rapidly undergoes disintegration and forms fat. This fat has, speaking generally, three applications. One part oxidizes and passing through the phase of glucose supplies the requisite energy for the general physiological work of the organism; another part undergoes incomplete oxidation and is transformed into carbohydrate which is stored up in reserve as glucogen; while the third part remains intact and is deposited as fat. The proportion of fat which is fixed during the digestion period varies with the abundance of the repast and the richness of the organism in glycogen. If the animal is poor in glycogen it may happen that the whole of the non-oxidized fat may be converted into glycogen. Calorimetric investigations demonstrate that if the anaerobic decomposition of albumin really occurs the process is not attended with any disengagement of heat.—*The Lancet.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 26, 1897.

THE FAILURE OF THE CONSOLIDATED-COLLEGE SCHEME.

THE time-honored name of Bellevue Hospital Medical College is to remain intact and assume its old prestige in the history of clinical teaching in New York, where it had been temporarily left during the recently pending negotiations with the University Medical College. Doubtless the thousands of its alumni in every clinic will rejoice to know that their alma mater is neither dead as a distinct entity, nor lost to sight in the amalgamation with copartnership interests. During thirty-seven years of existence it has made an enviable record for itself and earned the reputation of a first-class metropolitan medical school. It would be a pity that such a good name should be lost in any attempt to trim to an apparently temporary expediency of joining interests with a general university, which, with all its present claims and future prospects, has yet to make its own reputation. It is a matter for congratulation that the Bellevue Hospital Medical College can act independently in its own interests and has enough backbone to take care of itself, irrespective of any outside help that might directly or indirectly cripple its original purposes.

The same may be said for the University Medical College, which has even a longer record as a leading medical school and plenty of resources to guarantee its continued prosperity. Individually they are scarcely susceptible of improvement, but the attempt to join them in a consistent whole has been a lamentable failure.

There were numerous reasons for arriving at such a final and definite issue. These had reference mostly to the arrangement of details which would give each faculty in the proposed combination a proper division of interests. When once the discussion was started all sorts of complex questions arose. Promises and compromises were in order, until finally the differences of opinion as to relative rights became so irreconcilable that, to use an expressive though inelegant business phrase, "the deal was definitely declared off."

As usual under the circumstances the leading managers on both sides were naturally tempted to look after their own interests in joining their fortunes with the combination. The equitable distribution of chairs in the new faculty was a serious matter, in view of the necessity of dropping some of the teachers who had served long and honorably in their respective positions.

The plan for a radical reorganization of the prospective faculty was naturally viewed with disfavor by such as were not in close and confidential relations with the leaders on either side. The appointment to a responsible position in one of the faculties of a gentleman who was unknown to the profession by any work he had done was not calculated to inspire confidence in such members of both faculties as had fairly made their own records. Thus the pecuniary influences as bearing upon the future policy of the parent plant became ominously pronounced. But, further than this, each member of the faculties had a right to consider himself as a leader in his own line, with that proof which success as a teacher always makes manifest by a well-maintained following of appreciative students. The difficulty of finding suitable places for all and giving each his proper position was painfully apparent from the first. In acordance with the well-known law, two bodies could not occupy the same place at the same time.

A still greater trouble in reconciling different views as to relative rights was occasioned by inviting gentlemen already connected with other universities to occupy prospective vacancies. This was scarcely to be construed as a compliment to those who had already filled such positions. The yielding of certain special privileges in the assumed interests of the consolidation as a whole was another matter which provoked much discussion and ended in much disagreement. The peacemakers on either side had a hard time, accordingly. Finally it became quite evident that each medical college had much more to lose than to gain in any attempt to adjust these difficulties, and the result is as we have mentioned. From what we can learn the course is an eminently wise one, and the many friends of both institutions will rejoice in the opportunities which the recent experience have given them of realizing how much each has had in the past and how much more each will have in the future.

THE EXPERIMENTAL PRODUCTION OF FAT NECROSIS.

A SERIES of experiments of an interesting character has lately been made by Dr. Herbert W. Williams, at Buffalo University. The experiments were with the object of producing fat necrosis in animals, with a view to demonstrate the connection between it and affections of the pancreas. That there is a connection cannot be doubted, but its significance has yet to be proved. Opinions differ on the subject. Fitz says that most cases of pancreatic hemorrhage occur without fat necrosis, and that simple necrosis usually takes place without hemorrhage. Even in severe varieties of fat necrosis accompanying pancreatic hemorrhage, the fat necrosis cannot be regarded as the essential cause of the hemorrhage in such cases. Ponfick, the first to recognize the relationship be-

tween fat necrosis and affections of the pancreas, held the view that fat necrosis when extensive was associated with old and fresh hemorrhage. Baker was of the same opinion. Hlava excited a hemorrhagic pancreatitis with fat necrosis in a cat by injecting the diphtheria bacillus into the pancreas after laparotomy. The experiments at Buffalo University were conducted in the same manner as those of Hildebrand. "The animals selected were two dogs, one rabbit, and seventeen cats. They were anæsthetized with ether. The operations consisted in the placing of a ligature about the gastro-splenic portion of the pancreas near the duodenum, or the duodenal portion of the pancreas, or both. In most cases as many as possible of the veins leaving the pancreas were also tied. In the majority of cases a solution of continuity in the pancreas was effected. In one instance the gastro-splenic portion of the pancreas was cut through on the distal side of the ligature. From the two dogs the results were negative. In the rabbit there were traces of fat necrosis close to the ligature. From the seventeen cats ten results were negative. In two there were minute areas probably of fat necrosis, and in five there was well-developed fat necrosis. In all the animals studied the diagnoses were based on the microscopic examination of the tissues."

It will be seen from the foregoing account that these experiments were fairly successful, and, when the results of preceding experiments are taken into consideration, it appears evident that ligation of the pancreas in the cat may lead to fat necrosis. As Dr. Williams says, however: "It seems unjustifiable at present to say more than that extensive injury to the pancreas can cause fat necrosis." Experiments are also being conducted with the object of testing the direct action of the excised pancreas upon fat tissue, and it is believed that the results will be successful. Any account of these would as yet be premature, as more time is required to observe the conditions under which the change is effected. In some countries hogs are very subject to fat necrosis. Balser found it in the fat tissue or about the pancreas in nearly all Hungarian swine, frequently in Algerian, and in a few German. In order to determine the condition of the swine of America in this respect, Dr. Williams examined the pancreas of one hundred hogs, and says: "It was impossible to learn anything more concerning the animals than that they were raised either in Ohio, Indiana, Illinois, or Michigan, and were apparently sound and healthy. The pancreas of the hog is surrounded by a quantity of adipose tissue, which is also abundant between the lobules. The fat cells are very large. Little white flecks, consisting of single fat cells or groups of fat cells, are often seen in the pink parenchyma. Not rarely one meets with dark red spots in the parenchyma, several millimetres in diameter, apparently the result of hemorrhage. The organ, taken as fresh as possible, was cut in slices, one to three millimetres thick, and each slice carefully examined. In two cases fat necrosis was found." The fact should be mentioned that in three of the cases of fat necrosis of a marked type in cats a diplococcus infection was associated.

THE ANTIVACCINATION CELEBRATES.

A HANDFUL of cranks calling themselves members of the Antivaccination Society of America gave a dinner in this city recently to celebrate what they regarded as a victory over the national sin of protective vaccination. The State of Illinois, which has made itself famous in times past by its stupid health enactments, refused to pass a bill making the vaccination of school children by boards of health compulsory, and hence the rejoicing. It is quite certain that the intelligent people of the State, including the large majority of the well-educated medical men of that commonwealth, were either too indifferent to show their strength in combating the machinations of a few wrong-headed individuals, or they concluded that the utility of vaccination had passed beyond argument. In either case the intelligent majority has yielded its rights to the irresponsible and fanatical minority. It is the old lesson which enforces the necessity for watching even the best of laws, against the possibility of their being altered and thus rendered nugatory. The fact that the antivaccinators have won means nothing but future disaster. It is the fool laughing in the face of danger. To call it a victory is like hurrahing for sheol. It is more than a shame that in this century of progress, marked by so many brilliant triumphs in medicine, one of the greatest of the latter should suffer its high claims to be ignored and its grand usefulness to be curtailed by the senseless and persistent wails of a few fanatics. If Illinois is to be the banner State for this movement, the skull and crossbones are its proper insignia.

News of the Week.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 19, 1897. June 14th.—Surgeon E. Z. Derr ordered to duty with new naval rendezvous, New York. June 16th.—Passed Assistant Surgeon J. F. Urie detached from marine rendezvous, Boston, June 24th, and ordered to the *Wabash* same day. Surgeon F. B. Stephenson detached from the *Wabash* June 24th, and ordered to marine rendezvous, Boston, same day. June 17th.—Assistant Surgeon W. B. Grove ordered to the naval laboratory, New York, June 21st. Passed Assistant Surgeon L. W. Spratling ordered to the naval hospital, Norfolk, July 1st.

Jubilee Honors.—The list of medical honors at the Jubilee celebration was very short. Sir William MacCormac and Dr. Samuel Wilks, President of the Royal College of Physicians, were created baronets.

A Charge of Attempted Bribery.—The editor of the *Lancet-Clinic* says that at the recent meeting of the American Medical Association a western railway agent offered free transportation to the members of the committee on nominations if they would select Denver as the next place of meeting. He acquits the Colorado delegation of any previous knowledge of the railway man's offer, but he rightly says that in future

the proof of such a proposition being made by any interested party should be a sufficient cause for a rejection of the claims of any city.

Aseptic Oath Taking.—A sanitary Bible for the use of courtrooms has just been put on the market. It is bound with white celluloid instead of leather, and it can therefore be washed and disinfected from time to time.

A Case of Leprosy in Baltimore.—A woman who was taken to the Johns Hopkins Hospital recently, suffering from some undiagnosed skin disease, was found to have leprosy. She was promptly isolated, and when it was learned that she had come from another city she was sent back in a private car, that is to say, alone in a freight car.

The Johns Hopkins Medical School, in Baltimore, held its commencement on Tuesday, June 15th, on which occasion the members of the first graduating class of this school received their diplomas. There were fifteen in the class, one being a woman. All of the graduates will remain for a year of graduate work in the hospital. One of the graduates has been appointed to the faculty.

The Victoria Jubilee in Denver.—At a meeting of English residents in Denver, recently held to consider the best means of celebrating the Queen's reign of sixty years, it was decided to erect an addition to St. Luke's Hospital in that city, to be called the "Victoria Wing."

Father Kneipp, the Bavarian priest, who lately became famous on account of the wide spread of his guesses at hydrotherapy, died on June 17th in Woerishofen, at the age of seventy-six years.

An Encounter with a Jersey Mosquito.—The newspapers contain an account of an Italian, forty-two years old, who rashly went to visit some relations in New Jersey a few Sundays ago. While there he was bitten by a mosquito, the wound became painful and infected, and the man became wildly delirious and was taken to Bellevue.

International Congress of Forensic Medicine.—An International Congress of Forensic Medicine will be held at Brussels August 7th. The following are the questions proposed for discussion: (1) The internal factors of the putrefaction of corpses; (2) the place and duties of the medical jurist in expert evidence as to accidents caused by tainted meat; (3) the toxicology of acetylene; (4) poisoning by carbonic oxide; (5) criminal lunatics and asylums; (6) professional secrecy in the courts; (7) the lung test in the determination of live birth; (8) the medico-legal significance of subserous ecchymoses; (9) responsibility, particularly partial responsibility; (10) hypnotism in relation to crime.

Professor Fresenius died at Wiesbaden, on June 10th, from apoplexy. He was born in 1818 at Frankfort-on-the-Main, and was made professor of chemistry at the institute there in 1845.

Protecting the Health of Prisoners.—Intending convicts in Missouri must take care not to expose themselves to any contagious disease, otherwise they will not be permitted to enter jail. The board of health of that State has recently issued an order that all officers who bring prisoners to the penitentiary must carry with them a certificate of health signed by a local physician and countersigned by the secretary of the State board of health, which certificate must state that the prisoner has not been exposed to any contagious disease for thirty days prior to his transfer to the penitentiary.

Trouble at the Homœopathic State Hospital.—The managers of the new State hospital at Collins, N. Y., recently removed the superintendent, and now fear that they cannot find another, and yet cannot open the hospital until they do. The superintendent must be a homœopathic physician, must have served at least five years as physician in some insane hospital, must have had some experience in homœopathic treatment of the insane, and must be a citizen of New York State. The only two men who are eligible under this rule, it is said, are personal friends of the removed superintendent, who absolutely refuse to accept the appointment in his place.

Small-pox still lingers in this city, isolated cases being every now and then discovered by the health inspectors. One case was recently found among the patients in the waiting-room of the Vanderbilt Clinic. The patient had been sitting with the others for upward of an hour before the nature of the disease was discovered. A physician in New York was recently arrested on a warrant granted by the board of health, on the charge that he failed to notify the board that two children whom he was attending were suffering from small-pox.

Beriberi prevails alarmingly in Santiago de Cuba.

Dr. Columbia Rivera, of Mexico, has been licensed as a physician, and appointed to the San Andrés Hospital. She is said to be the first woman to be admitted to practice in that republic.

International Exhibition of Dentistry.—An international exhibition of dentistry, dental surgery, and hygiene of the mouth is to be held at the Marlborough Hall, Polytechnic Institute, London, in September of this year.

Yellow Fever.—The steamers arriving at this port from Colon now bring yellow-fever patients regularly among their passengers. The *Finance*, which arrived on Monday last, had had two deaths on the passage and brought three passengers ill with yellow fever to quarantine. Dr. Sanarelli delivered a lecture on June 10th before a large assemblage of physicians and scientists, members of the diplomatic corps, and others in Montevideo. He described the bacillus which he had discovered and believed to be the specific micro-organism of yellow fever: he calls it the bacillus icteroides. It is found in the blood and also in several of the internal organs of those suffering from the disease. Dr. Sanarelli said he had not yet succeeded in obtaining an efficient antitoxin, but was working at the problem constantly, and hoped

soon to discover a serum by means of which preventive inoculations can be made.

A World-Language Symposium.—A new scheme looking to the adoption of an international language comes from Russia. The inventor of "Esperanto," a manufactured speech, analogous to "Volapük," Mr. L. Samenhof, of Grodno, invites all who have ideas on the subject to send him an article embodying them. He will have these printed and copies sent to each of the writers. The latter must read all the articles and then write another very brief essay embodying his final judgment. We do not know whether the question will be decided by a majority vote of the writers or by Hospodin Samenhof himself. In any case it would seem that polyglots only can take part in the discussion, since it is necessary that each one should read all the articles written by all the other contributors from all parts of the earth. The scheme would be a practical demonstration of the necessity of an international language, but we doubt whether it will settle the question of the choice of such a common speech.

The International Congress.—First-class railway tickets from the Russian frontier to Moscow and return will be given free of charge to all members of the congress who have already paid their subscription of $5. Such may obtain the tickets by making application to the Secretary-General, Prof. W. K. Roth, at Moscow, with a statement of the route which it is intended to take from and to the frontier. The ladies accompanying members will not be entitled to free transportation. A special committee has been formed to arrange for hotel and lodging accommodation for visitors, under the presidency of Professor Chervinsky, of Moscow, to whom applications may be made for information. Rooms may be retained in advance, and offices will be established at each of the railway stations in Moscow, where applications may be made on arrival. The cost of rooms will average about two rubles (one dollar) a day. A committee of ladies has also been formed with the object of insuring the comfort and convenience of ladies belonging to the families of members of the congress. This committee will have a central office, at which visitors on their arrival may obtain any information they require. The committee wishes to be apprised in advance of the names of all ladies who will be present, and notice should be given to Professor Savelieff, through the general secretary. The organizing committee of the section on military surgery announces that many papers have been promised, and it begs all intending contributors to send the titles and abstracts of their papers, before June 1st, to the president of the section, Prof. Lewshine Volhouka, maison Mihalkoff, Moscow. The committee offers to members of the section free lodging in the wards of the surgical clinic. The wards were emptied on June 1st, and are now being painted and put in thorough order, and the beds will be disinfected. There will be accommodations for seventy-five persons, eighteen in rooms by themselves, the other fifty-seven in the wards, of which there are seven with four beds each and four with eight beds. It is announced that Professor Herzen, who was to deliver one of the general addresses, will be unable to attend the Congress. In his place the Committee has elected Dr. Léon Frédericq, of Liége, who is to represent the Belgian Government at the Congress.

Dr. H. D. Didama.—A dinner was given on the evening of June 9th to Dr. Henry D. Didama, of Syracuse, N. Y., to celebrate the fiftieth anniversary of his graduation in medicine.

Inspection of Ice.—Health Commissioner Reynolds, of Chicago, proposes to have the ice sold in that city regularly inspected, in order to prevent the use of impure ice taken from the Chicago River and other more than suspicious sources.

The Sale of a Practice.—An account is printed in the Lynn (Mass.) *Evening Item*, of June 4th, of a successful suit of one physician against another to restrain him from practising in that city contrary to his agreement. The case, as reported, was that Dr. E. B. Herrick came to Lynn from Amherst, and bought a resident physician's practice, the latter signing an agreement not to practise in the city as long as Dr. Herrick remained here. He then left the city, but about a year later came to Swampscott, which is close to Lynn, and resumed practice, and, as he admitted upon the stand, again began practice among his old patients in Lynn. Dr. Herrick brought a bill in equity in the superior court against the offending colleague, to have him restrained from practising in Lynn. As a result Judge Dunbar enjoined the defendant from practising in Lynn in violation of his promise.

Dr. W. A. Adams, of Fort Worth, Texas, has recived the degree of LL.D. from Mercer University.

A Special Steamer for Montreal.—So many members of the British Medical Association have expressed their intention to go to Montreal that it is feared the regular steamships of the St. Lawrence lines will be unable to accommodate them. Accordingly it is proposed to charter a special boat to go from Liverpool to Montreal and return, remaining on this side ten days.

Feeders for the Hospitals.—If the cable cars of this city continue their work of destruction, it may before long become necessary to build a special hospital for the accommodation of their victims. On Monday last the papers gave a long list of casualties of the day before, and the injured were distributed so that nearly every hospital in town had the care of one or more of them.

The Late Dr. Wm. T. Lusk.—At a meeting of the medical board of St. Vincent's Hospital, held on the 14th of June, 1897, to take action on the death of Dr. Wm. T. Lusk, it was resolved to give expression of the deep sorrow of the members of the board at the death of one who had labored so long and so well for the institution and for its inmates, and of a

colleague who, by his courtesy and geniality, had won the high esteem of his associates. It was further resolved to express to the family of the deceased the condolence of the members of the board, and to forward a copy of the action to the medical journals.

Mr. Ernest Hart and "The Lancet."—The statement having been made in an English contemporary that Mr. Ernest Hart, editor of the *British Medical Journal*, was once a co-editor of *The Lancet*, the editors of the latter hastened to deny the fact, stating that the gentleman once occupied merely a subordinate position on the editorial staff. Mr. Hart has replied that the present editors know nothing about it, and asserts that he was for a time co-editor with the late Mr. James Wakley, a fact which he is in position to substantiate by means of the formal agreement.

The Third Mexican Medical Congress will be held in Guadalajara on July 7, 8, 9, and 10, 1897. Dr. Rafael Lavista is president and Drs. M. Carmona y Valle and Eduardo Licéaga are honorary presidents; the secretary-general is Dr. Luis E. Ruiz. The programme of subjects for discussion in the various sections gives promise of an interesting meeting.

Apotheosis of the Queen's Nurses.—One of the many funny things happening in relation to the Queen's diamond jubilee is the recent publication of a "Hymn in Commemoration of Queen Victoria's Nurses," written by the Dean of Rochester. The comicality of loyalty could hardly go farther.

The Plague in Bombay is practically at an end. Since the outbreak of the disease in that city, thirty-eight Europeans have been attacked, of whom fourteen have died. Yersin treated fifty cases of plague with his serum, and of this number thirty-three were cured. The mortality had been eighty-three per cent. Cases treated with small doses of serum have a death rate of sixty per cent.; with large doses, seven per cent. A telegram from Vienna, dated May 21st, states, however, that the commission sent to India has reported to the Academy of Sciences that neither Professor Yersin's nor Professor Haffkine's serum has been successful in the treatment of cases of bubonic plague. Haffkine had a disagreeable experience upon arriving at Agra from Bombay. He had gone there to continue his studies on the plague, and for that purpose took with him some cultures and mice, but the authorities feared some of the germs or infected mice might run away, so they burned them all up.

Small-Pox in Madrid.—The epidemic of small-pox which prevailed in Madrid during the last half of last year has now subsided. The total number of deaths caused by the disease in 1896 was sixteen hundred and seven.

Foreign Medical Practitioners in Italy.—In answer to a question recently raised in the Italian Chamber of Deputies, the government gave out that it intended to introduce a bill shortly to forbid the practice of medicine in Italy by any foreign physician who had not passed the official examination and fulfilled the other conditions imposed upon native practitioners. The opponents of such a measure say that it would drive away thousands of English and American tourists and residents who now contribute very largely to the supply of ready money in Italy. But these tourists go to Italy to see the antiquities and art treasures and to enjoy the climate, and not to meet physicians of their own nationality unless misfortune compels them. Moreover there will be plenty of English and American practitioners who will, if necessary, seek and obtain Italian qualifications, so that there will, as now, be no dearth of foreign physicians, and the natives will thus gain nothing and neither will the visitors suffer for want of their own doctors.

A Congress of Balneology and Climatology will be held in Russia in 1898, to mark the centennial of the discovery of the mineral springs of the Caucasus, the best-known and most popular of all the Russian health resorts.

Women Physicians in Hungary.—The University of Buda-Pest has followed the example of the University of Vienna by conferring the degree of doctor of medicine on Frau Wilhelmina Wartha, Countess Hugonay. The lady's husband is a lecturer in the medical faculty of Buda-Pest.

Philadelphia Polyclinic.—Dr. T. B. Schneideman, formerly adjunct professor, has been elected professor of diseases of the eye in the Philadelphia Polyclinic. Dr. G. Hudson Makuen, formerly lecturer, has been elected professor of defects of speech. Dr. C. W. Burr has resigned the professorship of diseases of the mind and nervous system. An invitation was extended to visitors during the meeting of the American Medical Association, and during the week before and the week after, to attend all clinics, lectures, and demonstrations free.

The Sick-List of Armies.—Taking the mean for three successive years, the number of admissions to hospital in the armies of Europe was, per 1,000 of strength, Germany, 27.3; Russia, 43; France, 43.8; Great Britain (home), 203.7; (India), 438.

Letter Counting.—The Paris correspondent of the *British Medical Journal* mentions a curious case reported to a Bordeaux society by Dr. Ginostos. The subject was a young man who has, since the age of ten years, had an irresistible impulse to count the letters contained in a word or phrase that he hears, sees, speaks, or thinks. This habit is practised from the time he wakes to the time he goes to sleep. At night he sleeps without dreaming. When he does not talk he invents phrases and counts the letters in them. Thirty-two is a number which gives him satisfaction; thirteen displeases him, but nevertheless he does not recoil from arranging phrases with thirteen letters. This unceasing automatic operation does not in any way interfere with his daily work, or reading, or carrying on a conversation. Unless previously informed it would be impossible and extremely difficult for anyone to detect the silent mental labor the young man—he is now twenty-seven—is always engaged in.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, April 26, 1897.

ROBERT A. MURRAY, M.D., VICE-PRESIDENT, IN THE CHAIR.

Treatment of Acute Broncho-Pneumonia in Children.—DR. HENRY DWIGHT CHAPIN read the paper (see page 901).

DR. JOSEPH E. WINTERS opened the discussion. He said the author had well covered the ground, and he would limit himself chiefly to emphasizing certain points. He would attach special importance to early diagnosis and the late appearance of physical signs of broncho-pneumonia. Broncho-pneumonia was always secondary to disease of the bronchi, never occurred primarily as a disease of the alveoli, and it was only after forty-eight to seventy-two hours after the onset of the alveolar involvement that we first recognized physical signs of consolidation. If we were to recognize broncho-pneumonia early enough to make our treatment effective at the outset of the disease, the diagnosis must be made by the change in the symptomatology which took place when the disease extended from the bronchi to the alveoli. It was not by the temperature, nor by the pulse, nor by the respirations alone that the diagnosis was made, but rather by a change in the symptoms with advance in the temperature, pulse, respirations, etc. Above all it was a change in the character of the cough. There was no resemblance between the cough of a bronchitis of the small or large tubes and the cough of a broncho-pneumonia. On involvement of the alveoli there was expiratory character added to the respiration—an expiratory dyspnœa and an expiratory moan.

Dr. Winters attached great importance to inhalations in broncho-pneumonia. Expectorants, he said, were absolutely useless and only disturbed the stomach. For inhalation he would use steam alone, for anything added would make the baby object to the one agent which was of benefit, namely, the steam. He gave oxygen freely, which he had found both beneficial and harmless. It was possible that a flaxseed poultice would relieve cough the first twenty-four hours, but he was very much afraid of adding any weight to the chest in babies suffering from broncho-pneumonia, for in these cases death resulted from failure of respiration, not from heart failure. Personally he never used poultices and was inclined to think they did harm. But when there was a filling up of the bronchial tubes, and one heard numerous moist râles over the chest, there was nothing more valuable than mustard paste, one part of mustard to four of flour, applied over the chest. This could be resorted to at intervals several times a day, or throughout the disease. Regarding cold compresses, he was very cautious about them in general, but he thought they were useful in broncho-pneumonia when employed as stated in the paper. They tended to diminish the secretions in the tubes. He also thought emetics had a place. When the child was becoming cyanotic from accumulation of mucus in the tubes, an emetic given at night, once in twenty-four to forty-eight hours, would relieve when other things failed. Alcohol was the best stimulant when one was needed, and disturbed the stomach least. Caffeine and atropine were also sometimes useful. But it must be remembered that these patients did not die of heart failure, as adults with pneumonia did, but rather of respiratory failure.

Cardiac Failure or Respiratory Failure?—DR. BEVERLEY ROBINSON could hardly agree with the author and the last speaker that the cause of death in broncho-pneumonia in children was respiratory failure rather than heart failure. While his experience with pure broncho-pneumonia in children had been limited, yet he had seen many cases, if those complicating measles, diphtheria, etc., were included. In not a few an autopsy had been made and seemed to confirm the clinical diagnosis of heart failure. In treatment he had for years been accustomed to keep the room full of creosote vapor in broncho-pneumonia, and in older children he also administered the drug internally. He presented a boy of about thirteen years who had recently recovered from an attack under the creosote treatment. While in practice it seemed to have proven its value, theoretically it seemed to be indicated, for broncho-pneumonia was believed to be an infectious disease. He knew of no drug which possessed germicidal power which could be administered internally in any notable quantity except beechwood creosote. Its use in tuberculosis was well known. While his experience with creosote in broncho-pneumonia was limited, especially limited in young children, he still had strong faith in its value, at least in older children.

Dr. Robinson regarded the antimony salts as among the best of expectorants. We were not always advancing by taking up new things, and might well give some attention to this agent as one among the good ones which had fallen largely into disuse. As to temperature, unless it went quite high, we might better let it alone, lest our antipyretics do more harm than good. This warning was especially applicable to the use of phenacetin and like drugs. Regarding poultices, they were heavy and nasty. Mustard was not pleasant. The same purpose could be accomplished with greater comfort to the patient by applications of soap liniment and spirits of turpentine to the chest and covering, if desired, with oiled silk.

Only Physical Diagnosis Reliable.—DR. HENRY KOPLIK said it was with considerable diffidence that he disagreed with the author and the first speaker on the diagnosis. Accelerated respiration did not mean much in a baby; any febrile movement would cause it. He begged his hearers not to make the diagnosis of pneumonia unless the physical signs were present; otherwise the necessity might exist next morning for explaining to the family why the baby was afebrile—a very disagreeable thing to do. If one would search for the crepitant râle he would very likely find it; if not the first day, the second day. Pneumonia was a disease of very limited duration, and the prognosis in babies was good; let them alone and most of them would get well. But the question was what to do for them while they were getting well. The physician should support them and look out for complications. He was not sure that expectorants and emetics had done anything but harm. By all means disagreeable drugs should be avoided. It should be borne in mind that the baby was trying to get over a disease, and it was our duty to spare the stomach as far as possible. Therefore one should not use camphor, ipecac, ammonia, tartar emetic, aconite; he should use as little of drugs as possible, and the patient would get well if it was so intended. As to inhalations, Dr. Koplik believed in pure air. He had never been able to convince himself that turpentine or creosote inhalations, which he could not stand himself, were agreeable to or good for the baby. He did not object to some steam in the air to make it moist. He did not use poultices or mustard pastes. It compromised the infant's chances of recovery to compel it to lift a pound weight with every inspiration. In short, he treated only symptoms. There were one or two drugs which were very useful, but they must be

given in very small doses. These were digitalis in drop doses, and strychnine, one-four-hundredth grain. He had not been able to convince himself that nitroglycerin was so useful a drug. As to alcohol, he used it less and less, for it interfered with digestion and was borne very badly by babies. The pyrexia of pneumonia was of short duration and seldom required antipyretics. Ice bags on the chest were of little use; they did not reduce the temperature so well as ice bags to the whole body. He rarely used the bath. Opium in small doses relieved pain and also tended to support the heart. Too much would paralyze the heart and cause œdema of the lung. One should look forward to complications, the most important of which was pleurisy.

Dr. William H. McEnroe mentioned Dr. W. H. Thomson's use of creosote and manner of administering it in ginger. Digitalis was dangerous, and the speaker would hesitate to give one-one-hundredth grain of nitroglycerin to a child. He had a great deal of faith in aconite, and would give the tincture until its influence was felt on the pulse, even up to five minims. It had been shown that, while beef tea stimulated the heart temporarily, it did not furnish nutrition, but rotted in the stomach. He would give milk or kumyss. Dry air would be better than a poultice if it could be applied.

Dr. J. Milton Mabbott agreed with his teacher, Dr. Robinson, with regard to the cause of death being heart failure in some cases of broncho-pneumonia. He had been at the bedside of many dying infants in the Nursery and Child's Hospital, and had witnessed many autopsies. While some infants with bronchopneumonia died for want of oxygen and from lung failure, others died of exhaustion and heart failure—inability of the heart to force blood to the cerebral centres and maintain life; others, again, of the two conditions combined.

Dr. Chapin said he had often thought that it was fortunate laymen were not present at medical meetings, especially when therapeutics was under discussion. He, too, believed in supporting the patient rather than in too much drugging, but it was possible to become too pessimistic, not to say nihilistic, with regard to therapeutics. One speaker's scientific conscience would not permit him to believe that the ice bag around the chest would reduce the temperature, yet it did. With the reduction of temperature the respirations also fell, and such applications sometimes made the difference between life and death. While alcohol did cause coagulation in the stomach, this could be avoided by largely diluting it. He had himself deprecated its careless use. As to creosote, his paper treated of broncho-pneumonia in very young children. He had tried creosote in all forms, and had never been able to give it without disturbing the stomach to infants. Of course this was not questioning the value of the drug in tuberculosis and bronchitis in adults. As to mode of death, in his experience the respiration had failed first, the child breathing faster and faster while the heart action was still pretty good; but at the last this, of course, also failed. In bronchopneumonia complicating diphtheria the influence of the diphtheria might cause the heart to fail first.

Hypochlorhydria.—

℞ Tinct. gentianæ,
Tinct. quassiæ,
Tinct. cascarillæ,
Tinct. absinthi.....āā 10 gm.
M. S. Teaspoonful ten minutes before meals.

The patient should further take ten or fifteen drops of hydrochloric acid in a little water at the end of the noon and evening meal.—Cardarelli.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

FOURTH TRIENNIAL SESSION.

Held in Washington, D. C., May 4, 5, and 6, 1897.

William H. Welch, M.D., of Baltimore, President.

(Continued from page 894.)

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Second Day—Thursday, May 6th.

The second session was opened on Thursday morning at nine o'clock with the account of

Epithelioma of the Lower Lid.—Dr. C. H. Williams, of Chicago, Ill., reported a case of removal of an epithelioma of the lower lid, in which the main point of interest was the production of anæsthesia by cocaine cataphoresis, one pole of the battery being placed on the outside, the other on the inner side of the eyelid. The anæsthetic effect was eminently satisfactory.

Ptosis.—Dr. Robert Sattler, of Cincinnati, Ohio, reported the cases of a father and four sons, all with ptosis and epicanthus. The father had myopic astigmatism, the sons were hypermetropic. The levator palpebræ in each case was absent or extremely weak. Photographs were exhibited showing appearances and the results of operation for epicanthus.

Dr. W. H. Wilder reported a new operation for ptosis. It consisted essentially in folding the tarso-orbital fascia upon itself and holding it in position by means of a buried suture, there being no interference with the orbicularis muscle.

Dr. C. A. Oliver reported two cases of resection and advancement of the levator palpebræ muscle in traumatic ptosis with distortion. The two papers on ptosis operation were discussed by Drs. Fridenberg, Tansley, Sattler, and Harlan.

Relation of Weight to Vision.—Dr. George M. Gould read a paper on the law of refraction change following increase or decrease in body weight. He related several cases in which decided increase in body weight was accompanied by a very appreciable diminution in the amount of myopia, the change being most marked in the more myopic eye. *Per contra*, a very fat patient undergoing treatment for reduction of flesh in three or four months complained of deterioration of vision, and fifteen months later it was found that the refractive condition had changed from +1 to −1.

Refractive Changes in Diabetes.—Dr. S. D. Risley related two cases of saccharine diabetes accompanied by refractive changes, varying with the changes in the condition of the general affection. With disappearance of sugar in the urine the hypermetropia increased from + 2 D. to + 5 D. Ten days later the sugar reappeared and the glass was reduced to +3 D.

Cataract Extractions.—Dr. R. L. Randolph reported a series of one hundred and forty-nine consecutive cataract extractions, one hundred and seven with iridectomy, and forty-two simple. The complications in simple extraction were not due to prolapse of the iris but to plain iritis, just as in cases in which iridectomy was performed. He did many extractions without any expert assistance and among unfavorable surroundings, but these circumstances did not appear appreciably to affect the results.

Dr. O. F. Wadsworth, of Boston, Mass., reported several cases of intra-ocular hemorrhage during and following the extraction of cataract. This hemorrhage began at varying periods, in one case occurring

immediately after the completion of the section, in another at the completion of the operation, and in still another fifteen minutes after the operation.

Dr. L. A. W. Alleman, of Brooklyn, N. Y., reported the case of a child with opaque lens containing cholesterin crystals. After he had needled and removed as much as possible of the lens matter by suction, the cholesterin was clearly visible.

Dr. H. W. Ring, of New Haven, spoke of using eserine and pilocarpine instead of atropine after extraction, for fear of inducing prolapse of the iris. He wished to emphasize the value of the pressure bandage in prolapse.

Dr. Lucien Howe exhibited fixation forceps for use without assistance.

Dr. Risley inquired of Dr. Randolph when iritis occurred in his cases, and was informed that in all it occurred a number of days after the operation, and was believed to be infective. Dr. Risley had had cases like those of Dr. Wadsworth, and questioned why they occurred. In some of the cases there was evidently some disease of the vessels.

Dr. S. B. St. John desired to emphasize the practicability of cataract extraction without expert assistance. He controls the patient, when iridectomy is necessary, by instilling cocaine into the anterior chamber after the section is made and then waiting a minute or two before incising the iris. There is no pain. He spoke of cases in which the pupil appeared clear at the end of the operation, and some time after the operation soft lens matter filled up the whole opening. He reported a case of mania after cataract extraction when atropine had not been used.

Dr. David Webster, of New York, reported a case similar to those of Dr. Wadsworth, except that in his case not only the vitreous but the retina, and perhaps the choroid, had been extruded, and the eye was enucleated.

Dr. E. E. Holt, of Portland, Me., corroborated the experience of Dr. St. John, but said that he did not often perform irridectomy.

Dr. John Green, of St. Louis, had also had some experience with cases of hemorrhage after extraction. He related a case of a high degree of corneal astigmatism after operation, reaching 12 D.

Dr. Weeks spoke of Köller's method of obtaining anæsthesia of the iris, by injecting one or two drops of cocaine beneath the loose conjunctiva over the corneal margin.

Dr. J. M. Ray, of Louisville, Ky., spoke of the effect of dacryocystitis on extraction. In these cases he relied on the conjunctival flap for early union, and opened the eye early.

The discussion was continued by Drs. Williams, Howe, Murdoch, Wadsworth, Wilson, and White, and closed by Dr. Randolph.

Taxis of the Eyeball.—Dr. S. O. Richey, of Washington, D. C., read a paper on taxis in increased tension of the eyeball. He stated that in the venous stasis accompanying the condition, taxis carefully performed tended to prevent thrombosis of the choroidal veins and referred to the oblique course of the venæ vorticosæ through the sclera as a factor in preventing the escape of blood through the vessels in increased tension. He wished to persuade his colleagues to transfer their attention in these cases from the anterior to the posterior segment of the eye.

Retinitis Proliferans.—Dr. J. E. Weeks, of New York, reported a case of retinitis proliferans, with exhibition of drawings of microscopic sections. He stated that an essential in retinitis proliferans was the extension of the membrane from the retina into the vitreous.

Dr. E. Fridenberg, of New York, exhibited a water-color of a case of retinitis circinata, remarking upon the pathognomonic importance of differentiation between the affection under discussion and nephritic retinitis. He also called attention to an appearance of newly formed vessels in the retina, and believed it had not been mentioned before in this connection.

Tobacco Amblyopia.—Dr. G. E. de Schweinitz, of Philadelphia, Pa., described a case of tobacco amblyopia, with autopsy and microscopic examination of the specimens, and exhibited photographs of the same, showing the bundle of nerve fibres affected in different portions of the optic nerve.

Dr. S. Theobald reported a case of marked impairment of central vision following prolonged use of the affected eye, occurring in a student at Johns Hopkins University while he was engaged in calibrating burettes. Ophthalmoscopic examination disclosed white spots in and around the macula. Vision, $\frac{8}{200}$. Treatment, pilocarpine, and later biniodide of mercury; result, $V=\frac{20}{20}-$.

Dr. A. A. Hubbell, of Buffalo, N. Y., read a paper on "Hysterical or Functional Blindness," describing three cases.

Optic Atrophy Following Sexual Excess.—Dr. J. A. Spalding, of Portland, Me., related the history of a group of four cases of optic atrophy following sexual excess. Treatment was ineffectual, and all four subjects gradually lost useful vision, though they did not become totally blind.

Standards of Form and Color in Railway Service.—Dr. C. H. Williams read a paper on what standards of form and color should be required in railway service. He had used representations of semaphores, made on the same scale as the test type, and found that they answered the requirements. He thought that while absolutely perfect vision should be required for entrance into the service, the standard for old employees might be somewhat reduced with safety. In the matter of color, he used a light behind a screen with an opening permitting the light to shine through, and varied the color of the light. He found that a hole two millimetres in diameter corresponded to the $\frac{20}{30}$ of the test type as to accuracy of perception of color, and increased the aperture with the distance, so that a record could be made of the color and light perception in the same way as that of form.

Officers.—At the executive session the officers of the society were re-elected for another year, and the place of meeting selected for next year was New London, Ct.

(*To be Continued.*)

Amputations at the Hip-Joint.—Dr. Charles B. Parker (*The Cleveland Medical and Surgical Journal*, January, 1897) summarizes the advantages of the external incision in amputations at the hip joint as follows: 1. The hemorrhage can be completely controlled by the Esmarch elastic ligation, and if placed as suggested in this article it can never slip. 2. The vertical incision is made in the least vascular area, and the circular is placed so low that the gluteal and sciatic vessels are not divided. 3. The plane of division of the limb may be placed lower than by any other method of amputation, and thus the shock may be very much diminished. 4. The future artificial limb is to rest principally upon the tuber ischii, and the scar is farthest removed from this point and from the anus. 5. In certain cases, especially of severe or chronic hip disease, the condition can be explored through the vertical incision, and, if it is too extensive to be relieved by resection or curetting, the incisions can be extended and the amputation carried out. 6. It is the best form of incision when it is desired to make the operation subperiosteally. 7. By this method of amputation, the flattening of the hip and consequent deformity are less.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

LOYALTY AT THE COLLEGES AND SOCIETIES—COLLEGE MEMBERS NOWHERE—HOSPITAL-REFORM ASSOCIATION — MEDICAL COUNCIL — SUBCLAVIAN ANEURISM — CLINICAL SOCIETY—DEATH OF MR. GREIG SMITH—OPHTHALMIC HOSPITAL—BEATTY VERSUS CULLINGWORTH.

LONDON, June 4, 1897.

THE rapidly approaching "Queen's day" is absorbing public attention to a degree that is itself a remarkable "second." Of course the profession participates in the excitement. Loyal addresses are the order of the day in all the medical societies. The royal colleges have passed solemn resolutions to affix their seals to such documents—I should perhaps rather say the governing bodies of these corporations. The meeting of the College of Physicians is limited to fellows—the members having no vote. The surgeons are still more restricted. Only the council act in the name of the college. The absurdity of the position is patent on the face of it, for the address begins, "We, the president, vice-president, and council, etc." So the twenty-four councillors address the Queen, as if they constituted the college or in any way represented the twelve thousand members who are allowed neither part nor lot in the proceedings.

The fellows of the College of Physicians had a slight discussion on the memorial of the Hospital-Reform Association. Some questioned the facts stated in the document, some held that the mattter did not concern the college, some talked of exaggerations, and some spoke of hospital abuse as practically *nil*. The president admitted he was unable to come to a conclusion in his own mind, for, while he saw animus in the memorial, he felt that if a *prima-facie* case were made out the college should look into the matter. Eventually it was agreed *nem. con.* to refer the matter to the council; so we shall see—what we shall see.

The Reform Association is making better play in the provinces. The Manchester meeting was presided over by Mr. Walter Whitehead and a resolution was passed, declaring the time to have arrived for inquiry into the administration of medical relief in the hospitals and dispensaries. Dr. Horder gave an address, in which he laid down in forcible terms that outpatients should be admitted only on the recommendation of competent medical advice. It is hardly likely that managers are prepared for so sweeping a change. The next meeting is to be held at Bristol on the 18th.

There is not much further to report on the session of the Medical Council. A gratuity of £1,000 was voted to Mr. Millar, who has resigned the registrarship on account of ill health. Mr. H. E. Allen was appointed registrar for one year at a salary of £500 a year, and the office is henceforth to be an annual one. The assistant registrarship is at the same time abolished.

There was an excited talk about the Scotch universities not desiring increased disciplinary powers. It appeared that the executive committee had had communications with the university commissioners, who would do nothing, and now the council determined to follow their example, in spite of a vigorous attempt to make a move. It then transpired that a letter from the privy council on the subject, dated July, 1896, had not been communicated to the commissioners, although it stated that the universities could obtain disciplinary powers by ordinance. The council nevertheless negatived a proposal to bring this letter to the notice of the commissioners, and so it remains pigeonholed. Truly "how not to do it" is well understood in the council chamber. A worse blunder, in most people's view, was the council's action as to the examiners for the Dublin Apothecaries' Hall. Obliged by order of the privy council to appoint examiners, the medical council revenged itself by rejecting the two eminent Dublin surgeons nominated by the hall. One of the gentlemen imposed on the hall is a Scotch surgeon of nine years' standing, and already there is an outcry that Irish surgeons are insulted by the council. Certainly the two refused by the council are not complimented, but their reputations are so high they may well join in the contemptuous laugh at an act which is characterized as "too spiteful for a committee of angry old women."

In refusing the nomination of the gentlemen in the front line of Dublin hospital surgeons, whose names must have been familiar to all the members, the council cannot shift the blame on to its subcommittee, but every member must be responsible for his share in the transaction. Another strange proceeding occurred. The privy council having requested the opinion of the medical council on the midwives bill, a letter was sent asking whether it was desired that the opinion should be given in the present session. An affirmative reply was received, whereupon it was resolved to postpone the subject until next session. Is this to be considered as an attempt to snub the superior authority, or is it to be regarded as a declaration that Bacon's dictum, that "manners makes the man," does not apply to councils?

The session terminated on Monday with an unusual expression of thanks to and admiration of Sir R. Quain as president.

At the last meeting of the Royal Medical and Chirurgical Society Mr. H. H. Clutton related a case of aneurism of the third part of the right subclavian artery, for which the first part of the artery was ligatured twice, and a few days after the second occasion a distal ligature was applied to the first part of the axillary artery. On March 18, 1896, a ligature prepared from gold-beaters' skin was applied on the proximal side at the junction of the first and second part of the subclavian artery, and tied by means of the "stayknot," recommended by Ballance and Edmunds, with sufficient tightness to arrest the circulation, but without rupturing the coats. The superior intercostal artery was also tied at the same time and in the same manner. At the end of five or six weeks the aneurism and the radial artery were pulsating as they did before the operation, probably due to the ligature becoming absorbed. On June 10th the first part of the subclavian artery was tied with floss silk on the proximal side of the first ligature, and the internal mammary and thyroid axis were also tied with the stayknot, the walls of the vessels being approximated without sufficient tightness to rupture the coats. On June 17th the aneurism was again pulsating. The first part of the axillary artery was therefore immediately tied in the same manner with floss silk, so as to cut off all the collateral vessels from the intercostals in the axilla. After this operation the aneurism ceased to pulsate and gradually disappeared, so that the patient left the hospital on August 8th without any swelling above the clavicle. Mr. Barwell had urged fifteen years ago that it was dangerous to rupture the coats of a vessel so near the heart as the subclavian artery and so exposed to strong unavoidable pulsation: even if the ligature held, an aneurism might form at its seat. He agreed it was not safe to ligature the artery in two places and divide it.

Mr. Bernard Pitts had met with a very similar case a short time since. He tied the first part of the subclavian artery with a floss-silk ligature, and tried, unsuccessfully as it proved, to avoid rupturing the coats.

The pulsation and pain returned after a time, and Mr. Ballance in his absence ligatured the first part of the axillary artery, but hemorrhage from the site of the exploration occurred a few weeks later, and it was found that at the first operation the coats of the artery had been ruptured, owing to their being unusually soft, and that an aneurism had formed on the proximal side of the ligature.

The annual meeting of the Clinical Society was held last Friday. The report shows prosperity in the accession of new members and an increased bank balance. The retiring president, Dr. Buzzard, received a cordial vote of thanks. Mr. J. Langton is the incoming president.

Deep regret is widely felt at the death of Prof. Greig Smith, of the Royal Infirmary and University College of Bristol, aged only forty-two years. His name was as familiar on your side the Atlantic as here, for his surgical work was of the highest order and his successes in abdominal operations were great. When the British Medical Association met at Bristol (1894) he delivered the address in surgery, and his other contributions to societies and journals were numerous and always valuable. For some time he edited the *British Medical Journal*. His "Abdominal Surgery" has reached a fifth edition and is regarded as of permanent value.

The Prince of Wales, accompanied by the Princess, laid the foundation stone of the new buildings of the Royal London Ophthalmic Hospital on the 28th ult., and made a neat speech on the occasion.

Miss Beatty's petition for leave to bring her case before the House of Lords *in forma pauperis* has been rejected. So an appeal against the decision in Beatty *vs.* Cullingworth can only be had on the usual terms.

DEFORMITIES OF THE HARD PALATE IN DEGENERATES—A CRITICISM OF DR. WALTER CHANNING'S STUDY.

To the Editor of the Medical Record.

Sir: In your issue of June 5th is an editorial entitled "The Significance of Palatal Deformities in Idiots," which is a summary of a paper with the same title published by Dr. Walter Channing in the *Journal of Mental Science* for January, 1897. If the writer of the editorial had read Dr. Channing's paper with extreme care, he would have found that the author does not really discuss the palatal deformities of idiots, although his paper bears that title. I say "with extreme care," because Dr. Channing does not make it plain that his study is of something quite different.

He read this same paper before the American Medico-Psychological Association at Boston in May, 1896, and an abstract with the discussion is printed in the transactions of that body. He illustrated the paper with a fine collection of casts of the palates of a large number of idiots and normal children, and also with charts and diagrams. I was present at this meeting and discussed the paper. My remarks, which are printed in the transactions referred to, were as follows:

"I think there must be a good deal of confusion as to what is meant by the hard palate. I may be wrong in this matter, but I have taken the view that the hard palate is composed of the palatal bones and the palatal portions of the superior maxillary bones. As far as I can learn, Dr. Channing calls the hard palate the teeth and alveolar processes. In describing the arch he always means the dental arch and not the arch of the palate. In my illustrations here [taken from my paper on The Hard Palate in Degenerates] which are selected because of the very great deformity of the hard palate, there is no particular deformity in the dental arch. I do not note the dental arch [in my investigations], but the vault of the palate only. If you examine Dr. Channing's casts of the hard palates of normal and idiotic children, you will observe great differences in the palatal arch, very marked deformities in many of his idiots. If you look at the dental arch only, as Dr. Channing has done, I agree with him that there are no particular differences."

Two months later the doctor's paper was read before the Medico-Psychological Association of Great Britain, and seven months subsequently printed in the *Journal of Mental Science*, but without giving more explicit details as to the real object of his study, which was deformity of the horizontal arch made by the upper row of teeth (though why the dental arch of the lower row should have been neglected I do not know).

For instance, in one place he gives what he calls "a classification of the *palates* of pathological individuals" (italics mine) as follows:

1. V-shaped.
2. Partial V-shaped.
3. Semi-V-shaped.
4. Saddle-shaped.
5. Average or U-shaped.

One would hardly suppose from his introductory words to this classification that he is classifying merely the shapes of the dental or alveolar arch, yet such is the case. This classification has nothing to do with the shapes of the palate.

Again he quotes my classification of deformed hard palates, evidently under the impression that I, too, was classifying the shapes of the arch made by the upper row of teeth. Thus, in reference to the second in my series, the "palate with horseshoe arch," he observes: "The palate with the horseshoe arch, which is entirely different from that figured in Dr. Peterson's article, is usually regarded as the type of the normal palate" (!!).

Yet in the illustration the deformity of the hard palate thus described by me is very distinct, and any one in examining it would observe its extreme abnormality. Dr. Channing was looking merely at the arch made by the row of teeth.

There has been some confusion, especially in odontological literature, in the use of the word arch. Some of the dentists imply by this the dental arch, but, as far as I know, all medical writers in mentioning the palate, the hard palate, and the arch of the hard palate, mean the roof of the mouth, using the terms in their definite anatomical sense. Dr. Channing is an exception.

The conclusions to his paper, quoted by the Medical Record, must therefore bear a widely different construction when read as Dr. Channing ought to have written them.

Note his conclusions again, but substitute for the word "palate" the words "dental arch:"

1. Two-fifths of the palates of idiots are of fairly good shape.
2. Palates of normal individuals may be deformed.
3. In the idiot it is a difference in degree, and not in kind.
4. In either case it shows irregular development anatomically.
5. Palates of average children and idiots under eight years of age probably do not in the majority of cases markedly differ.
6. There is no form of palate peculiar to idiocy.
7. The statement that a V-shaped or other variety of palate is a "stigma of degeneracy" remains to be proved.

Interpreted in this way, and this is Dr. Channing's actual meaning, though the words do not reveal it, it is clear that his investigation does not militate against the results of any studies of the hard palate hitherto made, for the reason that his work does not relate to

the hard palate at all. The title of his paper is therefore incorrect and misleading. I do not deny that he has made a very thorough and painstaking study, and it is in a new field, which thus far he has almost entirely to himself, but the real value of his research has been obscured by a misuse of terms.

FREDERICK PETERSON.

60 WEST FIFTIETH STREET,
June 10, 1897.

THE TREATMENT OF TIC DOULOUREUX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I beg to enclose the following account of the treatment of a case of tic douloureux, which account was sent me by Dr. Josiah Swinney, of Floris, Iowa. The story is told with unornamented directness, and it seems to me to be worth placing on record.

CHARLES L. DANA, M.D.

NEW YORK.

"DEAR DOCTOR: I wrote you some time in August or September last in regard to a case of tic douloureux, a patient of mine. Before I received your answer to my letter my patient became despondent and made moves that showed suicidal intent, he having suffered for many months with but short spells of rest, but none of any moment for about three months. He had rubbed his face until the skin on that side and on the nose was entirely gone. He presented so pitiable an aspect that as a matter of relief I operated by dividing the nerve. That only afforded temporary relief. He had most of his teeth extracted, and all the modern modes of treatment were of no avail. I placed him on the following, which entirely stopped the pain:

℞ Fluid extract black cohosh ..... ℥ iss.
Fluid extract gelsemium ..... ℥ iss.
Fluid extract valerian ..... ℥ i.
M. S. One teaspoonful every four hours.

This stopped the trouble in twenty-four hours. My patient was resting quietly. I then commenced the injections of one-sixtieth of a grain of strychnine sulphate, gradually reducing the dose of the former and increasing the latter until one-twentieth of a grain was reached, my patient staying at his home in the country and acting as doctor by using the hypodermic himself, I visiting him only about twice a week. About this time I found he had been out of the strychnine several days, and was out building a hogpen when I called. I again put him on the strychnine, going back to one-eightieth of a grain and increased to one-fifteenth of a grain. Characteristic symptoms being present, treatment was stopped. I then put him on one-fiftieth of a grain strychnine nitrate in tablet three times a day before meals. Patient gained rapidly in flesh; spirits good; made an eighteen-miles drive all winter once a week to the city with farm produce; can now chew on that side of his mouth; can whistle; can touch the teeth and gums or rub his face on that side without the least pain, all of which he could not do for two or three years before. All that now remains of the old trouble is a shrunken condition of the tissues on that side of his face, due, I think, to the rubbing and adhering of the soft parts firmly to the bones of the face; and a slight twitching at the point of my incision, which may be due to it. This has existed ever since the operation. It is only just perceptible to the patient and is without any pain. He is now overseeing a large farm and laboring himself, and says he feels better than ever before in his life. I write you this long letter of description in appreciation of your kindness to me, etc., thinking perhaps it would be of some interest to you. This is from memory, not notes, and I sincerely hope you will pardon its length."

New Instruments.

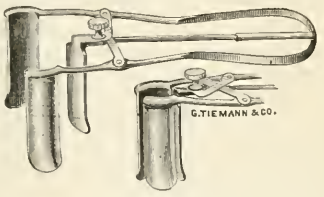
A TRIVALVE NASAL SPECULUM.

BY HERMAN L. ARMSTRONG, M.D.,

SURGEON TO MANHATTAN HOSPITAL, BROOKLYN, NOSE AND THROAT DEPARTMENT.

SURGEONS who operate under general anæsthesia within the nasal cavity have realized, no doubt, the inadequacy of all forms of nasal specula now in general use, not only as to their inability to dilate the parts in a satisfactory manner, but also their liability to be continually slipping out of the orifice.

With these deficiencies in my mind, I have devised the instrument a cut of which is here given, which will



admit of more light being thrown upon the field of operation than any other instrument of like character now in use. Especially will this instrument be found useful in operations upon the nasal septum, as it can be so inserted as to leave the same entirely free for saw, trephine, or drill; besides it is self-retaining, which will enable the surgeon to use both hands in the employment of instruments necessary to the operation in hand.

It is so constructed as to admit of any degree of dilatation, from the minimum to the maximum, and these degrees can be maintained throughout the operation by means of a set screw upon the cross hinge bar. Another advantage is that it feels perfectly comfortable to the patient when used without either local or general anæsthesia. It can be inserted or removed from the orifice instantaneously, and cannot be made to injure the parts with which it comes in contact.

It is manufactured by George Tiemann & Co.

777 DE KALB AVENUE.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 19, 1897:

	Cases.	Deaths.
Tuberculosis	153	108
Typhoid fever	7	3
Scarlet fever	182	10
Cerebro-spinal meningitis	1	3
Measles	234	6

Reciprocity in Medical Licensure.—Dr. William Warren Potter, of Buffalo, president of the national confederation of State medical examining and licensing boards, chose this for the subject of his annual address at the eleventh annual meeting of that body, held at Philadelphia, May 31, 1897. He first paid tribute to the memory of Dr. Perry H. Millard, of St. Paul; then in an introduction reviewed some of the essential points of progress that had been made in

State control of medical practice, and finally considered his subject.

The problem: The most important question now to be discussed pertains to the interstate exchange of licenses, and every friend of State control is interested in establishing this principle. It is one of the objects this confederation is laboring to accomplish, but a most difficult problem for solution. A national registration bureau is desirable, where legally qualified and reputable physicians may be recorded — physicians whose names appear on this register to be allowed to pass from State to State in the enjoyment of all privileges pertaining to the practice of medicine. Those chiefly agitating the question of reciprocity, however, are specialists who desire to spend profitable vacations at summer resorts, and do not relish the idea of taking State examinations in the localities chosen for their holiday practice. Another class of men, compelled by circumstances to change residence, is more deserving of sympathy; they take the examinations uncomplainingly. Shall a State require of its own citizens a compliance with its practice laws, while granting to thrifty summer specialists exemption from their operation? As the State laws forbid discrimination against the inhabitants of each, there is both a legal and a moral bar to such exemptions.

Obstacles to reciprocity: Equality of standards for admission to the study and practice of medicine is the only enduring basis on which reciprocity can be established. When the several States adopt a uniform level of preliminaries; a uniform period of collegiate training, including uniformity of methods of teaching; and, finally, an absolute similarity in the methods of conducting State examinations and granting licenses —then reciprocity will be equitably and permanently established. It is important for the State medical examiners to come to an agreement on these several points, that they may act with intelligence on a common platform. The State imposes a post-graduate examination, and none should be admitted to it who are not holders of diplomas legally obtained from registered and recognized colleges. It is understood, of course, that there must be established a uniform system of recognizing and registering medical schools in the several States.

The solution—legislative enactments: The remedies lie in legislative enactments. Those who most loudly and persistently demand interstate indorsement aim their criticisms at examining boards; whereas these have nothing to do with the question. The statutes in States that have established licensure prohibit interstate exchange except between such as have equality of standards. The demands of the restless and migratory doctors must be taken to the State legislative halls. Meanwhile, the members of this confederation may assist in bringing the matter to a more speedy conclusion by acquainting their legislatures with the difficulties to be overcome, and by urgently recommending the adoption of such amendments to existing laws as will meet and remove the present defects. Great care must be exercised, however, in the preparation of amendments; the State laws are for the public weal, reciprocity is only for the few. Amendments to existing statutes should be proposed only through State medical examining boards or State medical societies; they are familiar with defects, and best know the remedies needed. When legislatures can be persuaded to turn a deaf ear to all amendments that are proposed outside of official sources, it will be a happy day for the friends of State license. The object of this discussion is to divert into the proper channel further criticism of the delay of reciprocity. If legislators could be made to appreciate the fact that public health interests are involved in the question of State license, that every attempt to weaken the principle is a blow at public sanitation, and that higher standards of medical education mean better health for the people, then perhaps it would be easier to obtain and maintain the necessary laws to protect the commonwealths against that kind of ignorance, superstition, or superrefinement that always lurks in the environment of quackery.

The Mud Baths of New Mexico. — The hot springs of New Mexico are on the Santa Fé Railroad, six miles from Las Vegas, and they are situated in a basin about thirty acres in extent, surrounded on all sides by hills rising to a height of from three hundred to four hundred feet, shielding the place from wind and sand storms. The mud baths which are famous for their curative effects are to be had in only two places in the world, here and at Carlsbad, Germany, and it has been shown that the mud found at the hot springs of New Mexico, and which is used in giving the baths, is of the same chemical composition as that of Carlsbad. It is very interesting to note the formation of this mud or peat. It is formed by the vegetation which has been washed down from the hills probably a century ago, and which, settling among the rocks, has become decomposed and formed into a substance which is practically carbon impregnated with salts, magnesia, soda, lithia, and various other ingredients. This peat is gathered from the rocks, dried, and put through a fine sieve in order to remove the silicates, and after this treatment it is as soft as flour. It is then taken to the mixing-room, where it is put in large tubs and the water from the hot springs mixed with it until it is of about the consistency of mush. The mud is now ready for use and it is taken into the bathing-room, where the patient is placed in a tub and covered, with the exception of the head, and allowed to remain in the mud for from ten to thirty-five minutes. The application of the mud has an effect similar to a mild poultice and draws the impurities from the body through the pores of the skin. The patient is then removed from the bath, placed upon a slab, and submitted to a vigorous rubbing, the chemical composition of the mud being such that it can be rubbed from the body with a dry towel, leaving the flesh in a clean condition. A great many people come to this place to take the mud-bath treatment, and some marvellous cures are effected; in one instance I remember to have seen a man who was all drawn up with rheumatism, and after two weeks of this treatment he had been relieved. The treatment is said to be especially beneficial to persons afflicted with neuralgia, rheumatism, and skin diseases.—*Denver Republican.*

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE VERTEBRATE SKELETON. By S. H. Reynolds. 12mo. 559 pages. Illustrated. The Macmillan Company, New York. Price, $3.00.

THE LIFE AND TIMES OF THOMAS WAKLEY. By S. S. Sprigge, M.B. 8vo, 509 pages. Longmans, Green & Co., New York.

THE EYE AS AN AID IN GENERAL DIAGNOSIS. By Dr. E. H. Linnell. 8vo, 248 pages. Illustrated. The Edwards & Docker Company, Philadelphia, Pa.

REFERENCE BOOK OF PRACTICAL THERAPEUTICS. Vol. II. By various authors. Edited by Dr. Frank P. Foster. 8vo, 618 pages. D. Appleton & Co., New York.
